Technology Advances for Dynamic Real-Time Optimization

L. T. Biegler

Chemical Engineering Department, Carnegie Mellon University, Pittsburgh, PA 15213 USA

Abstract

Integration of real-time optimization and control is an essential task for profitable process operation in a highly competitive environment. While integrated large-scale optimization models have been formulated for this task, their size and complexity is often a challenge to many available optimization solvers. On the other hand, recent development of powerful, large-scale solvers leads to a reconsideration of these formulations, in particular, through application of efficient large-scale barrier methods for nonlinear programming (NLP). Moreover, in-built NLP sensitivity capabilities quickly compute approximate solutions of perturbed NLPs. This allows on-line computations to be drastically reduced, even when large nonlinear optimization models are considered. Moreover, extensions of these approaches to consider dynamic complementarity systems allow the treatment of a class of discrete decisions. These recent results motivate the development of dynamic real-time optimization (D-RTO) strategies that can be used to merge and replace the tasks of (steady-state) real-time optimization (RTO) and (linear) model predictive control (MPC). This is enabled by continuing advances in nonlinear model predictive control and its generalization to deal with economic objective functions. Finally, successful implementation of D-RTO suggests a bottom up strategy starting from MPC to build a single D-RTO layer with consistent dynamic models, rather than modifying the existing RTO layer.

Keywords: Model Predictive Control, Real-time Optimization, Dynamic Real-time Optimization

1. Introduction

With the development of efficient strategies for the optimization of differential-algebraic equation (DAE) systems, recent research has focused on the development of on-line optimization of dynamic systems. Currently, RTO systems consist of two layers, as shown in Figure 1. The MPC layer typically consists of linear dynamic models while the RTO layer consists of nonlinear steady state models. While this approach can work well when there is an adequate separation of time scales, difficulties have been reported in the two-layer structure due to inconsistency of different optimization models in each layer, inadequate treatment of unmeasured disturbances, and the corresponding impact on stability of the RTO loop. A number of these issues are discussed and analyzed in [16]. Many of these difficulties can be addressed through the adoption of a single layer that combines both MPC and RTO, as shown in Figure 1 and initially suggested in [13]. With provisions to deal with a consistent optimization model that is made compatible with the plant, better performance of the process can be expected and further extensions can be made that would better integrate on-line operations with planning, scheduling and other off-line decision-making tasks [3, 10].

Moreover, recent advances in the development of fast, large-scale NLP methods for dynamic optimization are key enablers to realizing D-RTO loops. This study explores these advances in dynamic optimization strategies, particularly for time-critical applications. In the next section, we briefly discuss fast nonlinear MPC (NMPC) strategies that include state/parameter estimation with nonlinear, dynamic models. Two case studies that demonstrate the effectiveness of these approaches are briefly summarized in Section 3. In Section 4 we describe additional elements that needed to incorporated within D-RTO. These include analysis of NMPC strategies with economic objective functions, treatment of uncertainty through robust problem formulations and embedded observers, and the incorporation of hybrid elements through the use of complementarity conditions that allow switching in the dynamic system. Finally, Section 5 concludes with a few remarks on the realization of D-RTO through a bottom-up approach that exploits these advances.

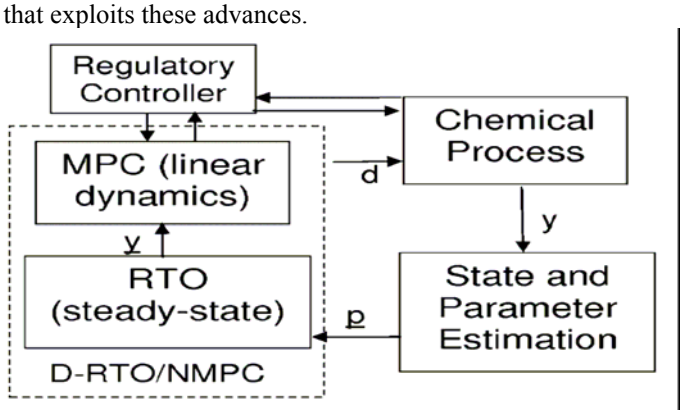

Figure 1. Emerging Structure for Dynamic Real-time Optimization

2. Advances in Model Predictive Control

Linear Model Predictive Control (MPC) has been widely applied for advanced control for over 30 years. Most recent MPC implementations rely on linear dynamic models in state-space form, which enable the treatment of feedforward disturbances, offset correction for model mismatch and robustness to noise. Moreover, as summarized in [6], numerous extensions to hybrid systems have been developed, including the use of complementarity conditions to model discrete decisions. The evolution of MPC to NMPC requires the application of nonlinear DAE models, particularly first principle models that describe the process over a wide range. This extension is essential for nonlinear processes that exhibit wide swings in operation, require frequent product transitions, and consist of multi-stage and non-standard operations. For over ten years, significant advances have been made in the solution of dynamic optimization problems, and they have been applied in practice for time-critical NMPC applications, see e.g., [1, 4, 5]. In particular, the simultaneous collocation approach discretizes the DAEs along with the state and control profiles to form a large-scale NLP, which can be solved very efficiently with full-space barrier NLP solvers such as IPOPT [14]. For a fixed set of parameters, p_0, the resulting NLP can be written as:

$$x^*(p_0) = \arg\{\min f(x, p_0),\ s.t.,\ c(x, p_0) = 0,\ x_l \le x \le x_u\} \quad (1)$$

Moreover, as IPOPT is a Newton method, which exploits exact first and second derivatives, we can easily compute the *sensitivity of the optimal solution* with negligible

computational cost. Under mild conditions, this scheme leads to a first order estimate of $x^*(p)$ where p is any small perturbation from p_0. For NMPC we solve (1) over a predictive time horizon at time t_k with an initial state estimate ($p_0 = x(k)$). A serious drawback of NMPC (and D-RTO) strategies has been computational feedback delay (i.e., the time between receipt of the measured output and injection of the input into the plant) induced by solution of a potentially large NLP. A large delay leads to deterioration of NMPC performance and possible loss of stability.

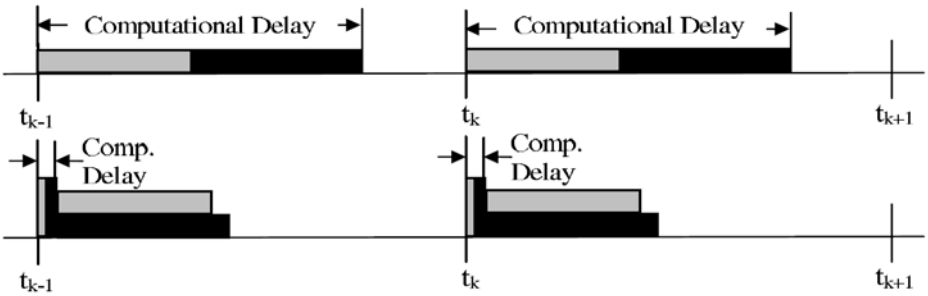

Figure 2: Top graphic depicts computational delay for MHE (gray) and NMPC (black). Bottom graphic indicates background asMHE (gray) and asNMPC (black) calculations (horizontal bars); vertical bars indicate sensitivity calculations.

Recent NMPC advances avoid this delay by restructuring the NLP calculations based on fast solution and sensitivity strategies. Note that the optimization model (1) remains the same for all time horizons, except for the initial state estimate in the horizon. As a result, a real-time iteration strategy (see [4, 15, 17]) allows decomposition of the NMPC into background solutions of (1), between the sampling times, updated with fast on-line *sensitivity* components, once the measured output is received. This approach, called advanced-step NMPC (asNMPC), was developed in [17, 19] and a corresponding nonlinear moving horizon estimator, called asMHE, was developed in [18]. The partitioning of background and on-line calculations is sketched in Figure 2. Even though the injected input is only a first order approximation to the optimum, asNMPC has surprisingly strong stability properties [17]:

- Assuming that NLP (1) can be solved within one sampling time ($t_k - t_{k-1}$) and ideal NMPC stability assumptions hold, then the nominal stability properties of asNMPC are identical to the ideal NMPC controller (i.e., without computational delay).
- Assuming that NLP (1) can be solved within one sampling time and that robust stability assumptions hold for ideal NMPC, then there exist bounds on output noise and model mismatch so that the resulting closed-loop system is input-to-state stable.

The local robustness property is encouraging, but to evolve to handle greater model mismatch and unmeasured disturbances, the optimization framework can be extended in two ways. First, we can embed robust observers and estimators (e.g., MHE, Extended Luenberger Observers, and Extended Kalman Filters) within (1) in order to update the NMPC model with output measurements and thereby reject uncertainty quickly. Recently, recent robust stability results [9] that that this embedding leads to input-to-state practical stability of the combined NMPC system. Second, we can extend (1) to perform robust optimization to determine a control sequence that is feasible for a broad instance of process models. This task can be captured by a multi-scenario formulation [8], with manipulated variables common to all uncertainty scenarios. Fortunately, due to intrinsic local robustness of NMPC, the multi-scenario formulation does not require a dense population of uncertainties.

3. Case Studies of asNMPC and asMHE

Two challenging process case studies are summarized in Table 1 to demonstrate the performance of these advanced step strategies. The first is a low density polyethylene (LDPE) process, which consists of the polymerization reactor and ancillary equipment (see [19]). In these reactors, high-pressure ethylene polymerizes over multiple reaction zones. Heat produced by polymerization is removed in cooling jackets and careful treatment of fouling layers is needed to prevent loss of production and eventual thermal runaway. The LDPE optimization model (1) consists of very large sets of partial DAEs that describe the evolution of the reactor mixture. After axial discretization, a typical LDPE reactor model can easily contain more than 10,000 DAEs. An initial study for a smaller model [18] demonstrated the application of asMHE, while a much larger model was used in [19] for NMPC. The fast performance for the large model was facilitated through a nested dissection of the linearized DAEs in each optimization iteration.

The second case study is an air separation unit (ASU) consisting of coupled low and high pressure columns for the production of high purity oxygen and nitrogen. The ASU distillation model contains MESH equations for 80 trays leading to 800 DAEs [7]. This process is subjected to 30-40% feed ramps along with 5% process noise. Its performance is significantly better than linear MPC and much more robust to noise and model mismatch. The results in Table 1 also show the multiscenario case where three instances of the ASU model are coupled to develop a robust NMPC strategy over a broad uncertainty range [8]. All of these cases consider very large NLPs and on-line sensitivity computation is at least two orders of magnitude less than background NLP.

Table 1. Case study results for asNMPC and asMHE

Case Study	# DAEs	#Vars./#Eqns.	Background CPU s.	On-line CPU s.
LDPE–asMHE [18]	294	27416/27121	202	0.9
LDPE–asNMPC [19]	~10000	243960/242850	120	0.33
ASU–asNMPC [7]	800	117140/116900	120 - 240	1.0
ASU–robust MS [8]	2400	350940/350700	1200-1800	2.0

4. Evolving to Dynamic Real-time Optimization

The previous section describes the enabling tools for the extension of NMPC to D-RTO. In particular, the advanced-step strategies allow us to now consider fast state estimations as well as control with large models. Nevertheless, widespread realization of D-RTO requires additional research in the following areas.

First, NMPC approaches need to be extended to *include economic objectives for D-RTO*. Industrial NMPC with economic objectives has already been realized by Odloak and co-workers at Petrobras [11, 13], and by Bartusiak and coworkers [1] at Exxon Chemicals. These indicate considerable improvement over tracking objectives. For instance, a recent D-RTO study [19] to maximize production in the LDPE process led to 3% LDPE production increase over the (optimal) tracking case. However, questions still remain in assessing stability and robustness with economic objectives. In particular, economic functions do not have properties of Lyapunov functions [5, 11] so additional analysis and modification of the NMPC strategy is needed to ensure stability and

robustness properties of D-RTO. A promising approach is the use of state regularization, similar to the schemes used in the IPOPT solver.

Second, the D-RTO systems require *efficient and robust state estimation schemes*. This can take the form of MHE, solved in parallel with the NMPC step or through embedding of fast observers or state estimators directly within the NMPC model. In either case, these formulations need to extended to reject measurement noise and process disturbances along with treatment of model mismatch. Analysis of stability and robustness properties of such combined schemes has seen recent activity, but still has many open questions (see [9]). In addition, reliable performance requires the incorporation of suitable noise models and extensions to consider fault detection and data reconciliation.

Finally, large integrated D-RTO formulations require the incorporation of *discrete decisions and hybrid elements.* A class of these elements has recently been explored through the application of complementarity conditions [2, 6], i.e.,

$$\min f(x, p_0),\ s.t.,\ c(x, p_0) = 0,\ x_l \le x \le x_u,\ \ 0 \le u \perp v \ge 0 \qquad (2)$$

where $x = [u^T, v^T, w^T]^T$ and (2) is a mathematical program with complementarity constraints (MPEC). Under mild assumptions, the (2) can be reformulated as an NLP and solved using the same NLP tools as in the NMPC strategies described above [2]. This allows many discrete decisions found in RTO models and scheduling tasks to be incorporated within the D-RTO through MPEC formulations.

5. Synthesis of Concepts and Future Directions

Based on the continuing advances described above, this concluding section explores a gentle evolution of current two-layer RTO strategies to a one-layer D-RTO strategy. Industrial successes with the one-layer strategy [1, 11, 13] have shown such a strategy to be successful. Moreover, as MPC loops are more widely applied and better understood than RTO implementations, it appears that a bottom-up D-RTO evolution should be quite suitable for many process systems, using the following guidelines.

- A natural starting point would consider large MIMO MPC applications (up to 50 inputs and outputs); many have already been implemented. These could be retrofitted to replace current linear state-space models by nonlinear DAEs that capture process behavior over a wider range. In addition, the tracking objective then evolves to an economic objective. This evolution leads to an approach analogous to [1].
- Additional robustness can be gained through the addition of embedded state estimators within the NMPC formulation, or through MHE models solved in parallel. The application of advanced-step strategies will allow these tasks to be calculated even for large models with negligible on-line computation.
- Ready extensions to multi-stage operations can be enabled through multiple models and complementarity constraints that handle model transitions and other discrete decisions. These models then evolve to handle additional dynamic features including the management of inventories and external demands, and dynamic integration with other processes. Many of these features cannot be handled by current two-layer RTO.

As a result, implementation o the above advances suggests that D-RTO can be within reach and can lead to significant benefits over current RTO strategies.

How far can D-RTO implementations go? Clearly this is motivated by the need to capture nonlinear dynamic behavior of challenging processes, and also to provide consistent models of process performance. In addition, there is a need to integrate control and RTO tasks with higher level planning and scheduling that can directly exploit the (optimized) performance capabilities of the plant [3, 10]. Finally, the integration of D-RTO over multiple plants requires further development of decentralized nonlinear control [12]. These remain as important and exciting challenges for the work ahead.

Modelling for PSE and Product-Process Design

Rafiqul Gani

CAPEC, Department of Chemical & Biochemical Engineering, Technical University of Denmark, Soltofts Plads, Building 229, 2800 Lyngby, Denmark

Abstract

This paper gives a perspective on modelling and the important role it has within PSE and product-process design. Different modelling issues related to development and application of systematic model-based solution approaches for product-process design is discussed and the need for a hybrid model-based framework is highlighted. This framework should be able to manage knowledge-data, models, and associated methods and tools integrated with design work-flows and data-flows for specific product-process design problems. In particular, the framework needs to manage models of different types, forms and complexity, together with their associated parameters. An example of a model-based system for design of chemicals based formulated products is also given.

Keywords: Modelling, Product-Process Design, Process Systems Engineering,

1. Introduction

Process systems engineering promotes the solution of problems in a systematic manner [1]. In a changing world, the topics covered within chemical engineering are also changing, influencing thereby, the scope and significance of process systems engineering [2, 3 & 4]. Therefore, although PSE has traditionally been applied by the chemical engineering community to solve problems for the oil, chemical and petrochemical industries, its potential application range is much wider. This is because the word “process” also implies, among others, the process of solving a problem; design of biochemical / biological processes for conversion of biomaterial to specific chemicals; and, the process of finding/designing chemicals with desired properties. That is, through the application of a systems approach, a wide range of problems associated with product-process engineering can be analyzed and solved.

In the area of product-process design, the problems differ in terms of the type of chemical(s) being produced. The products (and the processes that make them) from petrochemical and chemical industries are usually commodity chemicals, which could be classified as small and/or structurally simple molecules, produced in large amounts. In this case, process optimization in terms of operational efficiency and cost is usually a defining factor for a candidate product-process. The products (and the processes that make them) from life sciences, pharmaceutical, food and related industries, on the other hand, are usually large and/or complex molecules, produced in small amounts. Here, process optimization in terms of operational reliability and time of operation is usually a defining factor for a candidate product-process. This means that although the steps in the systematic solution of product-process design problems could be the same, the models and data, and the methods and tools that employ them in the various solution steps may be very different.

As illustrated in Fig. 1, models play a very important role in the systematic solution of product-process design problems. Various types of product-process design problems are listed on the right hand side of the figure. These problems are solved through corresponding methods of solution (algorithms) when enough knowledge and/or data are available. Since in most cases, the necessary knowledge and/or data may not be available, models are needed to supplement the available information. For example, models are needed to predict the behaviour of the product-process, to evaluate the performance of the product-process, to monitor and/or control the product-process, and many more. These models may be of different type (different types of equations are used to represent the system); scales (may involve sub-systems requiring different size and time scales); complexity (number of equations, degree of non-linearity, dimension, *etc.*) and simulation mode (steady state, dynamic, batch, identification, *etc.*).

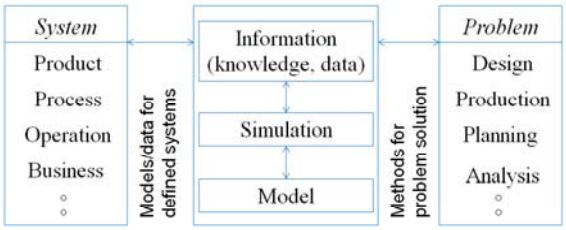

Figure 1: Need for models/data in problem solution

Product-process design in the life sciences, pharmaceutical, food and related industries, as opposed to the oil and petrochemical industries, is principally dependent on experiment-based trial & error approaches, providing thereby, opportunities for PSE to develop model-based solution approaches to reduce some of the experiments. Also, concerns related to increasing industrial activities accompanied by rapid depletion of resources and increase in pollution / waste, have provided opportunities for PSE to develop and implement issues such as energy management, supply chain and sustainability within an enlarged system boundary for product-process design problems. This means that solution approaches for product-process design need to address many inter-related issues, three of which are discussed below:

- Multi-scale: important data related to the chemicals may come from different sources, at different scales of time and size; for example, the properties that define the product characteristics could be based on the microstructure of the molecule or material, while the process behaviour that needs to be monitored and controlled during operation may be defined by the macroscopic (end-use) properties of the chemical system; the supply chain and sustainability issues need to be addressed at the mega-scale.
- Multidiscipline: the conversion, for example, of the biomaterial through biocatalysis requires knowledge of organic synthesis, enzymes, reaction catalysis, bioreactor design and operation – information about these topics come from different disciplines; sustainability analysis requires data, methods and tools from different disciplines.
- Integrated computer-aided techniques: lack of models to predict the behaviour of chemicals at different scales, of enzymes during organic synthesis, of reaction kinetics, *etc*., means that appropriate model-based computer aided techniques have not been developed and use of experiment-based techniques is the only option for these problems. Also, the multi-scalar and multi-

disciplinary nature of problems point to the need for integration of appropriate methods and tools.

In principle, product-process design (and development) needs to consider the demand for improved chemical-based products, made from more sustainable raw material resources and employing more efficient processes to make them. Therefore, methods and tools suitable for current and future product-process design need to manage a collection of sub-problems that require efficient and consistent handling of data and knowledge from different sources and at different time and size scales. A systems approach that can efficiently "manage the complexity" becomes therefore a very desirable option.

This paper provides a perspective on the opportunities for the development and use of hybrid model-based frameworks for systematic solution of chemical product-process design problems.

2. Managing the Complexity

The generic mathematical definition of the product-process design problem is given by,

$$F_{obj} = \{\boldsymbol{S}^T \underline{y} + f(\underline{x})\} \quad (1)$$

Subject to

$$\underline{D_1} = \underline{h_1}(\underline{x}, \underline{z}, \underline{p}) \quad (2)$$

$$\underline{D_2} = \underline{h_2}(\underline{x}, \underline{z}, \underline{p}) \quad (3)$$

$$0 \geq \underline{g_1}(\underline{x}, \underline{z}, \underline{p}, \underline{\theta}) \quad (4)$$

$$0 \geq g_2(\underline{x}, \underline{z}, \underline{p}, \underline{\theta}) \quad (5)$$

$$\boldsymbol{B}\underline{y} + \boldsymbol{C}\underline{x} \leq \underline{d} \quad (6)$$

In the above generic problem definition, the performance index (Eq. 1) needs to be minimized or maximized and may include multiple terms; the process model (Eq. 2) satisfies the conservation of mass and/or energy as a function of the product-process variables ($\underline{x}$), design variables ($\underline{z}$) and model parameters ($\underline{p}$); the product performance model (Eq. 3) predicts the behaviour of the product during its application; the product-process structure equations (Eq. 6) generate the feasible molecular-flowsheet structures as a function of decision (integer) variables ($\underline{y}$) and $\underline{x}$; and finally, the product-process constraints (Eqs. 4-5) define operational and/or chemical functional constraints ($\underline{\theta}$). Considering that the models maybe multi-scalar, non-linear and the variables involved may be integer as well as real, the generic problem defined above could represent a complex multi-dimensional problem of the MINLP type. Several variations of the above problem have also been formulated and solved in process optimization [3], heat-mass exchange networks [5], and in product-process design [6].

Before the generic product-process design problem defined above can be solved, several issues need to be addressed. For example, how to generate (or create) the product-process model objects for a large range of chemical systems? How to collect the necessary data for $\underline{z}$ and $\underline{p}$ for a wide range of models and systems? How to find a good initial estimate for $\underline{x}$ and $\underline{y}$ for different types of problems? One way to manage this complexity would be to provide a hybrid model-based framework for handling a diverse set of design work-flows corresponding to a wide range of problems, through an integrated computer-aided system. Such systems need to have a knowledge base of data, a library of models, a collection of algorithms (the work-flow and data-flow guiding the engineer/scientist through the solution steps), and, other associated methods-tools (such

as a tool to analyze data; a tool to create the missing model; a tool to screen feasible alternatives). An important question here is what is the role of models?

2.1. Model Role

The role of models within the context of product-process design is briefly discussed here. Should the model be used to simply replace the experiment, or, should the model play a more active role in finding truly innovative solutions? That is, should the model(s) be used mainly to verify a design (for given $\underline{y}$, $\underline{z}$, $\underline{p}$, $\underline{\theta}$, verify if the optimal $\underline{x}$ is obtained and if the value of the corresponding F_{obj} is really optimal?); or should they be used as part of a trial & error solution approach (assume values for $\underline{z}$, calculate $\underline{x}$ and $\underline{y}$, and, check if $\underline{\theta}$ is satisfied, check if F_{obj} is optimal - if not - repeat the procedure for another value of $\underline{z}$); or should the problem be decomposed into sub-problems and solved according to a derived hierarchy?

For the verification role, a validated model (in the form of a process simulator) performs the same function as experiments. The design decisions, are however, obtained separately (using the same models in a different role). For the trial & error solution approach, a model-based simulator simply replaces the experiment. While experiment based trial and error is sometimes the only alternative to solve a specific product-design problem, if the appropriate models are available, the search can be conducted over a larger space and the time and resources used to obtain a design can be significantly reduced. In this case, the experimental resources are reserved for the verification step in the final stages of the design process, rather than using them in the early stages of the design process. Here, the process model is used to define design targets ($\underline{x}^*$, $\underline{\theta}^*$) for the chemical product, while a collection of property models are used in the search for a match of the target. The method is called "reverse design" because first the optimal solution is located and from it, the design targets are defined. Then, the set of values for the design variables ($\underline{z}$) matching the targets (the optimal solution) is determined [7].

2.2. Model Generation

The application range of the hybrid model-based solution approach depends on the application range of the available models. Therefore, to achieve a wide search space during the early stages of the design process, the corresponding models need to be predictive by nature. In the later stages of the design process when quantitative values of the design variables are determined, the models need to be quantitatively correct but the application range does not need to be wide. In this respect, a multi-scale modelling scheme that can generate the necessary model(s) would be an interesting option, especially if the necessary model parameters ($\underline{p}$) can be predicted on-line without the need for additional experimental data. The main idea here is to use the same set of experimental data to regress model parameters at different scales. The models at the lower scales need less parameters to represent the same dataset and the model descriptors for the lower scales can be used to estimate the missing parameters in the adjacent higher scale. In this way, the predictive power of the model-based framework for product-process design is extended without the need for new data.

2.3. Problem Decomposition

The principal idea here is to decompose a complex problem into a set of sub-problems that are easier to solve and identify those that can be solved through model-based solution approaches. Solving these sub-problems according to a pre-determined sequence helps to reduce the search space through each subsequent sub-problem solution, until a sub-problem cannot be solved with models anymore. At this point, the

experiment-based trial and error approach takes over to determine the final solution. The advantage of this combined hybrid (systems) approach is that during the early stages, where enough data and models are available (or could be easily generated), the search space is rapidly reduced. In the later stages, where quantitative values become important and data/models become more unreliable, the experimental resources are employed, sometimes only to evaluate a few feasible alternatives to identify the truly innovative and best solution.

3. Example: The Virtual Product-Process Design Lab

Here, only one example of a model-based system, the *virtual* product-process design lab for design and analysis of various chemicals based formulated products, is briefly highlighted. Examples of other integrated systems managing the complexity can be found in [3, 4 & 9].

The idea behind the *virtual* product-process design lab is the following: instead of doing the experiments needed to search for a product and its process to manufacture it, the engineer / scientist performs *virtual* experiments, through the *v*PPD-lab software. The *forward* and the *reverse* solution approaches are available. The software contains a large knowledge base of data (of chemicals, of solvents, of plants, of microcapsule devices, *etc*.); a large collection of models (models for property prediction, models for controlled release, models for mixing, *etc*.); of design algorithms (methods for formulation design, methods for molecule design, methods for polymer design, methods for process flowsheet synthesis, *etc*); other tools (property prediction software; model generation software; equipment design software; design of experiments software, etc.). These are organized through a framework for efficient management of the complexity. Figure 2 gives an overview of the main features of *v*PPD-lab, which has been used in the design and evaluation of the controlled release of a drug active ingredient through a polymeric microcapsule, pesticide formulation, paint formulation, fuel-cells, and many more.

In the first step the problem is defined (for example, identity of the active ingredient; the desired controlled release parameters, *etc.*, are given in the "documentation" box of *v*PPD-lab). In the second step the selection of the application source (for example, codeine released into the body) and the primary properties of solvent and the polymer (needed by the controlled release model) are made. If the user is unable to provide this information, methods for solvent design and polymer design are used to generate a list of candidates to select from. In the next step the selection and calculation of the functional properties needed to evaluate the controlled release design is made (if models are not available, the modelling software helps to generate new models). In the next steps, the product performance model is used to predict the product behaviour. If the desired (target) performance is matched, then the last step of verifying the product performance through experiments is performed. If the target is not matched, it is possible to repeat from any of the earlier steps with a new design alternative.

Important issues to note from this example are that multi-scale models have been used, data and knowledge from different disciplines have been used and, design / evaluation problem has been effectively used by solving a collection of sub-problems according to a pre-determined sequence. The final step (not shown) would be to select a few of the alternatives and perform the necessary experiments to validate the selection. Therefore, the experiments are done not to design the product but to verify the product. This approach has the potential to save time and money in bringing a chemical based product to the market. Obviously, the accuracy and range of application of the *v*PPD-lab software depends on the available data and models in the software.

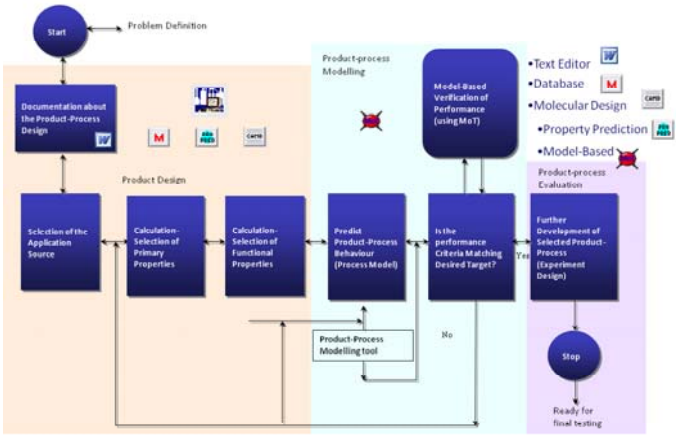

Figure 2: Virtual Product-Process Design Lab [10]

4. Conclusions and future work

The products of PSE are ideally suited to manage the complexity related to the analysis and solution of various types of product-process design problems. For the methods and tools to be able to solve a wide range of problems, models valid for a wide range of problems also need to be available. A systematic computer-aided modelling framework can play a major role in advancing the state of the art in PSE. The role of the model, however, needs to be clearly defined. This paper highlighted some of the opportunities and needs related to the development and use of systematic model-based solution approaches for chemical product-process design.

WebLabs Dilemma in Chemical Engineering Teaching: Hindering or Promoting Creativity?

Roberto de Campos Giordano

Department of Chemical Engineering, UFSCar, Brazil
roberto@ufscar.br

Abstract

The universal spreading of links to the world net, in exponential growth, is an irreversible trend. Simultaneously, there is a continuous expansion of the accessibility to Internet 2 in Universities and Colleges of different countries, including Brazil. Ever-decreasing latency, bandwidth enhancement, a growing number of available tools and computational resources, all these trends are expected to change several aspects of the teaching/learning interaction.

The field of Chemical/Biological and Process/Bioprocess Engineering is certainly part of this process. And one important aspect in this area is the access to experimental set-ups, which are essential for development and consolidation of knowledge, assimilation of theoretical concepts, stimulation of critical reasoning and induction of cooperative work.

In this context, one important tool may be the use of WebLabs, remote-access laboratories available through the commercial or advanced Internet. Here we define a WebLab as a real experiment, properly automated and linked to the net, which may me operated from distance. Of course, virtual labs are important, too, and usually are part of the WebLab – allowing training, repetition when the apparatus is off-line, and so on. But one first point that we put forth is that the real experiment remains essential, at least in our field of knowledge.

The idea of using remote-access real experiments, connected to the internet, was brought about by MIT's iLab program, in mid-90's, focusing mainly on electronic, structural and chemical engineering experiments that would be available 24x7. Of course, within this conception, the experiment must be designed for stand-alone operation. Despite the breakthrough concept of opening didactic laboratories for www access, this approach provides limited space for a creative intervention from the students themselves.

Here, we discuss the feasibility of building a different methodology. The question is: can WebLabs be used as a tool that promotes creativity, and stimulates active or cooperative learning (both understood within the scope defined by the works of Felder, www4.ncsu.edu/unity/lockers/users/f/felder/public/, accessed in March 2009)?

Some real cases will be presented, involving cooperative Weblabs, that is, experiments performed collaboratively between two groups of undergraduate students, from two different Institutions, remotely joined in one team.

That was the result of a joint project, gathering four Chemical Engineering schools (USP, UFSCar, USP-RP and UNICAMP), funded by the São Paulo research agency FAPESP, within the Kyatera-TIDIA program (from the Portuguese acronym for Information Technology for the Development of the Advanced Internet).

Particularly, Universities in Brazil and France, and Universities from different regions in Brazil, have taken part in this pedagogical experiment. We believe this was a unique approach for the application of WebLabs in undergraduate Engineering education. Besides the improvement of cooperation abilities for hands-on problem solving, the students were exposed to different cultures, enhanced their communication skills and, last but not least, had a deeper insight of the fundamentals involved in the problem under study. Hence, this approach aimed to partially fulfill the lack of interaction in this level of engineering education, within an active learning environment.

To go further, in the direction of cooperative learning, the students should be involved in long-term projects and, under supervision, would have to understand the fundamentals of the problem on focus, to get acquainted with the experimental facilities that are available, design (all the group) and set-up (local fellows) the experiment, run assays, analyze results, go back to the lab... and write reports. The continuous contact with the remote fellows would emulate the real-world professional environment of the modern global economy, where remote interaction between professionals in different countries, working on the same project, becomes evermore frequent.

In conclusion, the point we make here is that it is possible to involve mixed groups of students of different Institutions, even from different countries, in open experiments, demanding initiative and teamwork. But this will only happen if professors and lecturers of both Institutions are committed, also as a team, to establishing new teaching methodologies. However, one might ask: are they available for this kind of work nowadays?

Research Challenges in Planning and Scheduling for Enterprise-wide Optimization of Process Industries

Ignacio E. Grossmann

Center for Advanced Process Decision-making,Department of Chemical Engineering, Carnegie Mellon University, Pittsburgh, PA 15213, USA

Abstract

Enterprise-wide optimization (EWO) is a new emerging area that lies at the interface of chemical engineering and operations research, and has become a major goal in the process industries due to the increasing pressures for remaining competitive in the global marketplace. EWO involves optimizing the operations of supply, production and distribution activities of a company to reduce costs and inventories. A major focus in EWO is the optimization of manufacturing plants, which often requires the use of nonlinear process models. Major operational items include production planning, scheduling, and control. This paper provides an overview of major challenges in the development of deterministic and stochastic linear/nonlinear optimization models for planning and scheduling for the optimization of entire supply chains that are involved in EWO problems.

Keywords: supply chain optimization, planning, scheduling, mixed-integer programming, stochastic programming.

1. Introduction

The goal of this paper is to provide a general overview of the role of planning and scheduling in Enterprise-wide Optimization as applied to the process industry. This paper is largely a follow-up of the ideas, concepts of our previous paper in the area (Grossmann, 2005). It has also been motivated by our experiences in the Enterprise-wide Optimization project of the Center of Advanced Process Decision-making at Carnegie Mellon University (http://egon.cheme.cmu.edu/ewocp/) which involves faculty from Carnegie Mellon, Lehigh and University of Pittsburgh in collaboration with ABB, Air Products, BP, Dow Chemical, ExxonMobil, Nova Chemicals, PPG, Praxair and Total.

Enterprise-wide optimization (EWO) has become a major goal in this industry due to the increasing pressure for remaining competitive in the global marketplace (Grossmann, 2005; Varma et al, 2007). EWO involves optimizing the operations of R&D, supply, production and distribution to reduce costs and inventories. A major focus in EWO is the scheduling of production facilities, as well as their modeling at the proper level of detail, often requiring nonlinear process models. Major operational items include planning, scheduling, real-time optimization and control. One of the key features in EWO is integration of the information and decision-making among the various functions that comprise the supply chain of the company. This is being achieved with modern IT tools. To fully realize the potential of transactional IT tools, the development of deterministic and stochastic linear and nonlinear optimization models and algorithms (analytical IT tools) is needed to explore and analyze alternatives of the

supply chain to yield overall optimum economic performance, as well as high level of customer satisfaction. An additional challenge is the integrated and coordinated decision-making across the various functions in a company (purchasing, production, distribution, sales), across various geographically distributed organizations (vendors, facilities and markets), and across various levels of decision-making (strategic, tactical and operational).

As an example of a large-scale EWO problem consider in Fig. 1 the supply chain in the petroleum industry which comprises many intermediate steps starting from the exploration phase at the wellhead, going through trading and transportation, before reaching the refinery, and finally the distribution and delivery of its products at the retail level (e.g. gasoline). In this case it is clear that the effective coordination of the various stages is essential to accomplish the goal of EWO. As another example, Fig. 2 shows the supply chain in the pharmaceutical industry that starts with the R&D phase for testing of new drugs, a major bottleneck that must be eventually coupled with batch manufacturing and global distribution for drugs that achieve certification.

From the two examples, we can define Enterprise-wide Optimization as optimizing the operations of R&D, material supply, production, distribution and financial activities of a company to reduce costs and inventories, and to maximize profits, asset utilization, responsiveness and customer satisfaction. The goal of achieving Enterprise-wide Optimization in the two examples is clearly still elusive and motivates the research challenges outlined in the paper.

Fig. 1. Supply chain in the petroleum industry (courtesy ExxonMobil).

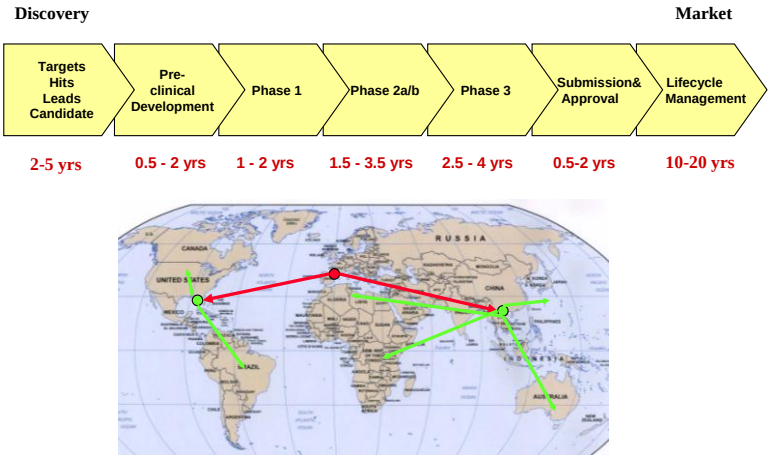

Fig. 2. R&D coupled with manufacturing and distribution in the supply chain of the pharmaceutical industry

One of the key features in EWO is integration of the information and decision making among the various functions that comprise the supply chain of the company. Integration of information is being achieved with modern IT tools such as SAP and Oracle that allow the sharing and instantaneous flow of information along the various organizations in a company (Fig. 3). While these systems have become quite powerful, they do not provide comprehensive decision making capabilities that account for complex trade-offs and interactions across the various functions, subsystems and levels of decision making. Therefore, companies are faced with the problem of deciding as to whether to develop their own in-house tools for integration, or else make use of commercial software from vendors. While progress has been made in developing generic commercial tools, the great diversity of application areas as well as the integration that is required across geographical and time scales for EWO continues to be a major barrier for the effective deployment of these commercial tools. Therefore, currently there is still need for significant in-house development in order to exploit the particular features of the problem at hand so as to produce effective, practical useful tools.

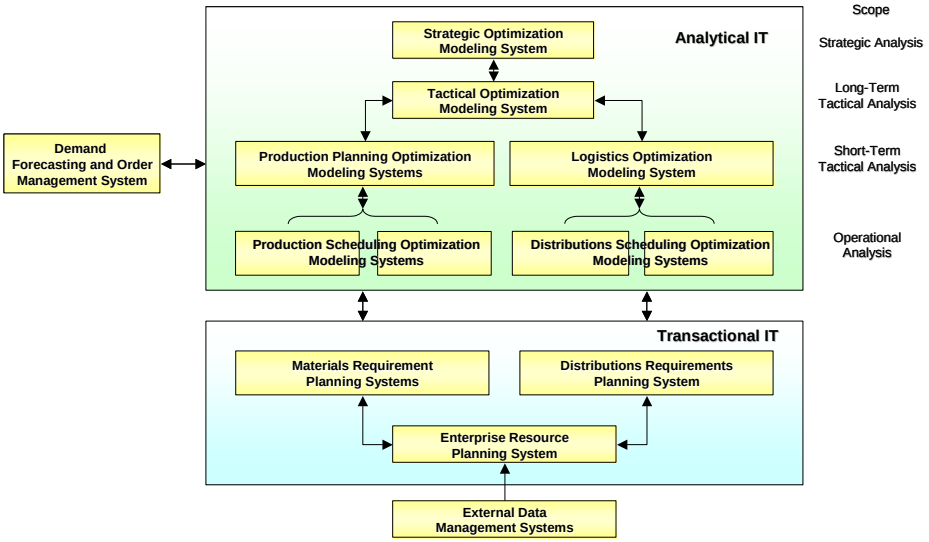

Fig. 3. Transactional and Analytical IT (Tayur et al., 1999).

2. Challenges in Enterprise-wide Optimization

A major challenge that is involved in EWO of process industries is the integrated and coordinated decision-making across the various functions in a company (purchasing, production, distribution, sales), across various geographically distributed organizations (vendors, facilities and markets), and across various levels of decision-making (strategic, tactical and operational) as seen in Figure 3 (Shapiro, 2001). The first two items conceptually deal with issues related to *spatial integration* in that they involve coordinating the activities of the various subsystems of an enterprise. The third item deals with issues related to *temporal integration* in that they involve coordinating decisions across different time scales. Addressing these spatial and temporal integration problems is important because they provide a basis to optimize the decision-making in an enterprise through the IT infrastructure.

In order to achieve EWO throughout the process industry, this goal will require a new generation of computational tools for which three major challenges must be addressed:

a) *The modeling challenge:* What type of production planning and scheduling models should be developed for the various components of the supply chain, including *nonlinear* production processes, that through integration can ultimately achieve enterprise-wide optimization? Major issues here are the development of novel mathematical programming and logic-based models that can be effectively integrated to capture the complexity of the various operations.

b) *The multi-scale optimization challenge:* How to coordinate the optimization of these models over a given time horizon (from weeks to years), and how to coordinate the long-term strategic decisions (years) related to sourcing and investment, with the medium-term decisions (months) related to tactical decisions of production planning and material flow, and with the short-term operational decisions (weeks, days) related to scheduling and control? Major issues involve decomposition procedures that can effectively work across large spatial and temporal scales.

c) *The uncertainty challenge*: How to account for stochastic variations in order to effectively handle the effect of uncertainties (e.g. demands, equipment breakdown)? Major issues here are the development of novel, meaningful and effective stochastic programming tools.

As described in Grossmann (2005), there are also many algorithmic challenges, particularly for solving mixed-integer linear and nonlinear programming problems. For a recent review on MILP models and algorithms that are relevant to this area see Pochet and Wolsey (2007).

The modeling challenge. While the area of planning and scheduling has seen the development of many models in Operations Research (OR) (e.g. Pinedo, 2001), over the last decade a significant number of planning and scheduling models have been proposed in process systems engineering specifically for process applications (Kallrath, 2002). In contrast to general OR scheduling models, the process-oriented models may require the use of material flows and balances, and very often network topologies that are quite different from the more traditional serial and multistage systems. Furthermore, they address both batch and continuous processes, and may require the use of detailed nonlinear process models. One of the most important issues in the development of planning and scheduling models is time representation, namely discrete and continuous time representations. Discrete time models, which often have tighter relaxations, have become more competitive since it is increasingly possible to solve problems with smaller time intervals due to great advances in MILP optimization. Nevertheless, continuous time models are still required, especially when sequence dependent changeovers are involved. Recent reviews on discrete and continuous time scheduling models can be found in Floudas and Lin (2004) and Mendez et al, 2006.

The multi-scale optimization challenge. Planning and scheduling of process systems are closely linked activities since they deal with the allocation of available resources over time to perform a collection of tasks required to manufacture one or several products (Bodington, 1995; Kallrath, 2002). The aim in planning is to determine high

level decisions such as production levels and product inventories for given marketing forecasts and demands over a long time horizon (e.g. months to years). Scheduling, on the other hand, is defined over a short time horizon (e.g. days to weeks) and involves lower level decisions such as the sequence and detailed timing in which various products should be processed at each equipment in order to meet the production goals set by the planning problem. Integration and coordination of planning and scheduling are key components in EWO. Conceptually, the simplest alternative for solving planning and scheduling problems is to formulate a single simultaneous planning and scheduling model that spans the entire planning horizon of interest. However, the limitation of this approach is that when typical planning horizons are considered, the size of this detailed model becomes intractable due to the potential exponential increase in the computation. The traditional strategy for solving planning and scheduling problems is to follow a hierarchical approach in which the planning problem is solved first to define the production targets. The scheduling problem is solved next to meet these targets (Bodington, 1995; Shapiro, 2001). The problem of this approach, however, is that a solution determined at the planning level does not necessarily lead to feasible schedules. These infeasibilities may arise because the effects of changeovers are neglected at the planning level, thereby producing optimistic targets that cannot be met at the scheduling level. Therefore, methods and approaches are being developed that can more effectively integrate planning and scheduling (e.g. Dimitriadis et al, 1997; Erdirik-Dogan and Grossmann, 2006; Sung and Marvelias, 2007). On the other hand, supply chain optimization (Neiro and Pinto, 2004; Shah, 2005) is another multiscale optimization problem where the dominant issue is the handling the spatial and temporal scales, which require the use of decomposition (e.g. Jackson and Grossmann, 2003).

The Uncertainty Challenge. Uncertainty is a critical issue in EWO. Furthermore, it is complicated by the fact that the nature of the uncertainties can be quite different in the various levels of the decision making (e.g. strategic planning vs. short term scheduling vs. control). Research in the process industry has largely focused on strategic uncertainty (e.g. Ahmed and Sahinidis, 1998; Goel et al., 2006). Handling uncertainty in inventory management (e.g. Zipkin, 2000) is only beginning to be considered in process systems engineering (e.g. You and Grossmann, 2008). The same applies at the tactical level for production planning with uncertain demand (Gupta and Maranas, 2003; Sand and Engell, 2004). The reason for this situation is that the corresponding deterministic optimization problems are difficult to solve, and hence the resulting optimization problems under uncertainty with probability distribution functions become extremely complex. A comprehensive review on methods for addressing optimization under uncertainty can be found in Sahinidis (2004).

2. Concluding Remarks

This paper has provided a brief overview of three major research challenges in the emerging area of Enterprise-wide Optimization: modeling of planning and scheduling, multiscale optimization and handling of uncertainties. From this overview it is clear that further research is required to expand the scope and size of production planning and scheduling models that can be solved in order to achieve the goal of EWO. Major challenges remain in the development of novel models for integrating, planning, scheduling and control. Of particular significance is the development of effective decomposition schemes that have the capability of handling large-scale problems over

geographically distributed sites and over wide temporal scales. There is also an increasing need for the effective global optimization of nonconvex planning and scheduling problems that incorporate process models. The development of effective and meaningful solution methods for stochastic programming problems for handling uncertainties continues to be of paramount importance. It is worth noting that all these developments will require a synergy of advances in basic algorithms and advances in large-scale computation. These efforts should help to expand the scope and nature of EWO models that can be effectively solved for real-world industrial problems.

Production Scheduling in the Process Industries: Current trends, emerging challenges and opportunities

Gabriela P. Henning

INTEC (UNL-CONICET), Güemes 3450, Santa Fe, CP 3000, Argentina

Abstract

This paper discusses the current trends and defies associated with production scheduling, both from an industrial and academic perspective. First, the new challenges that appear in the context of globalized and competitive economies are addressed. They stem from the need of considering scheduling as a building block of the Advanced Planning Systems (APSs) that nowadays participate in Supply Chain Management (SCM) functions. They are primarily associated with business process coordination and information integration requirements. Then, main features, strengths and limitations of current academic proposals are briefly addressed. Finally, some of the reasons for the slow acceptance and modest penetration of these research results are highlighted. Thus, challenges and opportunities to be faced in order to alleviate the miscommunication of the academic and industrial worlds are pointed out.

Keywords: Process Scheduling and Operations, Advanced Planning Systems, Supply Chain Management, Business Process Coordination and Integration

1. Introduction

Nowadays, most companies experience a growing international competition and recognize the needs of supply chain (SC) efficiency and responsiveness. These requirements originate from the pressures of shortened product life-cycles and increasing customer demands on a great variety of low-price, high quality products. On top of these needs, there are also higher expectations on accurate deliveries, with short lead-times and always rising customer service levels. The growth in globalization, and the additional management challenges it brings, has motivated interest in global Supply Chain Management (SCM). Successful SCM requires a change from managing individual functions to integrating activities into key SC business processes.

In order to compete, companies must be more efficient, transparent, and agile. This requires real-time visibility into their business operations and the ability to react if needed. To achieve this goal, Operational Intelligence (OI) focuses on providing on-line monitoring of business processes and activities as they are executed, in assisting them by identifying and detecting situations which correspond to interruptions, inefficiencies, threats, bottlenecks, etc., and communicating them to relevant stakeholders.

Since many process industries try to adopt SCM and OI philosophies, this introduces new pressures into the way they perform their scheduling activities. The trend is to adopt scheduling systems (SSs) which no longer are employed as isolated support applications. On the contrary, they are perceived as integrated building blocks of these advanced management tools. Thus, new tendencies and problems have appeared. Modern SSs are nowadays part of the Advanced Planning Systems (APSs) that industry

is quickly adopting (Stadtler and Kilger, 2005), and new functional and non-functional requirements have arisen for them. These new requisites are discussed in Section 2, along with more traditional industrial demands not covered yet in most SSs.
On the other hand, from the academic side, there has been enormous progress on methodologies to tackle scheduling problems in the last two decades. A brief overview of their strengths and limitations, as well as current trends, is presented in Section 3. Despite the flourish of approaches, a dichotomy between the industrial and academic worlds is still evident. Requirements that SSs need to face in a competitive and globalized context, as well as capabilities and characteristics that academic proposals need to incorporate to be accepted by the industrial community, are discussed in Section 4, which summarizes emerging challenges and opportunities.

2. Industrial practice: Activities in the context of Advanced Planning, Commercial Scheduling Systems and OI applications

As organizations strive to focus on core competencies, they have increased the manufacturing outsourcing of some components and intermediate products and have reduced the ownership of raw materials sources and distribution channels. Thus, the number of different partners along extended SCs has progressively grown. This led in most cases to complex planning situations having multiple products, manufactured at multiple work centers in multi-site production systems, which are transported by third or fourth party logistics. Under these circumstances, scheduling is crucial for achieving the timely and cost-effective execution of industrial production processes. However, the pressures being faced now are much higher than those identified by Shah (1998).
In the context of the burdens that globalization and networked economies pose, advanced concepts on supply chain management (SCM) have emerged. According to Stadtler and Kilger (2005), the goals of SCM can be achieved by resting on two pillars: the integration of the organizational network and the coordination of material, information, and financial flows. In turn, the coordination pillar comprises several building blocks: proper use of information and communication technology, process orientation, and advanced planning. All of them are quite relevant to define the context in which a scheduling system must operate and to specify the requirements it must fulfill.
Advanced Planning includes long, mid and short-term planning levels. Software products, referred as Advanced Planning Systems, are now available to support these tasks. APSs aim at complementing existing ERP systems and overcoming some of their weaknesses. ERPs have traditionally addressed planning tasks poorly and have focused on a single company. On the contrary, modern APSs are being designed for inter-organizational SCs. APSs try to find feasible, near optimal plans across the SC as a whole, while potential bottlenecks are considered explicitly (Stadtler and Kilger, 2005). In terms of software components, an APS means a broad group of integrated software applications developed by various software vendors, such as i2 Technologies, Manugistics, Oracle, SAP, AspenTech, etc. Fig. 1 shows the structure of a generic APS.
For the sake of brevity all of these systems are not discussed in detail; however, some advanced ones, such as Aspen Plant Scheduler (http://www.aspentech.com) or SAP Advanced Planner and Optimizer (SAP-APO) (http:// http://help.sap.com) are worth to be mentioned, since they exhibit a high degree of integration of their scheduling component with the other planning modules comprising the system. Regarding solution methodologies included in the scheduling element, the first of these systems uses decision rules and heuristics, while SAP-APO employs the ILOG´s optimizer library, as

other vendors, but pre-defined model formulations are not made completely explicit. SAP APO offers several solution approaches, among them mixed-integer linear programming (MILP), constraint programming (CP) models and evolutionary algorithms.

Embedded optimization models seem to be a problem associated with APSs since explicit, high level representations are not available yet. On the contrary, SAP APO as well as other ASP providers, have coded their models in C or C++. As suggested by Kallrath and Maindl (2006), this fact has several consequences: (i) Before starting an implementation of an APS, a thorough investigation of the applicability of the vendor's models is necessary, and (ii) knowledgeable users in modeling techniques are required to embed pre-defined SAP-APO models, as well as "own" optimization models. The users (consultants, schedulers) not only would need to understand the underlying scheduling approach, but also know how to make it interoperate with the transactional and master data that the APS handles.

Despite advances in the integration of the various planning functions, APSs do not seem to have specific tools to address reactive scheduling problems. To properly tackle them, besides having specific solution approaches, the integration of the APS with the Manufacturing Execution System (MES) is required. As pointed out by Harjunkoski et al. (2008), this integration is mandatory for the correct management of manufacturing operations and to perform control activities. Such integration should rely on the pillars of standard representations (ANSI ISA-95, ISA-88), business process modeling and service oriented architectures.

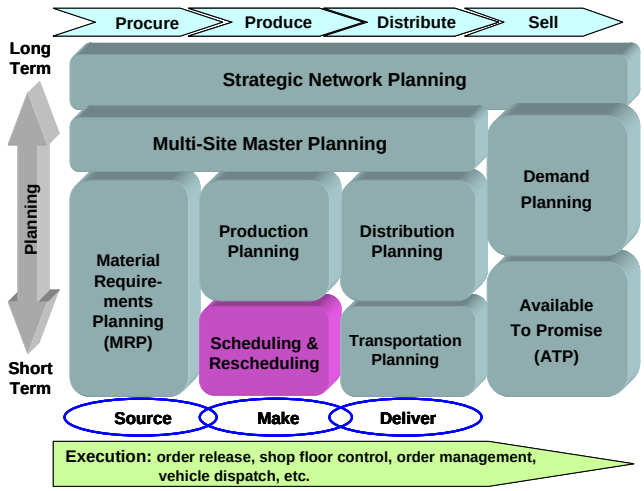

Fig.1. Components of a Generic APS

In addition to APSs, many commercial SSs have matured over the last decade. Over 100 software applications of Finite Capacity Scheduling (FCS) systems are available according to APICS (http://www.apics.org). However, the use of these systems is not widely spread yet. Among them is worth to mention some applications that are academic spin-offs. For instance, applications like VirtECS Schedule from Advanced Process Combinatorics (http://www.combination.com) and SchedulePro from Intelligen (http://www.intelligen.com) have powerful graphical capabilities and include interactive scheduling tools (ISTs), features that are always demanded in the industrial world.

However, the integration of these systems, similarly to other commercial packages, with the organization planning modules and the MES, does not seem straightforward.
Finally, it should be mentioned that most APSs and commercial SSs do not have explicit support for basic OI functionalities, like process traceability as well as the automatic and seamless generation of metrics and key performance indicators.

3. Research Efforts: Strengths and limitations of the academic proposals

Nowadays, the academic community is able to address more difficult and larger scheduling problems than those tackled twenty years ago. The most significant research efforts are highlighted in some excellent reviews, like the ones of Li and Ierapetritou (2008), Méndez et al. (2006), Floudas and Lin (2004), Kallrath (2002), Pekny and Reklaitis (1998), Pinto and Grossmann (1998) and Shah (1998). Usually, problems are solved by resorting to MILP formulations. Optimal solutions are many times reached for small and medium size problems, with reasonable computational efforts. This success basically comes from the remarkable advances in modeling techniques, algorithmic solutions and computing technologies that occurred in the last decade.
One of the key elements of the various MILP approaches involves time representation; current formulations can be classified into discrete-time and continuous-time models. Other essential issues are related to the characteristics of the production environment being considered: sequential or network process, operation modes, storage policies, type of critical resources, changeovers, etc. This wide scope of features has led to a variety of formulations that are generally oriented to properly address particular classes of problems. Despite recent advances, there is no general formulation that can tackle the various classes of problems with the same efficiency. For instance, it is not clear the extent to which methods aimed at addressing complex network processes, can also be successfully applied to other structures commonly found in industry, such as the multistage one. Efficiency is also highly dependent on the adopted objective function; however, no extensive evaluations have been done in this respect. Nowadays, nobody denies that schedule measurement is a critical aspect of the scheduling problem, which is multiobjective, multiattribute in nature. Schedules mean different things to different people and are used by various organizational groups in distinct ways. Even having a single scheduler involved in the evaluation process, the question of how to deal with the tradeoffs between the different metrics of interest is hard to address without keeping the human involved (Kempf et al., 2000). Few advances in this respect have been made by the academic world.
Formulations based on CP have also gained interest recently (Maravelias and Grossmann, 2004; Roe et al., 2005). The PSE community has started to adopt CP, mainly in combination with MILP models, because these techniques are complementary to each other when a cost or profit related objective function is chosen. Nevertheless, this hybrid approach has a poor computational performance when other objective functions related to time are tackled.
An analysis of current proposals shows that they are becoming more mature and progress is made along various research lines. Some works have improved the representations from a computational point of view (Janak and Floudas, 2008). Others have concentrated on the expressive power of the model, to be able to capture more realistic features (Giménez et al., 2009). Moreover, recent proposals have extended previous formulations to move the frontiers of the problems being tackled, thus addressing the integration of scheduling and design (Castro et al., 2005), planning and scheduling (Maravelias and Sung, 2008), of mid and short-term scheduling (Janak et al.,

2008a), etc. In fact, there is a new tendency to generalize basic formulations to address a wider scope of problems. Fortunately, the latest reactive scheduling proposals (Vin and Ierapetritou, 2000; Méndez and Cerdá, 2004; Janak et al., 2008b, etc.) follow this trend and share the basic representation with their predictive scheduling counterparts, facilitating the integration of predictive and reactive scheduling components.

4. Emerging challenges and opportunities

As seen, the industrial and academic worlds have given considerable attention to the scheduling problem and enormous advances have been achieved. Due to lack of space certain important problem features, such as uncertainty, or some solution techniques, as metaheuristics and evolutionary approaches, have not been treated in this work.

Despite this progress, most of the theoretical research done during the last 15 years is of limited use in the real world. In fact, while researchers provide answers to toy cases, practitioners have difficulties in explaining their needs and exploiting the opportunities that could come out from the utilization of advanced scheduling approaches. Naturally, this academic-industrial dichotomy has several causes. Some are pointed out below:

- Currently, a SS is one of the blocks of an APS, which in turn is part of a SCM system. This fact imposes requisites of applications' integration and business process coordination. On the other hand, academic proposals have focused on algorithms and computational performance; thus, they lack a business process view and do not have an explicit domain representation, which would facilitate integration. For instance, most MILP approaches rely on very sophisticated formulations (grounded on STN and RTN models, and artificial notions like time points, events and time grids) that do not have a direct mapping to ordinary problem elements, as they are perceived by industrial practitioners and to master data, as handled by industrial information systems. In consequence, to bring in industry representations which are oriented towards efficient problem solving, there is a need to revalorize the design of interfaces (CAPE-OPEN, 2001), as well as the development of ontologies and meta-languages.
- The role of the human scheduler needs to be stressed at the various problem solving stages: Problem definition, solution process and results analysis (Weirs, 1997). Schedulers must be able to manipulate, customize and tailor models/solution approaches as part of their day-to-day work. This manipulation should be done by means of high level constructs and visual languages. Visual modeling is nowadays used for many purposes in several industrial sectors, but not in the scheduling field yet. Besides, schedulers need to achieve independence from IT and domain specialists. Modeling should become almost as natural as sketching and scribbling. Moreover, the use of high level graphical tools for solution analysis must also be a routine practice. Finally, cooperative work among the various stakeholders must also be supported.
- Academic scheduling approaches need to be comprehensively evaluated. The current focus on just computational performance and solution quality needs to expanded to cover other features like ease of implementation and usability, robustness, extensibility, etc. (Pekny and Reklaitis, 1998). The adoption of a scheduling benchmarking service (Cavalieri et al., 2007) and the definition of new industrial-size benchmark problems (Kallrath, 2002) would certainly help in this respect.

By addressing the two first issues, an extra-added value will be obtained. The number of errors attributed to miscommunication between various organizational areas would drop due to the seamless integration of enterprise data into the SS and the proper dissemination of scheduling results. Similarly, the number of errors attributed to the scheduler would decrease substantially with his/her full articulation within the SS.

Chemical Logistics – Going Beyond Intra-Plant Excellence

I. A. Karimi

Department of Chemical & Biomolecular Engineering, National University of Singapore, 4 Engineering Drive 4, Singapore 117576

Abstract

While intra-plant logistics is critical to the effective function of a chemical plant, extra-plant logistics is pivotal to the survival and competence of a chemical supply chain. For years, the chemical companies overlooked the latter, assuming it just a fixed cost. Growing pressures of competition, globalization, integration, outsourcing, and resilience are making a sea change. Most chemical companies are now discovering that logistics is more than just a line-item charge. Producers and (service) providers alike are taking a fresh look at the art, science, and cost of chemical logistics. While the logistics for dry goods and merchandise has received the lion's share of attention in the open literature, the same for chemicals has not. In the pursuit of lean, integrated, and excellent enterprises and supply chains, some PSE researchers have rightly begun to study a variety of unaddressed issues and challenges in chemical logistics. This paper describes selected novel applications of PSE in maritime chemical logistics.

Keywords: Chemical logistics, supply chain management, enterprise-wide optimization, maritime transport.

1. Introduction

The Council of Supply Chain Management Professionals defines logistics as the part of SCM that plans, implements, and controls the efficient, effective, forward, and reverse flow, and storage of goods, services, and related information between the point of origin and the point of consumption in order to meet customers' requirements. Transportation moves goods and people, but logistics is much more than transportation. Over the last four decades, it has evolved through the integration of traditional tasks of materials management and physical distribution. It includes materials management (procurement, receipt, storage, handling, sales, delivery, disposal, cleaning, training, emergency response, labeling ...), warehousing, demand forecasting, purchasing and supplier management, industrial packaging and assembly, transportation, freight payment, transshipment, order management (documentation, customs clearance, brokerage …), production planning, inventory management, reverse logistics, etc. After years of optimizing intra-plant logistics, the chemical industry has rightly begun to focus (Karimi et al., 2002) on extra-plant (enterprise-wide or supply chain) logistics as a strategic rather than tactical issue.

Due to its global nature, the chemical industry globally sources, not just raw materials and catalysts, but also many other materials, equipment, and services, such as processing units, instruments, indirect materials (stationery and supplies), safety equipment, brokerage, order management, supplier management, customs and documentation, etc. that are crucial for its day-to-day operations. With its huge production levels and the necessity of moving hazardous materials in a safe manner, it is

not surprising that the chemicals-related industries rank the highest among all sectors in supply chain costs (Braithwaite, 2002). According to Mark Kaiser, the CEO of Cendian Corporation (Hoffman, 2002), "the US$1.5 trillion chemical industry spends US$160 billion annually on logistics, and has among the highest average supply chain costs (12% of revenues, compared to 10% for pharmaceutical companies and 9% for automotive manufacturers)." In 2004, the North American chemical producers spent US$33.2 billion transporting chemicals worth US$516.2 billion (Morris, 2006). However, when we consider the logistics costs as fractions of the net value-add, the figures for the chemicals-related industries are much higher than the other asset-intensive sectors. For instance, they are 43% for petroleum, 37% for chemicals, 36% for food and beverages, and 30% for paper, as compared to 28% for the automobile industry. While this is partly attributable to the need for maintaining high safety standards in moving hazardous chemicals, rising fuel prices and increasing regulations are placing even bigger demands on the logistics costs in the chemical industry. A study [ACHEMA, 2006] by EPCA (European Petrochemical Association) claims that an improvement of around 3-5% in the supply chain would be enough to boost noticeably the competitive standing of chemical companies. Clearly, efficient and cost-effective management of chemical logistics is crucial to the current and future financial success of global chemical supply chains. Whether it is a chemical company that owns and manages its logistics operations, or a shipping or third party logistics provider (3PL) that serves the chemical company, the ultimate cost of logistics has a significant impact on the bottom-lines of a chemical supply chain and its various entities.

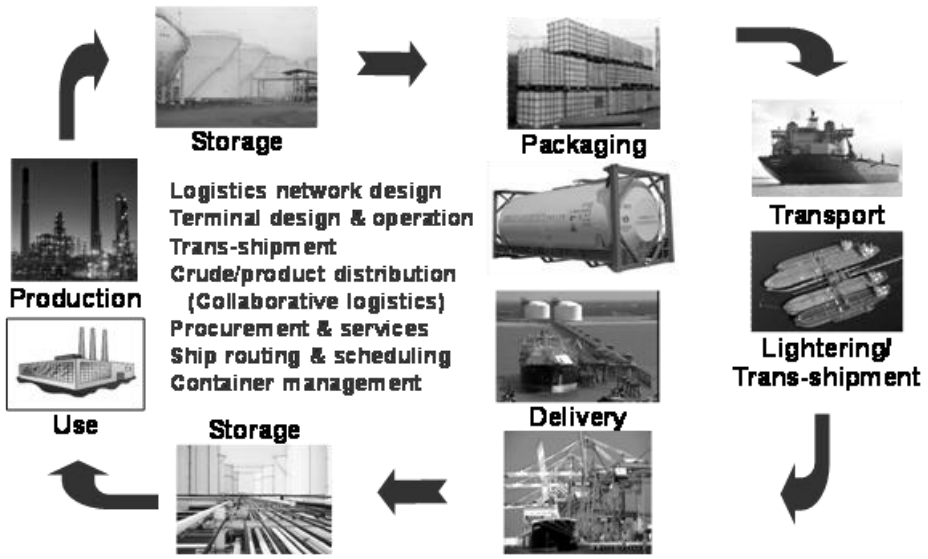

Fig. 1: Overview and scope of chemical logistics

Figure 1 gives an overview of logistics in a generic chemical supply chain. For years, most major chemical companies considered logistics as a core competency. Even now, many own or lease ships, tankers, tank trucks, rail cars, tank containers, etc. and run their own logistics functions. However, the growing trend is towards focusing on the core competency of chemical manufacturing, and whether to in-source or out-source logistics partially or fully has become a major issue in chemical supply chain

management. While transportation, warehousing, and customs brokerage top the list of most outsourced activities in general, many others such as transshipment, trans-loading, storage, distribution, packaging, freight forwarding, track-n-trace, invoice and payment services, scheduling, sourcing, inventory management, sales & distribution, customs documentation, packaging, blending, labeling, marking, drumming, break-bulk, etc. are increasingly being outsourced by chemical companies.

Chemical logistics employs a wide mix of means such as pipelines, rail, trucks, ships, barges, tankers, and planes. Pipelines are a common and important option in the chemical industry due to their low cost and higher capacity. A total of 265,440 km of oil and natural gas pipelines (as at the end of June 2008) exists in 37 Asian countries, of which roughly 45 percent carry oil/refined products/condensate (Venkatesh, 2008). Even in other regions such as South America, multiproduct pipelines transport a variety of petroleum products. This has led several PSE researchers (Rejowski & Pinto, 2008; Cafaro & Cerda, 2008; Relvas et al., 2009) to address the challenges in distributing petroleum products via multi-product pipelines. While transport via pipelines is quite a natural option for Chemical Engineer, it is not always possible or economical. For instance, rail and truck transports dominate Europe and North America. However, we are not aware of any work on the issues related to these in the PSE community. For products such as crude oil and LNG (Liquefied Natural Gas) with a few major sources, maritime logistics is preferred, as pipelines become uneconomical for transport over long distances. Maritime transport is the undisputed leader for Asian and increasingly global chemical industry. While land transport modes such as pipelines, rail, and road are important in themselves, and critical partners for maritime logistics, we focus mainly on maritime logistics due to the space constraints and the fact that maritime logistics is the workhorse of increasingly global chemical industry. Due to the lack of space, we confine our discussion to maritime transportation only, although PSE work exists on issues in other areas such as storage (Tay et al., 2005), network design (Bansal et al., 2008) etc.

2. Marine Transportation

Marine transportation in general has attracted the interest (Christiansen et al., 2004) of academic researchers since the 1950s. The following describes some recent work on marine transportation via various carriers suitable for a spectrum of chemical materials such as crude carriers for crude; LNG carriers for LNG; chemical tankers for many organic, inorganic, and petrochemical products; small parcel tankers for regional transport; and container ships for solvents, vegetable oils, fruit juices, etc. Lastly, we touch on the very timely issue of bunker fuel planning in view of the recent hikes in fuel prices.

2.1. Crude Transportation

Fully loaded crude oil tankers such as Very large crude carrier (VLCC) and Ultra Large Crude Carrier (ULCC) cannot pass through shallow channels or dock at shallow ports due to shallow drafts, narrow entrances, or small berths. Such tankers are “lightered” by small vessels at offshore deep-sea to enable their entry into shallow channels or ports. Tanker lightering involves the direct ship-to-ship transfer of crude oil from large tankers to small vessels. It is a critical step in the petroleum supply chain and a special case of the general transshipment described later.

Cheng & Duran (2004) addressed the global maritime transport of crude oil. Huang & Karimi (2006b) developed models that address a general and realistic form of the tanker-lightering problem with several realistic and practical features ignored by

previous work (Lin et al., 2003). These features include multi-compartment service vessels picking up different crude parcels during one voyage and making multiple visits to different VLCCs during one voyage, options of selecting crudes to lighter, accounting for the impact of crude densities, demurrage and time-charter costs, etc.

2.2. LNG Transportation

LNG is the most economical way of transporting natural gas over long distances. Being a cryogen, its temperature must be maintained at –163 °C during transportation by letting small amounts of LNG boil-off. To keep the ship tanks cold during the return voyage, a small amount of LNG is left to boil in the tank. This is known as heel. Minimizing boil-off losses during the entire round-trip and during loading and unloading is important. Recently, Hasan et al. (2009) performed rigorous, realistic, detailed, and extensive dynamic simulations of boil-off during various steps of LNG transportation, and studied the effects of various factors such as nitrogen content, tank pressure, ambient temperature, voyage length, etc. on boil-off losses. From their simulations, they determined the optimal heels for several scenarios of lean LNG transportation. They showed that heel can be reduced by up to 40% for a typical long voyage of 20 days, compared to the usual industrial practice of 5% of the cargo, and the reduction is significantly more for shorter voyages. Their results suggest savings of millions of dollars from heel optimization in LNG transportation.

2.3. Routing and Scheduling of Chemical Tankers

A chemical or parcel tanker employs multiple tanks to hold multiple liquid chemical cargoes unmixed. Efficient cargo assignment, routing and scheduling of parcel tankers are crucial to the financial success of a tanker company. An optimal assignment of cargos and schedules to a fleet of carriers is a complex combinatorial problem. It is accentuated by the need to comply with two safety regulations concerning cargo-tank and cargo-cargo compatibilities. Nevertheless, many small to medium-size shipping companies still route and schedule their ships manually. Hence, the potential for improving the scheduling process in maritime transportation is considerable.

Jetlund & Karimi (2004) developed a maximum-profit model for routing and scheduling parcel tankers engaged in the shipping of bulk liquid chemicals with cargo pickup time-windows (or pickup laycans). Their model can decide the most profitable spot cargos, their allocations to various ships, and voyage details of a fleet of ships. They proposed a heuristic decomposition algorithm to obtain the fleet schedule by repeatedly solving the base model for a single ship. Neo et al. (2006) presented a rudimentary approach to ensure ship stability by imposing limits on net longitudinal and lateral moments of each vessel. Their new model is an extension of the single-ship model of Jetlund & Karimi (2004) and involves deciding which ports should a ship visit and in which sequence, when and which cargoes it should pickup and unload, when and which tanks each cargo should use, etc. over the entire trip to maximize the profit. While their model does address some important safety issues, it is far from being practical, and still does not address factors such as fuel costs, delivery laycans, etc. These considerations, as discussed below, are extremely important in chemical business and we have developed a heuristic methodology (Oh, 2008) for accommodating these very practical features.

2.4. Chemical Transshipment

The major players in the ocean shipping industry normally operate fleets of large or deep-sea carriers with a focus on deep-sea trading. Over the years, there is a growing need for supplying and distributing chemicals to and from the industries within regions that large ships cannot serve. The increase in deep-sea and short-sea shipping activities globally and the myriad of mergers, acquisitions, and collaboration are increasing the

demand for trans-shipment operations that involve direct ship-to-ship transfers of chemicals from large to small ships in deep sea.
Huang & Karimi (2006a) introduced a scheduling model for a general trans-shipment scenario for regional distribution, where multiple large donor-carriers trans-ship bulk liquid cargos to multiple small recipient-carriers at a trans-shipment location. Their model determines the sequence in, the sides (larboard or starboard) from, and the times at which, each recipient ship should receive cargos to minimize the total time-charter costs of all ships. Compared to the manual procedures used in practice for such problems, their models could reduce the total operation costs. In a simple case study conducted by them, the costs reduced by 6.3%, which could be much higher depending on the scenario and its complexity.

2.5. Tank Container Management

Iso-tank containers carried by container ships are normally used to transport small quantities of liquid chemicals. These are cylindrical tanks set inside the frames of standard dry containers. Mismatch in product supply and demand results in an imbalance in the container flows across different regions. Empty containers accumulating at the demand centers must be "repositioned" to the production centers. Karimi et al. (2005) reported a comprehensive study of this important short-term tank-container management problem. They used an innovative, event-based, "pull" approach to develop a novel linear model for the minimum-cost or maximum-profit scheduling of the transport and cleaning of multiproduct tank containers (loaded and empty) given a set of projected shipment orders in the short-term. The authors illustrated the application potential of their models by using it to solve large and industrially relevant problems with key practical considerations such as alternate ship schedules, delivery time windows, and inter-modal transport routes.

2.6. Bunker Fuel Planning

Fuel expenses can be up to 90% of the daily operating cost of a tanker. Recent high fuel prices forced some companies to slow ships to save fuel. A sound management of vessel's fuel consumption is crucial to the profitability of tanker owners. However, bunker fuel prices are highly unpredictable and can exhibit significant variations across refueling ports. Furthermore, the fuel consumption rates of tankers are nonlinear functions of voyage speeds. Therefore, decisions on refueling and vessel speed require more than the experience and judgment of individuals. Oh (2008) has formulated this problem as a mixed-integer linear programming model with key operational constraints and a scenario-based approach for uncertain fuel prices. The constraints relate to pickup time windows, fuel level, and tonnage limits. The MILP model determines the optimal refueling ports, amounts, and probabilistic distribution for voyage profit. Oh (2008) has illustrated the approach on a realistic scenario with one tanker, ten port visits, three speed options, three potential refueling options at the end of each port visit, and 30 discrete scenarios of unit fuel prices for each refueling option. The stochastic MILP involved 1,597 continuous variables, 630 binary variables, 3,408 constraints, 18,514 nonzeros, and required 48 s of CPU time using GAMS/CPLEX on a Pentium 4 Xeon (2.8 GHz, 2 GB RAM) workstation. Although this model is intended for tankers for bulk maritime transport, it is useful for other vessel types including container ships, reefers, etc.

3. Conclusion

Chemical logistics beyond the plant borders is an important frontier in chemical supply chain management. The PSE community has the right tools, methods, and domain

knowledge to advance this relatively unexplored front. With increasing global chemical trade and corresponding logistics needs, the time is only ripe for us to address the practical needs of various stakeholders such as port operators, logistics service providers, freight forwarders, and chemical companies.

Systems Problems in Biorenewables Processing

Wolfgang Marquardt

AVT Process Systems Engineering, RWTH Aachen University, 52056 Aachen, Germany

Abstract

Different scenarios have been published in recent years which predict the depletion of fossil carbon resources for the production of fuels and chemicals in face of the demand of a growing world population. The switch from fossil to biorenewable carbon feedstocks is inevitable. This switch of feedstock will have massive impact on the chemicals and fuels value chain and the associated production technologies. This short paper will introduce some of the relevant systems engineering challenges to be tackled in the next decades. Furthermore, the objectives and the research strategy of a large collaborative research effort at RWTH Aachen University will be reviewed.

Keywords: Biomass, bioeconomy, biorefinery, biobased industrial products, biofuels.

1. Introduction

In the last few years several studies have been published which discuss different scenarios regarding the possible depletion of global fossil carbon resources comprising petroleum, natural gas and coal. An in-depth analysis of the current situation has recently been carried out by Pfennig and co-workers (Fayazz et al., 2009). These authors have formulated a coarse dynamic model with global coverage to balance the various raw material and energy flows. The model covers the known and the predicted amounts of fossil carbon resources on the one and the predicted consumption rate of the growing world population on the other hand. One objective of the model is to forecast the remaining availability of the three types of fossil carbon resources. According to this study, petroleum, natural gas and coal are expected to be depleted by roughly 2035, 2045 and 2070, respectively. One may debate the validity of this forecast given the unavoidable uncertainty in the data used in the model. However, the study clearly shows that a shift from fossil to alternative carbon resources for the production of industrial products is inevitable. Furthermore, serious research efforts have to start now given the scientific and technological challenges associated with such a major change which will affect all industrial segments.

There are only two alternatives to fossil carbon resources, carbon dioxide (CO_2) in the atmosphere and land-based or aquatic biomass, which are both available in abundance and which are continuously replaced by nature as long as solar energy is available on planet earth. Both carbon resources require novel processing technologies to convert them into useful industrial products such as fuels, chemicals and polymer materials. Despite some success with respect to promising catalytic pathways in the recent past (Sakakura et al., 2007), the direct conversion of CO_2 into chemicals and fuels is still economically not viable because of the low energy level of the molecule which results in high energy demand for its chemical conversion. Hence, the focus of most research programs is rather on biomass as a carbon feedstock.

Only biomass which does neither compete with the food chain nor result in a carbon depth (Fargione et al., 2008) should be considered. This requirement can only be

fulfilled if either waste biomass (e.g. straw, forestry residues, sewage sludge, organic waste from animal farming, organic municipal solid waste, etc.) or whole plants are used as feedstock rather than only (the often edible) parts of the plant like seeds or nuts as in the production of first-generation biofuels such as biodiesel and bioethanol. Alternatively, algae could be cultivated in open or closed aquatic systems to provide the necessary carbon source (e.g. Wackett (2008) for their use in fuels production) to avoid competition with the land-based production of agricultural food products. In this contribution, biorenewable carbon resources are consequently understood to consist of either waste biomass, lignocellulosic biomass or of aqueous algae suspensions.

2. Challenges and opportunities of biorenewables processing

There are few major established alternative routes for the processing of biorenewables (e.g. Huber et al., 2006) including (i) biomass gasification to synthesis gas and subsequent water-gas shift to hydrogen, Fischer-Tropsch synthesis to alkanes, or syntheses to methanol and other platform chemicals and (ii) liquid-phase processing starting with some pretreatment of the biomass (Sierra et al., 2008) followed by either enzymatic hydrolysis and conversion (Stephanopoulos, 2007, Wackett, 2008) or by chemical transformations (Corma et al., 2007) to fuel components and chemicals.

While gasification and subsequent synthesis gas conversion has the advantage of just replacing the very early steps from carbon raw materials to industrial products by novel processes but keeping the rest of the chemical supply chain intact, it does not fully exploit the synthesis power of nature. In particular, complex and highly structured biomolecules present in any biorenwables feedstock are decomposed to the smallest building blocks possible (i.e. H_2 and CO) during biomass gasification which are then assembled again to form functional molecules by means of a series of subsequent chemical transformations. Obviously, from a thermodynamics point of view it would be more favorable to directly isolate suitable functional building blocks from the biorenewable raw materials and to selectively refunctionalize them rather than first destroying the rich native molecular structures. Such an approach builds on low-temperature liquid-phase processing where particulate biomass is dissolved or dispersed in a solvent first and then transformed into products by bio- or chemocatalysis or a combination of both.

The deoxygenation of the oxygen-rich biomass can either lead to CO_2 or H_2O as reaction by-products. Obviously, the latter is preferred because it does not contribute to global warming and the resulting climate change. However, this approach to deoxygenation requires large amounts of hydrogen, which has to be produced in a sustainable way with minimum CO_2 footprint. Electrical water splitting using solar or wind energy as the primary energy source is presently considered to be a viable alternative. This strategy is favored over thermochemical water splitting requiring high temperature heat which can only be provided by solar or nuclear power plants.

While biomass gasification largely builds on existing process technology and targets at the established product families, liquid-phase biomass conversion requires novel processing technologies and might even aim at novel product families. In contrast to state-of-the-art carbon feedstock processing, liquid-phase reaction systems will be preferred over gas-phase reaction systems and low-temperature separations such as membrane processes, extraction and crystallization will be preferred over high temperature separations such as distillation. The viscosity of the biomass-derived liquid systems is typically very high. The raw material streams (derived from native biomass after pretreatment) show a much higher chemical diversity than petroleum or natural

gas. This is due to the variety of biomass feedstocks and the multitude of organic and anorganic chemical species the biomass consists of. Water or other solvents will be required in large amounts for liquid-phase processing. Hence, solvent recycling and management will constitute a major effort in addition to molecular transformation and product isolation and purification. Novel products with molecular structures different from the ones preferred at present and close to the native molecular structure prevalent in biomass feedstock will be derived according to users' specifications.

This short list suggests that the manufacturing technology of nowadays petroleum-based chemical supply chains will eventually be replaced by novel technologies which are tailored to the particular needs of biorenewables processing involving a variety of raw materials, alternative product families, novel reaction pathways and catalysts, different conversion processes and intensified processing equipment. Such a paradigm shift constitutes a massive scientific and technological challenge and presents a tremendous opportunity to replace current technology by sustainable production systems.

3. The systems nature of biorenewables processing

The short discussion of the various alternatives, challenges and opportunities reveal the systems nature of biorenewables processing. Any process systems engineering problem (Klatt & Marquardt, 2009) involves the representation, the analysis and the design of artifacts which comprise an often large-scale real-world entity, the process system, which is composed of interconnected subsystems showing numerous interactions. The complexity can only be dealt with, if abstraction across various hierarchical layers and suitable decomposition strategies are pursued. System design problems are often ill-defined because the objectives are numerous and often in conflict. Furthermore, the design objectives typically evolve with time during the design process. All these features are present in biorenewables processing.

We have argued that the ultimate replacement of fossil carbon raw materials by biorenewables suggests or even requires the reinvention of the chemis-tree and the chemical supply chain from raw materials to products. The system to be dealt with spans from raw materials to products and their use in diverse applications. Hence, biorenewables processing can be considered an integrated decision making problem which involves not only (i) process design – one of the classical problems in process systems engineering – but also (ii) product design (Gani, 2004), deciding on the molecular structure which is at the same time close to the structures present in biorenewable raw materials but still reflecting the product properties specified by the end user, (iii) the selection or even the design of chemical reaction pathways linking products and raw materials by a number of molecular transformation steps, and (iv) the selection of even the design of raw material streams with close links to plant sciences and biomass production. This decision making problem will be further explained and illustrated using biofuels as an example (cf. Fig. 1).

The replacement of petroleum-based fuels should target at a high quality designer biofuel with most favorable product properties. In particular, close-to-zero particulate and NO_x emissions and the efficient conversion of the chemical energy into mechanical energy are highly desirable. Obviously, this objective links the fuel properties not only with the combustion process but also with engine design. Most likely, the ideal future fuel will not consist of an ill-defined mixture of many chemical components as today but of a blend of carefully selected chemicals to meet all the requirements of the combustion process. The design of such a fuel product is therefore inevitably intertwined with the design of the combustion process, which itself is intertwined with

the design of the engine and even of the complete vehicle drive train. Hence, we have identified a first product-process design problem of a complex nature where the process refers to the "use process" rather than the "manufacturing process" of the product.

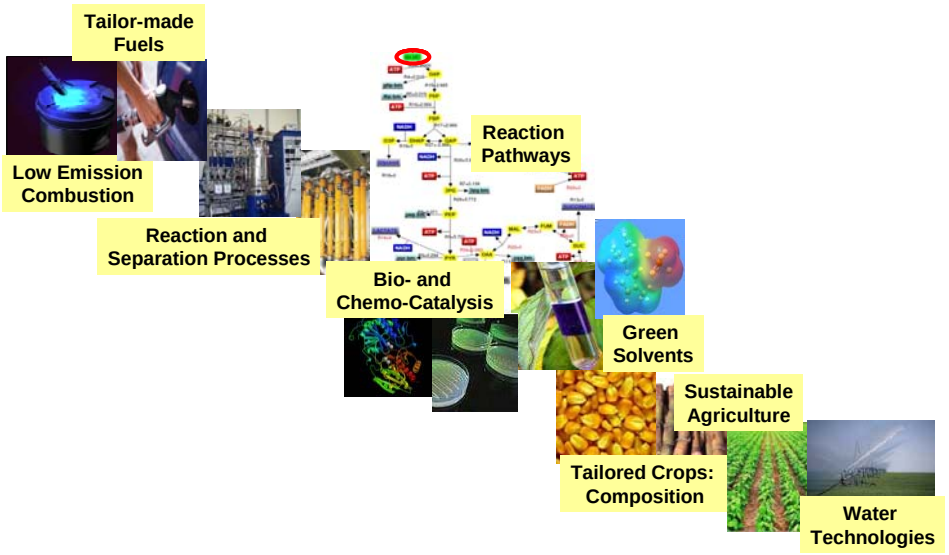

Fig. 1: Biofuels processing – a set of interacting systems problems

The components of the future biofuel have to be produced in a sustainable manner reconciling economical, ecological and societal needs. In particular, the carbon efficiency has to be maximized: the amount of CO_2 released in the whole supply chain from the production of the biomass to the wheel of the vehicle should be as close as possible to the amount inevitably produced in the combustion process.

The requirement for high carbon efficiency can not only be tackled by an integrated process design involving intensified equipment to minimize raw material consumption and energy demand (Klatt & Marquardt, 2009, van Gervent & Stankiewicz, 2009). Rather, the biofuel production process will rely on a novel chemistry to facilitate selective catalytic conversion of raw materials into platform chemicals by refunctionalization of the molecular structures present in the native biomass (Corma et al., 2008). New reaction pathways with highly selective catalytic transformation steps relying on novel catalytic systems and possibly non-classical green solvents such as supercritical fluids or ionic liquids besides water are required in this case. The selection of an appropriate reaction pathway together with suitable solvent systems minimizing solvent replacement steps is definitely another systems problem. It is determined by many factors including the available raw material components to start the molecular transformations with, the thermodynamics of the reaction steps involved and the availability and cost of highly selective bio- or chemo-catalysts which allow for highly selective conversion in every single transformation of the inevitably multi-step reaction network.

The type of raw materials and their chemical composition are by no means a given. The type of plant, the soil and climate of the geographical region, the cultivation and even harvesting conditions determine the chemical composition and the meso-scale structure of the biomass to a large extent. Therefore, the biomass feedstock can be tailored to some extent by genetic engineering and by the biomass production process.

Obviously, there is also a close link to intensified biomass production, using either land-based agricultural or aquatic cultivation systems including biodiversity requirements. Water and soil management are key issues for the sustainability of the intensified biomass production.
Last but not least, the low volumetric energy content of biomass requires sophisticated raw materials procurement and fuel production and distribution networks to minimize the amount of energy required to satisfy the needs of the logistics and shipping processes. Partly decentralized production plants are an attractive alternative for the preprocessing of the biomass feedstock into platform chemicals. These intermediates can then be shipped to large-scale fuels processing plants with a distribution network to the filling stations. Alternatively, on board processing of the platform chemicals into fuel components may evolve into an attractive alternative.
This discussion of the biofuels case clearly shows the complexity of the problems associated with a shift from fossil to biomass carbon raw materials. A number of integrated product-process design problems can easily identified: they link the various intermediate products, auxiliary materials and final products by different production and use processes. Integrated frameworks for model-based decision making are clearly required to mitigate risk and to reach truly sustainable solutions in a multi-disciplinary systems problem solving process.

4. TMFB @ RWTH Aachen University

A coordinated research effort addressing one of the prevalent systems problems in biorenewables processing has recently been initiated as a cluster of excellence (CoE) at RWTH Aachen University as part of the so-called Excellence Initiative (ExIni) of the German Federal and State Governments. The ExIni aims to promote top-level research, to improve the quality of German universities and to make Germany a more attractive and internationally competitive research location.
The objective and vision of the CoE “Tailor-made fuels from biomass” (TMFB) is to establish innovative and sustainable processes for the conversion of whole plants into fuels which are tailor-made for novel low-temperature combustion engine processes with high efficiency and low pollutant emissions, paving the way to the 3rd generation of biomass fuels. A tailor-made fuel is understood to be a well-defined blend of distinct molecular components with optimised physicochemical properties for future combustion systems, which can be produced by sustainable and economically viable production processes.
The definition of optimal fuel characteristics is understood as an inverse product design problem in the first place. Since the design of the combustion engine itself is not fixed and subject to modification, a first integrated product-process design problem results which calls for interdisciplinary interaction between combustion engineers and fuel design experts. This product-process design problem is focusing on the end use properties of the process where the properties of the fuel are considered to be the design parameters of the combustion process in a future engine. Another product-process design problem is related to fuel production process design which relies on the selection of chemical pathways and novel catalytic conversion processes. Likewise, these chemistry-centered decisions contribute to the decision variables of fuel production.
Both interrelated product-process design problems are addressed by a multi-disciplinary research team involving combustion engineering, physical chemistry and molecular thermodyamics, chemo- and bio-catalysis, process and reaction engineering as well as systems engineering and applied mathematics.

The research in the CoE has been started in late 2007 and is planned to involve more than 50 PhD students and post-doctoral researchers. It is structured into integrated research fields (IRF) supported by core interaction fields (CIF). The three IRFs focus on molecular transformations, process and reaction engineering as well as combustion engineering while the two CIFs provide methods and tools for physical property estimation and model-based fuel design. Despite its relevance, plant genetics and biomass production have been excluded form the cluster activities but are considered in collaboration with other research groups.

5. Summary

This short paper briefly introduced the systems problems related to biorenewables processing with an emphasis on biofuels production. This paper does not aim at a comprehensive literature survey or at the presentation of most recent research results. Rather, it intends to raise the awareness for the tremendous opportunities for process systems engineers beyond the classical issues related to process design given a chemical pathway, the plant capacity and product specifications. Sustainable solutions require a much wider perspective which at least addresses the various interdependent process and product design problems in an integrated manner. While process systems engineers do not have the expertise to contribute to all aspects of the overall problem equally well, they are in a very good position to address the multi-faceted and cross-displinary decision-making problems depicted in Fig. 1 in close collaboration with chemists, plant scientists, (bio-)chemical and process engineers as well as application experts.
An extended version of this paper will be prepared to give a more complete literature survey. This future paper will review selected research results to even better illustrate the opportunities and challenges for process systems engineering research.

Optimization in the Petroleum Refining industry – the Virtual Refinery

Lincoln F. Lautenschläger Moro

PETROBRAS SA, Av Chile 65, Rio de janeiro RJ 20031-915, Brasil

Abstract

As a result of the recent world economy slowdown many investment plans for refinery capacity expansions were postponed, and the optimization of existing process units, that had lost priority in relation to the design of new ones, came again to prominence. We cannot be sure if this priority will change in the near future but it seems sure that petroleum companies must be prepared to cope with a very uncertain scenario. This means that the abilities and the corresponding tools need to be well adapted to optimization and design activities, and the transition from one to the other has to be as quick and smooth as possible.

The tools used for both activities, e.g. process simulators, are usually diverse and the same applies to the teams in charge of optimization and design.

The present work tries to point out the main improvements that will have to be performed in the process engineering tools so that they may be better adapted to the this scenario.

The main improvement we point out is the so called “virtual refinery”, which is basically a rigorous dynamic model incorporating every piece of equipment in the plant. This model would be kept running continually in order to mimic the actual behavior of the plant and would be periodically upgraded to include new equipment and different operating modes. This model would then be able to represent the process in a comprehensive and detailed way and could supply the models used in simpler and narrowly oriented tools.

In order to make this vision come true several problems demand further investigation and development, and some of them are described.

Keywords: optimization, process control, petroleum, refining.

1. Introduction

For several years since the beginning of this decade the demand for petroleum products kept increasing sharply and, as a result, the crude oil prices as well as the prices of most products also increased. For example, prices for North-sea Crude Brent have increased from less than US$ 30 a barrel in 2003 to almost US$ 150 in mid 2008. Due to that several companies invested heavily in building new refining units as well as in expanding capacity in the existing ones. After an interval of several decades even grass-roots refineries were planned and built.

Then the situation reversed. The world economic growth slowed down and the demand of oil products flattened or even decreased. Many investments plans for capacity expansions were postponed. The crude oil prices fell to the levels of 2004, the same happening to the prices of most products. Despite that, the price margins, that is, the

difference between the price of a product (e.g. gasoline or diesel) and that of crude oil, after also falling sharply, quickly recovered.
As a result, the optimization of existing process units, that had lost priority in relation to the design of new ones, came again to prominence. At the present moment, we do not risk to forecast the world economy behavior in the medium term, i.e., if, after a pause, it will quickly recover the sharp growth patterns of the last years or if it will remain weak for quite some time.
Anyway, it became clear that flexibility is the keyword for everybody involved in the industrial sector, as is the case of process engineering in the refining industry. We cannot be sure if the priority in the near future will be the design of new facilities or the optimization of existing ones. This means that the abilities and the corresponding tools need to be well adapted to both and the transition from one activity to the other has to be as quick and smooth as possible.
In practice, this is not what we see. The tools used for these activities, e.g. process simulators, are usually diverse and the same applies to the optimization and design teams.
This situation holds true even when we look at mature and well-established activities like production planning and capital investment evaluation. Although the underlying technology is the same- linear programming- the commercial solutions available for both are different and are in general used by separate teams.
The present work tries to point out the main improvements that will have to be performed in the process engineering tools so that they may be better adapted to the this uncertain situation.

2. Current Process Engineering Tools

According to Magalhães (2004), the optimization of the refining business involves decisions that take place at three levels: strategic, tactical and operational.
At the strategic level, where the time horizon is normally years, these decisions deal with the long-term corporate objectives. Examples of decisions taken at this level are new products and markets to operate, new plant location, revamps for increasing capacity or flexibility, acquisitions and merges, partnerships, and so on. Typically the strategic plan covers a horizon of 10 to 15 years and is updated annually.
Tactical decisions cover the mid-term horizon (months, quarters) and emphasize the deployment of corporate strategies into a more detailed plan. In the refining industry, the corporate planning is an instance of these tactical decisions and involves several refineries, whose integration can provide significant synergies for the company as a whole. This plan covers, as a rule, a time span of a whole year, but treats with more detail the first month or quarter. Decisions such as crude purchase, target market to be supplied, products to be maximized in each facility and transfers of intermediate products among facilities are typical of this level.
Operational decisions are of the short-term type, where the time involved may vary from hourly to a monthly span. The main examples of decisions at this level are: refinery production and operation planning and scheduling, inventory management, transportation network utilization, process units' optimization and product blending.
There is no refiner nowadays that does not use advanced process engineering tools to improve business results (Moro 2001). Such tools range from advanced process control up to corporate long-term planning, passing through process optimization, scheduling, and short-term planning. Supporting these applications, one can find a myriad of tools like soft-sensors, data historians, relational databases, dynamic simulators, unit

monitoring systems, etc. The traditional structure of these applications is shown on figure 1.

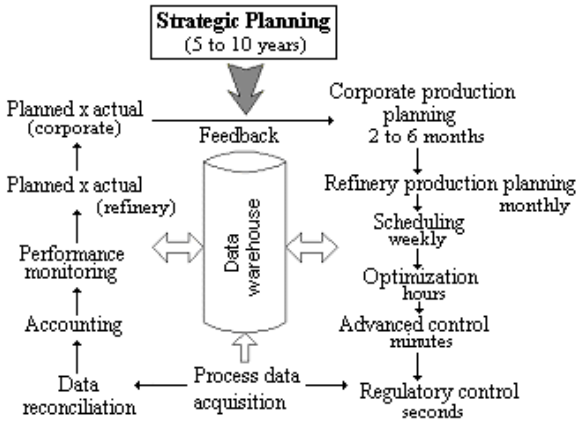

Figure 1 - Traditional structure of process engineering tools.

Very frequently these technological solutions are provided by different suppliers and are based on very different process representations. Even if one chooses to work with only one solution provider, this heterogeneity problem does not disappear because most commercial solutions were developed by different specialized teams and rely on different paradigms.

One can see in figure 1 that the piece that unifies this entire structure is the "Data warehouse". This can be roughly described as a relational and historical database responsible for feeding any application with the necessary input information and for storing its results for subsequent use by other applications. It is assumed that this architecture is able to guarantee an accurate representation of existing and planned assets in terms of expected performance.

In practice this is not good enough. Each application has a different way to model the process, e.g. linear programming, static rigorous models, dynamic rigorous and simplified models etc. This gives rise to several difficulties, since one cannot guarantee that all these models will give compatible results.

As an example of this situation, we can cite the strategic and tactical planning process in corporate and refinery levels. Companies usually use linear models for these activities but, very frequently these models were developed and are maintained and used by different teams, each one using its own tool. Due to that, although trying to represent the same production facilities, the models use different formulations and input and output variables and, understandably, give different results.

Analogous situation can be found when one looks at the rigorous process models used for the different purposes. Typical uses of such models are process design, case-studies and real-time optimization.

In general, design activities use process models covering a single process unit or even subsections of a process unit and the objective is to size new equipments or to define the modifications to be performed in existing ones. Sequential modular (S.M.) process simulators are considered to be the most adequate tool for these tasks. One of the main reasons that make them preferable over Equation-Oriented (E.O.) simulators is the

easier initialization. The simulators are usually used in simulation mode, i.e., the solver only looks for a viable solution.

We define opportunities or case studies as the activity performed by process engineers when searching for more profitable ways to operate existing facilities by changing operating conditions, streams routing and, eventually, feed quality. Best practices in this area indicate that one should use rigorous models covering an entire refinery or, at least, a few mutually interdependent process units. As a rule, engineers use sequential modular simulators capable to represent these several units in the same flowsheet, including reactors and separation equipment. Typically the simulators are used in optimization mode, with just a few variables free to be optimized by the solver.

Real time optimization (RTO), on the other hand, is better performed by Equation-Oriented, also called open-equations simulators, which solve, simultaneously, equations written in residual format. This format is very well adapted to changing modes of operation, which is a typical demand for RTO systems, since it is necessary to run them in a cycle that involves parameter estimation and optimization. The main difficulty with E.O. simulators relates to the initialization of variables because, since the equations are solved simultaneously, it is necessary to provide a reasonable starting point for every variable and there are thousands of them and many do not have a very well defined allowable range. This is not a big issue in Real-time optimization (RTO), since the previous solution provides a good starting point, but may pose significant practical difficulties for the design of new equipment.

Table 1 – Process engineering simulation and optimization tools.

Activity	Scope	Model	Time representation	Typical studies
Strategic Planning	Several plants	LP	Static	New hardware
Corporate production planning	Several plants	LP	Multiperiod	Feedstocks, products
Refinery production planning	Single plant	LP	Multiperiod	Intermediate streams routing
Refinery scheduling	Single plant	LP, MILP	Dynamic	Tank allocations
Optimization studies	Single plant	Rigorous-SM	Static	Operating conditions
Process design	Single unit	Rigorous-SM	Static	Operating conditions
Real-time Optimization	Single unit	Rigorous-OE	Static	Operating conditions
Operator training	Single unit	Rigorous	Dynamic	Controllability, Startups and Shutdowns
Multivariable predictive control	Single Unit	Transfer functions	Dynamic	Control

When it comes to dynamic simulators, the situation is similar. Typically, such simulators are used for operator training and for design of control strategies. These simulators are also rigorous but are usually not supplied by the same companies responsible for the static ones. The result is that the refiners end up with other tools,

used by other groups and there is no guarantee that the results are compatible and that the modifications in the real process will be adequately propagated through the several tools.
Table 1 describes some aspects of tools used for several process engineering activities. We can see that the scope may include several plants, which can be spread throughout the world or only a subsystem of a processing unit in a plant. Different kinds of models are also used, ranging from linear programming to rigorous dynamic models, based on differential equations. The time variable representation may be explicit, as in the dynamic models, or not even be considered, as is the case of the static models. An intermediate category is represented by the multi-period models that consist of a sequence of static models connected by inventories.

3. Virtual Refinery

In order to solve the main problems of the traditional structure described in the previous section we need a unifying tool that, working together with the data warehouse, is able to represent the process in a comprehensive and detailed way. This tool, which we chose to name "Virtual Refinery", can then supply the models used in simpler and narrower oriented tools.
In the limit the virtual refinery would basically be a rigorous dynamic model incorporating every piece of equipment in the plant, including storage tanks, piping, reactors, heat exchangers, pumps, columns etc. This model would be kept continually running in order to mimic the actual behavior of the plant and would be periodically upgraded to include new equipment and different operating modes.
This model would have to be continually updated and tuned to represent the dynamic behavior and the current situation of the production facilities. Besides ensuring that the model closely matches the plant behavior, this procedure would also supply information about process performance like, for instance, compressor efficiency, catalyst activity, and heat transfer coefficients. The model could, of course, be also used for engineer and operator training, controllability studies, design etc.
On the other hand, dynamic process simulators are not well adapted to some engineering activities. In fact, most optimization studies are performed off-line using static simulators that may cover a whole plant, but more frequently represent just a single unit. This means that it must be possible to quickly and easily transfer the dynamic model configuration to a rigorous static simulator. It can also be expected that engineers will eventually modify the static model configuration and such changes must also be available for the dynamic model. So the reverse configuration transfer, i.e., from the static to the dynamic must also be possible. The best approach would probably be to build a model database capable to store complete model configurations that could be accessed by both dynamic and static simulators, each uploading and downloading only the information necessary for its particular use. Current commercial tools do not provide such functionalities.
The rigorous static model could then be used to build simplified linear or non-linear programming tools for planning and scheduling activities. Analogously, the dynamic model could provide step-response curves to be directly used in the MPC's or, at least, to be compared with the curves obtained from step-testing procedures.
Figure 2 provides an overview of the relationship between the tools previously described.

4. Conclusions

At the first glance, the vision proposed in this paper seems easily achievable. Despite that, we do not expect to see it becoming true any time soon.

Some factors contribute to this apparent contradiction. The academic community seems to consider that all the interesting problems involved in this proposed structure have already been solved. When it comes to the solution providers, we can recognize two different situations. For those relatively small niche-oriented companies focusing on specialized solutions there is no incentive to invest in such integration issues. On the other hand, the solutions offered by large companies seem to be technologically divergent.

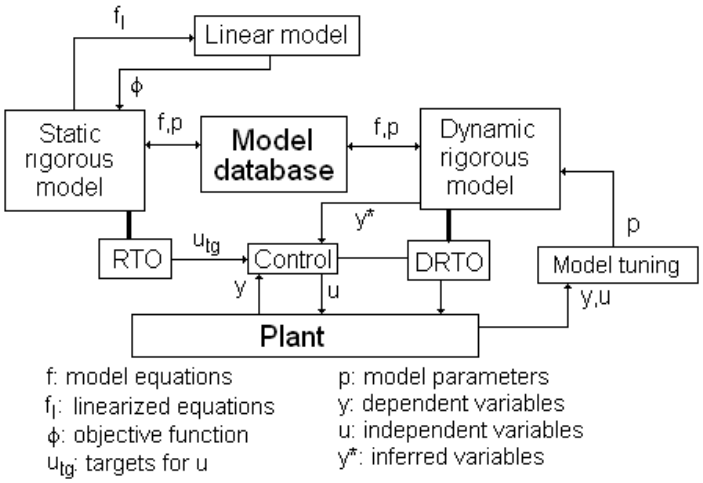

Figure 2 - Proposed structure of process engineering tools.

Among the several problems that demand further investigation and development in order that the proposed vision can someday be fulfilled, a few can be cited here:

- Procedures to tune dynamic models from live plant data;
- Dynamic modeling of reactors and other crucial processes;
- Direct use of dynamic models for on-line optimization, i.e. Dynamic RTO or DRTO;
- Development of a standard model configuration, well adapted to static and dynamic process simulators;

We hope that these and some other problems that hamper the attainment of the Virtual Refinery vision will be tackled by the academic community, and that the suppliers will identify business opportunities justifying the investment in solutions that contribute to this same goal.

Nonlinear Dynamic Data Reconciliation in Real Time in Actual Processes

Diego Martinez Prata, Enrique Luis Lima, José Carlos Pinto

Programa de Engenharia Química/ COPPE / Universidade Federal do Rio de Janeiro – Cidade Universitária – CP 68502 – CEP: 21945-972 – Rio de Janeiro –RJ – Brazil

Abstract

In this work, some recent developments regarding the real time monitoring of industrial processes based on robust data reconciliation and gross error detection are reviewed. Particularly, robust data reconciliation and gross error detection are performed on line and in real time in a real polymerization process.

Keywords: Data Reconciliation, Robust Estimators, Gross Errors, Industrial Data.

1. Background

The rigorous monitoring of variables that describe the present and the long-term behavior of industrial processes is one of the first conditions required to guarantee the optimal operation of the plant. For this reason, process measurements are taken and used in process control procedures and for evaluation of process performance. With the advent of modern desktop computers, hundreds or thousands of process measurements are simultaneously measured and stored in massive storage media for the continuous monitoring of the process behavior and for performing process studies, such as the development of robust process models and the online optimization of the process operation. Therefore, modern industrial plants may provide very detailed and rich data sets for development of fundamental modeling studies. However, as information concerning such variables comes from real measurements, numerical values are normally corrupted by different kinds of errors. As a consequence, the collected data generally do not satisfy the process constraints, such as the mass and energy balances. For this reason, implementation of data rectification procedures is essential for obtainment of reliable information about the process behavior.

The data rectification procedure comprises different steps, such as variable classification, gross error detection and data reconciliation (including parameter estimation in complex models). Variable classification is required in order to determine if the available information is sufficient for solving the proposed reconciliation problem and to identify sets of observable and non-observable process variables. Different solutions have been proposed for the variable classification problem during the last four decades and detailed description of published procedures can be found in Romagnoli and Sanchez (2000).

Procedures for gross error detection are required to identify (and possibly remove from the set of measured data) observed values that do not follow the statistical distribution of the measured data, as the presence of gross errors may lead to significant biases during data reconciliation and/or parameter estimation and also to poor decisions. Gross Error Detection (GED) has been (and still is) thoroughly analyzed in the literature using different theoretical and numerical approaches, as described in detail by Narasimhan and Jordache (2000). Finally, during data reconciliation the measured data

are adjusted in order to satisfy the required process constraints (or the process model) and obtain reliable estimates for the unknown desired parameters.

Mathematical models play an important role in modern process engineering because they can be used for evaluation of process states, including prediction of non-measured variables (soft sensors). Besides, reliable process models are fundamental for implementation of on-line optimization and advanced process control techniques. As industry is rapidly shifting towards real time optimization and some crucial process parameters (such as heat transfer coefficients and catalyst activities) are likely to change at plant site along the time, estimation of model parameters in real time based on available process measurements is becoming an increasingly important issue.

The scientific literature shows that joint data reconciliation and parameter estimation with simultaneous gross error detection has emerged as a fundamental tool for on-line industrial applications. Thus, the development and implementation of these powerful procedures in real time may be of paramount importance for certain process control and real-time optimization applications. However, the implementation of monitoring procedures in-line and in real time, with the simultaneous data reconciliation, estimation of process parameters, evaluation of non-measured process variables and multiple gross error detection, has seldomly been performed in real world processes due to the existence of some inherent numerical difficulties. Some of these difficulties are related to the necessary treatment of huge amounts of data in short periods of time (for real time applications), while other difficulties are related to the robustness of available numerical techniques (convergence problems are unacceptable in most real time applications), especially when multiple gross errors are present. This work presents a brief overview on data reconciliation and multiple gross error detection applied for real time industrial process applications.

2. Background

Data reconciliation (DR) procedures can be used in a broad range of distinct applications, such as process control, real time optimization, process monitoring, safety analysis, improvement of operational efficiency, detection of gross errors and process malfunctions, among many others. As a consequence, DR represents an important step for many engineering activities in industrial process.

The use of DR procedures for analysis of process data was originally proposed in the early sixties, encouraged by the increasing capacity of digital computers. DR may be defined as the adjustment of process measurements and parameters in order to satisfy a certain set of conservation laws and process constraints (as described by a mathematical model), while minimizing some sort of objective function that weighs the deviations between corrected and observed plant values. (In general terms, the estimation of model parameters from available plant data is certainly within this context.) For this reason, it may be said that joint data reconciliation and parameter estimation (DRPE) is useful for the simultaneous analysis of process data (allowing for identification and removal of inconsistent data sets) and process model building. Different solutions have been proposed for the DR problem during the last four decades and good reviews are provided by Crowe (1996a), Romagnoli and Sanchez (2000) and Narasimhan and Jordache (2000).

GED is of fundamental importance for adequate model building and interpretation of process data, as poor input data generally lead to very poor model responses. The commonest methods used for GED are based on statistical hypothesis testing, which requires the definition of a proper statistics for the test, assuming that the error

distribution is known *a priori* (Narashimhan and Jordache, 2000). A gross error is detected if the computed statistical test exceeds a critical value, which is calculated with the assumed distribution. It is frequently assumed that measurement errors follow the well-known Normal (Gaussian) distribution, with zero mean. In this particular case, application of the maximum likelihood principle leads to the *Weighted Least Squares* (WLS) DR problem. Although the assumption of normality of the error distribution is usual, it is not necessary for DR and GED (Crowe, 1996b).

When multiple gross errors are present, a strategy (not only a method) for gross error detection may be necessary. Three strategies are normally used to deal with multiple gross error detection (MGED): Serial Elimination, Serial Compensation and Simultaneous (or Collective) Compensation (Narashimhan and Jordache, 2000). Principal component tests have also been used for MGED, but significant improvement of the MGED has not been observed (Jiang *et al*., 1999). The main disadvantage of these MGED strategies is that they are based on residuals obtained from regression. As residuals may be heavily biased by the presence of gross errors, the implementation of iterative or combinatorial procedures may be necessary, increasing the computational effort. Despite that, these strategies have been widely used for analysis of steady-state or quasi-steady-state process conditions. As real time industrial applications require frequent MGED analysis of nonlinear dynamic models, the usage of iterative and/or combinatorial procedures may be inappropriate. (In practical implementations, it is common to use a time varying moving window in order to capture the recent behavior of the process and reduce the size of the optimization problem to manageable dimensions during the solution of dynamic DR problems.)

In order to deal with the joint nonlinear dynamic data reconciliation (NDDR) and MGED problems, alternative approaches based on cluster analysis (Chen and Romagnoli, 1998; Abu-El-Zeet *et al*., 2002), artificial neural networks (Vachhani *et al*., 2001) and robust estimators (Özyurt and Pike, 2004; Prata *et al*., 2008a) have been proposed and successfully applied in the literature. Among these alternative approaches, robust data reconciliation (RDR) has been used more frequently.

There are several classes of robust estimators. The most important for DR are the M-estimators, which are generalizations of maximum-likelihood estimators. Robust estimators tend to look at the bulk of the data and ignore atypical values (gross errors), due their mathematical structure. Table 1 summarizes the works that applied robust M-estimators for industrial process monitoring, based on RDR procedures. This strategy has been recently applied for in-line and real time monitoring of real industrial nonlinear dynamic systems by Prata *et al*. (2008b,c). Comparative analysis of the performances of distinct robust M-estimators were performed by Özyurt and Pike (2004) and Prata *et al*. (2008a) for steady state and dynamic systems, respectively. Prata *et al*. (2008a) concluded that the Welsch M-estimator (which presents continuous first and second derivatives) shows better global performance, reducing the negative effects of gross errors upon the obtained estimates.

It is important to notice that the implementation of RDR approaches can be difficult sometimes, as some robust estimators are non-convex, requiring very good variable initialization in order to avoid local optima. Besides, some robust estimators present discontinuous first and/or second derivatives. As the computation of first and second derivatives may be necessary during the optimization (depending on the numerical technique implemented for minimization of the objective function), this may lead to lack of numerical stability and require the usage of smoothing functions (making numerical implementation and calculation more complex).

In order to overcome the numerical difficulties, Wongrat *et al*. (2005) proposed the use of Genetic Algorithms (GA) to perform the optimization of RDR. Other non-deterministic optimization methods, such as Tabu Search (TS), Simulated Annealing (SA) and the Particle Swarm (PS), can also be used. These methods present some additional advantages, such as the global character of the search (which avoid local minima), the unnecessary computation of derivatives and the simplicity of the implementation, although they are usually characterized by the high number of objective function evaluations, which may require more CPU time than conventional methods. However, the computed values of the objective function can be used for rigorous statistical analyses of the confidence regions of parameter estimates, which can also constitute an important benefit of these algorithms (Schwaab *et al.*, 2008).

Reimers *et al*. (2008) applied non-deterministic optimization methods (GA, TS and SA) to solve steady-state DR problems in a real industrial case. Prata *et al*. (2008b) also applied a non-deterministic optimization method (PS) to solve the robust NDDR problem in a real industrial plant, in-line and in real time. As a consequence, one may conclude that non-deterministic procedures can be used successfully for solution of DR problems in real time.

Table 1: Industrial applications of robust M-estimators for DR and MGED.

Author (Year)	Industrial Scenario	M-Estimator
Zhang *et al*. (1995)	Sulfuric acid plant.	Contaminated Normal
Chen *et al*. (1998)	Sulfuric acid plant.	Fair and Lorenzian
Bourouis *et al*. (1998)	Multistage flash desalination plant.	Contaminated Normal

Lid and Skogestad (2008)	Industrial naphtha reformer	Contaminated Normal
Prata *et al*. (2008b)	Industrial Polymerization Reactor.	Welsch

It is important to emphasize that both traditional and robust formulations of DR problems depend on the relative magnitudes of the elements of the variance/covariance matrix of measured data. Robust estimators can also be used for the simultaneous characterization of the variance/covariance matrix of measurements and elimination of gross errors (Chen *et al*., 1997; Morad *et al*., 1999), resulting in improved characterization of the statistics of the process data.

3. Analysis of Real Industrial Data

Some of the obtained results are presented below for the bulk propylene polymerization performed in a stirred tank reactor (model and process description can be found in Prata *et al*., 2008d). Raw process data were obtained over a time interval of

7h, with a sampling time of 5 min (300s), using a time moving window of 1h (samples collected every 5 min for 22 measured variables, resulting in 286 reconciled variables in each window). The DRPE were conduced in two different computers using the *WLS* and *Welsch* estimators. The symbols (○), (●), (●) e (●) represent the plant measurements, laboratory analyses (obtained with delays of 8h, but synchronized after reconciliation), *WLS* reconciled values and reconciled values by the *Welsch* estimator, respectively. The letter (**E**) represents the gross errors detected by the *Welsch* estimator. The magnitudes of the measurement errors (associated with the instrument) and of the process noise (associated with the operation) were evaluated for all process signals based on the available data, but are not presented here for confidential reasons.

Figures 1 and 2 show measured and reconciled data for two variables: the propane concentration in the recycle stream and the reactor temperature, respectively. It can be observed that the results provided by the *Welsch* estimator are better than the results provided by *WLS* estimator, as the first one is much less sensitive to the presence of gross errors than the second one. It is important to note that deviations from the temperature setpoint (340.15 K) can not be greater than 1K (dot line); otherwise, control actions are taken in order to prevent potentially dangerous operation conditions. Figure 2 shows that some *WLS* reconciled values would violate this general rule, generating unnecessary control actions.

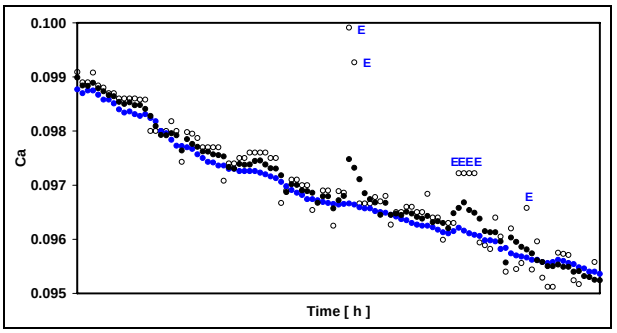

Figure 1. Ca – Propane concentration in the recycle stream.

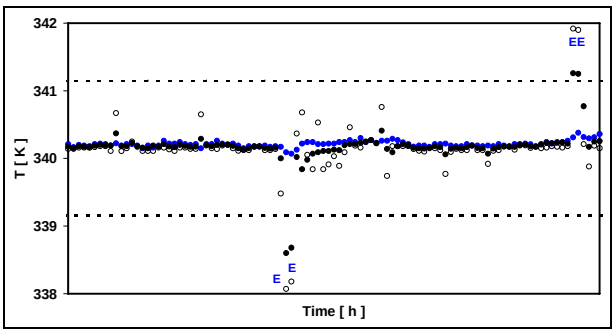

Figure 2. T – Reactor temperature.

Figure 3 shows measured, reconciled and laboratory data for the Melt Index of the polymer product. Again, it can be observed that the results obtained with the *Welsch* estimator are better than the results obtained with the *WLS* estimator. The in-line and real time MI inferences provided by the *Welsch* estimator are underpinned by the laboratory analyses (after synchronization), showing that in-line information provided

by a process rheometer is biased. It seems clear that the proposed RDR scheme based on *Welsch* estimators can provide better results than the in-line process rheometer, which requires frequently re-calibrations during process operation. Therefore, the RDR scheme can improve the safety and performance of the process operation, aggregating value for decision making.

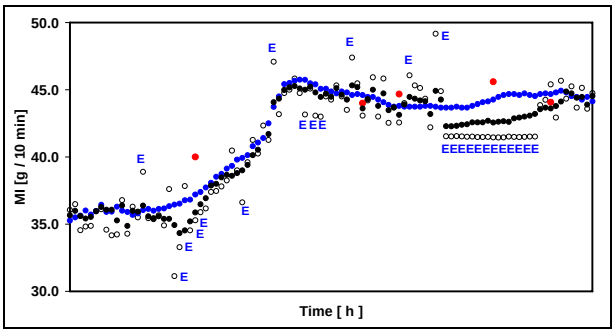

Figure 3. MI – Melt Index (after industrial extruder).

It is important to notice that the computational time required to accomplish all the calculations for each moving window (size=1h) using the *Welsch* robust estimator was roughly equal to 260s (250s for solution of the nonlinear DRPE problem with PS and 10s for data handling) in a standard Pentium 4 (single core 3.0 GHz) with 1024 MB memory, allowing for real time implementation of the code.

4. Conclusions

Some recent developments regarding the real time monitoring of industrial processes based on robust data reconciliation and gross error detection were reviewed. Particularly, a robust method for the joint nonlinear data reconciliation and parameter estimation with simultaneous gross error detection, based on the particle swarm optimization algorithm, was implemented. The proposed method was used to describe the operation of an industrial bulk propylene polymerization process and was validated with actual industrial data in-line and in real time. The negative influence of gross error was minimized with the help of a *Welsch* estimator. Off-line laboratory analyses confirmed the effectiveness of the proposed procedure, which indicated frequent failures of the process rheometer and allowed for improvement of the process performance. The numerical procedures required 260s of CPU in standard desktop computers, allowing for implementation of advanced process monitoring and control in real time.

Energy Systems Engineering

Paul I. Barton

Process Systems Engineering Laboratory, Massachusetts Institute of Technology, Cambridge, MA 02139, U.S.A.

Abstract

Meeting current and future demands for energy is often quoted as the most pressing problem facing humanity in the 21st century. This problem has to be addressed in a global environment where resources are constrained and diminishing, while at the same time raising standards of living for a growing population and preventing catastrophic climate change. Recent experience has shown that energy production is increasingly competing with other demands on the same resources, such as commodity chemicals production and food production, and all compete for water as a primary resource. In moving to a sustainable future, radical changes will have to take place in how we produce, transport and utilize energy and commodity chemicals. The solutions will be many and diverse, and highly dependent on geographic location and patterns of consumption.

In many respects, chemical engineers, and process systems engineers in particular, are uniquely qualified to address this grand challenge. The design, optimization and operation of a diverse range of novel, highly integrated processes and supply chains is our core competence. Furthermore, process systems engineering tools, techniques and formulations are highly developed and ready to meet this challenge, so the creative application of the best of these will have a tremendous impact. On the other hand, new challenges and applications also spawn new formulations and tools. The purpose of this talk is to use several examples from ongoing projects in the Process Systems Engineering Laboratory at MIT to illustrate how the energy systems engineering challenge is fostering both the creative application of the state-of-the-art and new formulations and tools.

Gasification of low-value carbonaceous feedstocks (e.g., coal, lignocellulosic biomass, oil shale, etc.) is a promising route to the *polygeneration* of electrical power, transportation fuels and chemicals. In order to reduce or even reverse carbon dioxide emissions to the atmosphere, novel processes have to be invented with integrated carbon capture and sequestration. We have recently used PSE tools to invent a novel high-efficiency process for power production from coal that almost eliminates the efficiency penalty of carbon capture and sequestration, and dramatically reduces the water consumption of the process. This process should be particularly attractive in water-stressed regions with large coal reserves, such as Northern China and the American West. The notion of polygeneration enables a plant to exploit fluctuations in prices and demands for several products (e.g., electrical power, transportation fuels) on several time scales. However, in this setting it is no longer optimal to design for a single steady state. Therefore, we are developing novel optimization formulations and algorithms for integrated design and operation that yield optimal profitability over a range of price and demand scenarios.

The productivity of transportation fuels and chemicals from the aforementioned processes can be significantly enhanced by the introduction of a carbon-free hydrogen source, specifically water splitting using heat and/or electrical power from nuclear and solar sources. Moreover, large amounts of carbon dioxide are produced from current and future hydrogen demands. One of the most promising processes for the production of hydrogen using heat from a nuclear reactor is the sulfur-iodine (SI) thermo-chemical cycle. At the heart of this process is the Bunsen reactor, in which water, sulfur dioxide and iodine are combined to form sulfuric acid and hydrogen iodide. Due to a fortuitous liquid-liquid phase split, the sulfuric acid and hydrogen iodide can be separated and thermally decomposed to generate oxygen and hydrogen, respectively. The key to designing and optimizing this process is accurate thermophysical property models that can predict phase and chemical equilibrium of multi-electrolyte, multi-solvent solutions. This challenge has prompted us to develop a new version of the electrolyte-NRTL model suitable for such solutions, and large-scale optimization techniques to develop self-consistent thermodynamic databases for parameter estimation. In addition, the challenge of fitting binary parameters to such complex phase diagrams required us to propose a new formulation for the parameter estimation problem as a bilevel program; the inner programs determine the stable phase splits by Gibbs free energy minimization, and the outer program minimizes the least squares error. Solution of this formulation requires our recent developments in algorithms for the solution of bilevel programs with nonconvex inner programs. Moreover, this advance has very broad implications for how binary parameters should be fitted to any phase equilibrium data.

The emergence of a global liquefied natural gas (LNG) market is facilitating the development of novel supply chains that enable the exploitation of remote natural gas combined with carbon capture, sequestration and enhanced oil recovery. The implementation of these supply chains require novel process designs at several stages in the overall supply chain, and a common feature of these processes is the need for heat and power integration between streams at varying temperatures and pressures. This problem is considerably more complex than conventional heat integration, and leads to novel nonconvex optimization formulations that vary temperature and pressure levels simultaneously to find the optimal process design. These formulations have prompted us to develop the novel notion of *global optimization of algorithms*, in which the process model is evaluated as an algorithm, and the algorithm is relaxed directly in the global optimization procedure. Such advances are making these complex problems tractable within a deterministic global optimization framework.

The quest for new sources of oil to meet ever-increasing demand is motivating the development of technologies for oil exploration and production in ultra-deep water (depths of one mile or more). At such depths of water, production facilities have to be located on the seabed and operated remotely. Due to the extreme costs associated with maintenance and repair of subsea production processes, an autonomous process must be designed that is guaranteed to be robust to input disturbances. These guarantees must be provided a priori at the design stage, which is motivating the development new formulations and optimization algorithms for robust process design.

Finally, the design and operation of processes for the production of transportation fuels from biomass via fermentation is motivating new dynamic optimization formulations and algorithms. The bioreactor can be modeled using conventional differential equation formulations, but this must be coupled with predictive models of the response of the

microorganism(s) to their environment. A common approach to this is a flux balance model that represents the behavior of a microorganism as a linear program (LP); increasingly, large-scale flux balance models are being constructed from genomic data. The overall model is a system of differential equations with LPs embedded, which can be reformulated as an equivalent complementarity system, a type of hybrid (discrete/continuous) system. This motivates the development of novel simulation and optimization algorithms for such complementarity systems, in particular drawing on ideas and techniques from nonsmooth analysis.

Thermally Coupled Distillation

José A. Caballero

Department of Chemical Engineering, University of Alicante, Ap. Correos 99, 03080 Alicante, Spain

Abstract

This paper presents a brief overview in the design of mixed thermally coupled-heat integrated distillation sequences. The approach considers from conventional columns (each distillation column with a condenser and a reboiler) to fully thermally coupled systems (only one reboiler and one condenser in the entire system). The advantages and disadvantages of thermally coupled distillation in comparison with conventional columns are discussed; the consequence is that the optimal configuration is usually an intermediate point between fully thermally coupled systems and conventional systems. The paper also includes 1. Structural relations between separation tasks and number of column sections, logical relationships that separation tasks must obey in order to select only feasible solutions avoiding configurations that are always sub-optimal. 2. The convenience of using a task based approach instead a column based approach to avoid the redundancy due to thermally couple configurations. 3. How to take advantage of thermodynamically equivalent configurations to synthesize more operable configurations. 4. Heat integrated – thermally coupled distillation systems.

Keywords: Process synthesis, Distillation, Thermally coupled distillation.

1. Introduction

Distillation is likely the most studied unit operation in the history of Chemical Engineering. This research effort is amply justified because distillation has been and continues to be the most widely used separation technique. The main disadvantage of distillation is the high energy requirement. Integration of distillation with the overall process can result in important energy savings[1,2] However, the heat integration between distillation and the rest of the process is often limited.

From the point of view of energy requirements, separation sequences using conventional columns (a single feed with two product streams, condenser and reboiler) suffer from an inherent inefficiency produced by the thermodynamic irreversibility during the mixing of streams at the feed, top and bottom of the column[3]. This remixing is inherent to any separation that involves an intermediate boiling component and can be generalized to an N component mixture. Theoretical studies developed by Petluyk and coworkers[3], showed that this inefficiency can be improved by removing some heat exchangers and introducing thermal coupling between columns. If a heat exchanger is removed the liquid reflux (or vapor load) is provided by a new stream that is withdrawn from another column, in this way it is possible to reduce the energy consumption and under some circumstances also the capital costs. A fully thermally coupled configuration (FTC) is reached when the entire vapor load is provided by a single

reboiler and all the reflux by a single condenser. Different researchers [4], [5], [6] have shown that thermally coupled configurations are capable of typically achieving 30% in energy reduction when compared to conventional systems. Halvorsen and Skogestad [7, 8, 9] proved that the minimum energy consumption for an N component mixture is always obtained for the FTC configuration. However the number of alternatives and the complexity for generating feasible –possible optimal- configurations greatly increases.
In spite of the reduction in energy consumption, there is a price to be paid when using thermally coupled systems: 1. The energy must be supplied in the worst conditions, at the highest temperature in the reboiler and removed at the lowest temperature in the condenser, preventing in most cases the uses of cheaper utilities. 2. When using conventional columns it is common to constrain the alternatives to sharp separations, for example in a three component mixture (ABC) –sorted by volatilities-, we postulate initially separations A from BC (A/BC) and AB from C (AB/C). However, in fully thermally coupled distillation we could introduce sloppy separations –an intermediate product is allowed to distribute along the column- and therefore, we are increasing the number of column sections. This increase does not imply an increase in the number of columns, but usually an increase in the total number of trays. A detailed discussion on number of columns section needed for a given separation can be found in Agrawal [10] and Caballero and Grossmann [11]. 3. In FTC systems, the minimum vapor flow is that of the most difficult separation [8, 9] and therefore some column sections will have large diameters. 4. Operation is more difficult due to the large number of interconnections between columns. Therefore, it cannot be concluded that complex configurations are always superior compared with sequences of simple columns. Instead, the optimum configuration will depend on the specific mixture and feed conditions and it is usually an intermediate situation between FTC and conventional columns.

2. 2. Structural Considerations

In the synthesis of distillation sequences using complex columns it is convenient to separate the concept of separation task from the equipment in which a separation task is performed. In fact, in complex columns, a single column usually performs more than a separation task. This aspect can be illustrated with a simple three component mixture (ABC). Using conventional columns we have two options. The direct sequence: separate first A (A/BC) and then B from C (B/C) or the indirect sequence separate first AB from C (AB/C) and then A from B (A/B). Note that in this case there is a one to one relationship between tasks and columns. However, in a fully thermally coupled configuration (sequence of tasks AB/BC, indicating that the component B distributes along the column, A/B and B/C), the distribution of tasks in columns depends on the alternative chosen among all the thermodynamically equivalent.
Of course, a sloppy separation is not constrained to columns with thermal links. The classical pre-fractionation arrangement shows this last case. However, having established that we have a source for the vapor load (i.e. a reboiler or a vapor side stream from another column) and a source for the reflux, the model of the first column in the pre-fractionation configuration is identical to the model of the first column in the Petlyuk arrangement. Two important consequences follow for the modeling of the problem:
1. *We can separate the heat exchange from the separation task.* In fact the heat exchange can be defined as a new task. Note that in systems with no heat integration, there is a one to one relationship between the heat exchange task and the physical

device that performs that task (the heat exchanger). However, in heat integrated systems, two heat exchange tasks are able to be joined in a single device.

2. *We can study the separation structure (sequence of tasks) without taking into account the presence or not of heat exchangers* (except those related to the streams that leave the systems, as we will comment latter).

A column section can be defined as the portion of a distillation column which is not interrupted by entering or exiting streams or heat flows. A separation task is formed by two column sections, a rectifying and a stripping section, and therefore, it is convenient to consider a separation task as a pseudo-column by similarity with conventional distillation columns, although in the final assignment of column sections to actual columns the two sections of a given separation task do not necessarily belong to the same column. From a structural point of view, thermally coupled configurations are much more complex than sequences of conventional columns. Agrawal [10]established that, in contrast to systems with conventional columns, the number of column sections is not fixed. Consider, for example, the sequence in Figure 1a. (This sequence is performing the separation tasks AB/C – A/B) It is possible to remove the heat exchanger related to stream AB and introduce a thermal couple between both columns. The resulting configuration is shown in Figure 1b. In this configuration the sequence of separation tasks is the same than in the original. It is possible to remove the heat exchanger B to create a FTC configuration. However, in this case it is necessary to introduce two more column sections (the resulting configuration is shown in Figure 1c), this modification also changes the sequence of separation tasks performed by the columns (AB/CD; A/C; C/D). Therefore, there is a trade off between the energy consumption and the extra number of column sections.

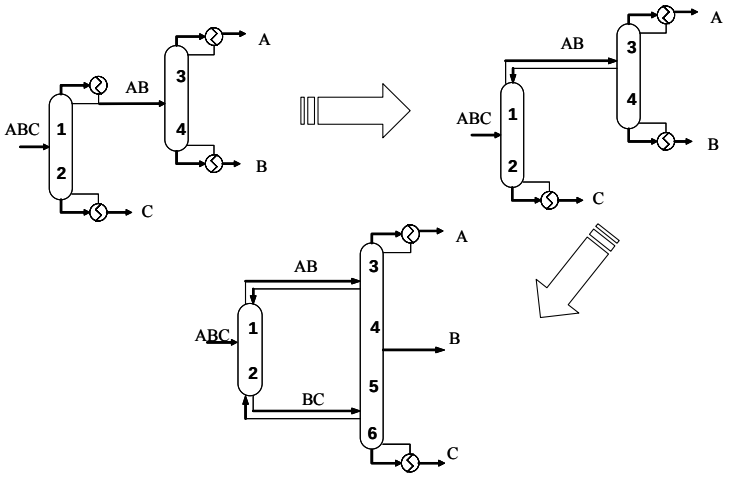

Figure 1. Graphical representation of the steps for going from a conventional system to a FTC system.

The minimum number of column sections (or tasks, each task produces two column sections) is related to the number of heat exchangers associated to final products (or more in general to streams that leave the system)[10, 12]. In an N component mixture in which all the final products have a heat exchanger there are 2(N-1) column sections – (N-1) separation tasks- the previous relationship is always true independently of the existence or not of heat exchangers associated to intermediate streams The heat exchangers associated to final products (pure components or streams that leave the

system) of intermediate volatilities can be removed, but in this case we have to add two more sections for each heat exchanger removed. In fully thermally coupled systems the minimum number of separation tasks is (4N-6)/2 [10]. However, it is possible to generate structures with up to N(N-1)/2 separation tasks. At difference of distillation sequences formed by conventional columns in which to generate valid separation sequences and eventually generate a superstructure is straightforward, this is not the case in thermally couple distillation, at least if we are not interested in including suboptimal separations like is the case of structures with duplication of key components or structures with duplication of separation tasks that has been shown that are always suboptimal solutions. The structural relations between the tasks require a detailed presentation that is out of the scope of this brief review, but it can be found in references [13-16] It is interesting remark that those relations between tasks can be easily transformed in logical rules that can be translated to algebraic equations in terms of binary variables and included in a mathematical programming code to extract the best sequence of columns. Besides, if we are interested in simply generate feasible alternatives it is possible algorithmically adapt those rules to generate alternatives [16].

3. Thermodynamically equivalent configurations

In the design of thermally coupled distillation systems an extra difficulty appears. Two configurations apparently different can be structurally equivalent (Thermodynamically equivalent). Consider Figure 2(b to e). This Figure shows different arrangements of two columns, but the sequence of separation tasks is the same. For example, it is possible to go from the configuration in Figure 2b to 1e by changing section 6 from column 2 to column 1, but flows, temperatures, pressures of the sections remain unchanged. This concept can be generalized to N component mixtures[15]. Note that in these cases a single column can perform more than one separation task. Therefore, in a preliminary design it is important deal only with thermodynamically different alternatives, because differences between thermodynamically equivalent alternatives are usually negligible and only important at the operational level.

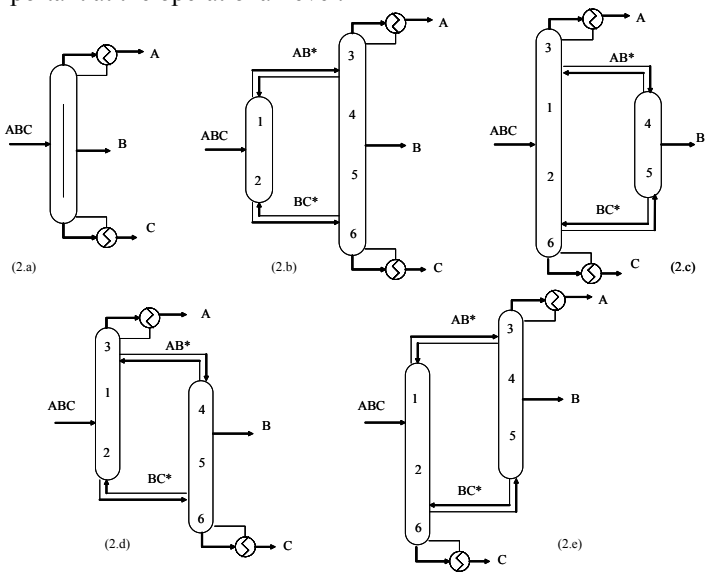

Figure 2. Thermodynamically equivalent alternatives for a three component FTC configuration.

For a given sequence of separation tasks it is of interest being able of generating all the different alternatives in which those tasks can be arranged in actual columns. Caballero and Grossmann showed [15] that the number of thermodynamically equivalent alternatives is equal to $2^{N^{\circ}\ of\ Thermal\ couples}$.
The differences in total cost between two thermodynamically equivalent configurations are not very important, at least when we compare with other structurally different sequences, but they have significant operational differences. Let us consider, for example, the Peltlyuk configuration of Figure 2b. In this configuration the vapor has to be transferred back, from the main or product column to the prefractionator, and forth, from the prefractionator to the main column. In these conditions the vapor flow rate has a difficult control, because neither of the columns has a higher nor lower pressure than the other column. Therefore, the bottom part of the prefractionator has to be at lower pressure than the lower section of the main column and the pressure in the upper section of the main column has to be lower than the pressure in the upper section of the prefractionator. The thermodynamically equivalent configurations (Figures 2d,e) have not this problem. Caballero and Grossmann[15] postulated that there is always a thermodynamically equivalent configuration in which it is possible to force the vapor to go from columns at higher to columns at lower pressure, and proposed a set of logical rules to extract these 'easier to control' configurations among all the thermodynamically equivalent alternatives.

4. Heat Integrated – Thermally coupled distillation sequences

Thermally coupled designs have important savings in energy and capital costs when compared with conventional column designs. However Rev et al[17] showed that for ternary mixtures the Petlyuk configuration is usually not superior to energy integrated systems even in energy savings. This is corroborated by Agrawal[18], in the case of three component mixtures. He found that the total heat duty of the double effect fully coupled configuration is always substantially lower than that of double-effect configuration, and that this results could easily be extrapolated to multicomponent mixtures. Although, the situation is much more complex in multi-component mixtures, again depending on the feed composition, available utilities, difference in volatilities etc; the optimal solution is expected to be an intermediate situation including thermal links as well as heat integrated columns, however, it has been also observed that in heat integrated designs the number of thermal couples decreases when compare with no-heat integrated sequences[16]. This fact complicate the design, because in general it is not truth the heuristics that says that the best no-heat integrated sequence is also the best when heat integration is considered. Therefore, the determination of the best columns sequence and heat integration must be considered simultaneously and not sequenctially.

Abstract

Model predictive control (MPC) has become a standard solution in the process industries, but there are still many open issues related to the acceleration of new implementations and the maintenance of good performance along the years. This paper will discuss some of these issues.

Keywords: performance assessment, regulatory control, advanced control system.

1. Introduction

The advanced control systems in oil & gas and petrochemical plants are an industrial reality (Qin and Badgwell, 2003). These advanced systems provide many advantages for the process units, as improved stability and safety, respect to constraints and higher profitability. PETROBRAS has been investing in the development of these systems for several years. Advanced control system is already a consolidated technology in its refineries with many model predictive controllers implemented (Zanin and Moro, 2004). To install and maintain these advanced systems with good performance is a great challenge. Its performance is influenced by instrumentation problems, bad tuning of the regulatory and advanced control, unreliable process dynamic models (Ender, 1993)(Kern, 2007), unmeasured disturbances, etc. This article will discuss the problems and challenges of advanced control in petroleum industries nowadays. It discusses some tools for diagnosis and tuning of the regulatory and advanced control. In spite of the several tools in the market that deal with industrial control, PETROBRAS has decided to invest on the development of its own tools and solutions in many situations, usually in association with some Brazilian universities. The goal of this paper is to show some challenges faced, solutions and results obtained in PETROBRAS facilities.

2. Regulatory Control Level

Process control aims to maintain certain variables within their desirable operational limits and could be visualized as a pyramid. In the base of this pyramid, the first level is the regulatory control, that uses PID controllers (Campos and Teixeira, 2006)(Ogata, 1982) and is configured in the digital systems (DCS - Distributed control system or PLC - Programmable logical controllers). In a second level, we have the advanced control systems that use for instance Model Predictive Control (MPC). This algorithm considers the interaction between control loops, and includes an optimization layer of the industrial plant. These algorithms are usually implemented in a process computer that

communicates with DCS or PLC systems by the use of OPC protocol (OPC, 2008). The outputs of this advanced control are usually the set points of the PID controllers. The architecture is conceived in such a way that if there is a failure in the advanced control level, the plant operation continues with the last PID set points in the DCS.

An advanced control system won't reach the expected benefits if is turned off constantly for the operators. Therefore, the instruments, valves and the regulatory control loops (PIDs) should operate appropriately. Hence, the performance of the regulatory control is fundamental for the success of the advanced control system. An industrial plant usually has hundreds of control loops, and less and less engineers to maintain the system. Therefore, the industries need tools to perform automatic analysis and diagnoses of the problems associated with the regulatory control. For example, these tools should be able to detect failures with the instrumentation (miscalibration, badly sizing, sensor noisy, out of scale, measurement resolution, etc.), non linear behavior in the process due to changes in the operational point, bad PID tuning (oscillation, stability, etc.) and control strategy problems (coupling between control loops, degrees of freedom, etc.).

There are several tools in the market that help engineers to maintain the regulatory control, but most of them require a well-trained engineers to interpret, analyze and define the correct actions, for instance: to change a control valve, tune PID controllers or to implement a new control strategy (decoupling, feedforward), etc. These engineers should also know very well the process in order to evaluate the better actions to be taken.

The great challenge for these tools will be to incorporate more "intelligence" to help engineers in the definition of the better actions. For instance, in certain case, only PID tuning could reach 80% of improvement in process variability reduction, and in some case, the process performance would improve only 10%. A lot of times in industries the engineer spends time and money with an action that won't bring great results. So, it is clear the importance of a tool that could perform the automatic diagnosis and assessment of the regulatory control (Farenzena et al., 2006). The most important features of this tool should be to have automatic ways to prioritize the actions for each process that might result in a better performance, and also to provide a standardized metric to compare different actions in different processes, even in different scales such as economical, environmental or safety (Harris, 1989)(Kempf, 2003)(Farenzena and Trierweiler, 2008). These features are a great development challenge for these tools.

Despite the several tools in the market, PETROBRAS and Federal University of Rio Grande do Sul (UFRGS) have developed their own tool, the software called “BR-PerfX”. BR-PerfX main purpose is to compute some universal key performance indicators that reduce the subjectivity in the analysis and help engineers in their assessments and decisions about problems affecting the regulatory control.

In order to face the PID tuning problem, PETROBRAS and the Federal University of Campina Grande (UFCG) developed the software "BR-Tuning" (Schmidt et al., 2008)(Arruda and Barros, 2003) “BR Tuning” is comprised by a group of techniques regarding open and close loop identification and the proposition of new tuning parameters. It communicates directly with the process automation system (DCS or PLC) using the OPC protocol.

As it was said previously, the challenge is to develop an "intelligent" layer that helps to make a diagnosis based on several indexes or indicators. The integration between different tools is also an important concern. The use of the OPC standard for the exchange of information could be an option. So, each tool could make available their indicators to others tools through OPC. This way, the engineers' work would be facilitated, avoiding losses of time and money.

The challenges in relation to controllers' tuning are associated mainly with the identification of the models, the determination of the non-linearities of the process, interaction between control loops, as well as defining the desired performance for each control loop.
There are some processes where the disturbances' pattern can change with the time, as in some off-shore petroleum platform. The slug flow can change its intensity for example due to changes in the gas-lift. So, we don't have a PID tuning tools and method that are good for all these different situations. In this case, it was developed an "intelligent" system that supervises the process plant and changes the PID tuning automatically when necessary. This control strategy is equivalent a "gain-scheduling" where the control performance (deviation between the process variable and the setpoint) is evaluated during a time, and the system decides what is the best tuning for that moment. All the possible values for the PID tuning are chosen off-line. This system was installed in several PETROBRAS's platforms. The figure 1 shows the system changing the PID tuning and the level PID performance. This project used a tool called MPA, which was developed by Catholic University of Rio de Janeiro (PUC-RJ) to PETROBRAS (Campos et al., 2008).
Another challenge is the development of non-linear controllers for some special cases, for example to pH control in certain plants, although PID will continue to be the algorithm more used in this regulatory layer control for several years.
Researches and developments for the regulatory control level are still necessary, and they can bring great economical earnings. For example, an application of these tools (evaluation, tuning and changes in control strategy) allows an increased of about 9% in the production of LGN (Liquefied Natural Gas) in a natural gas plant (Campos et al., 2007).

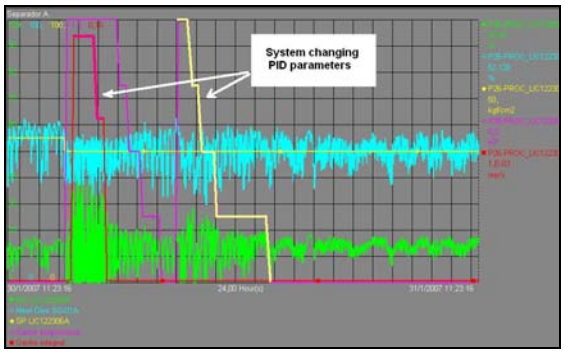

Figure 1– Performance of this control in production platform (1 day).

3. Advanced Control Level

The multivariable predictive controllers (MPCs) are powerful tools for the process optimization and are available in many industrial plants. This system can increase feed and preferred product rates, reduce energy consumption and waste material. These benefits are more visible in complex processes where challenging dynamic responses (significant time delays, non-minimum phase responses, control loop interaction, etc.) due to disturbances (feed flow and composition, energy integration, usefulness, etc.) that must be dealt with while taking into account process constraints and trying to pursue the best economic performance. As an example of the benefits achieved, figure 2 shows an increase of about 16% in the LPG yield due to the implementation of an APC system in a natural gas plant.

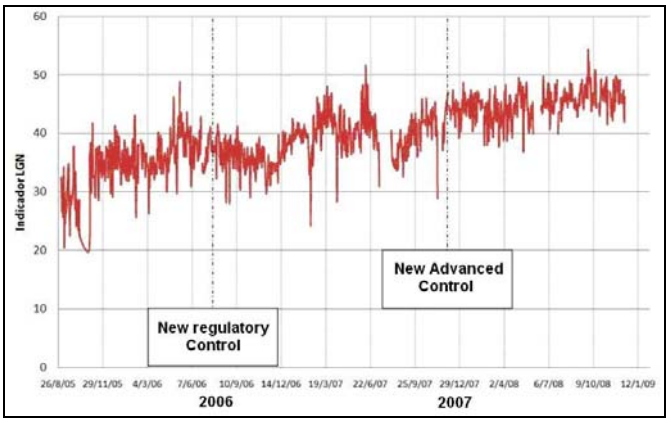

Figure 2– LPG yield increase in a natural gas plant due to MPC.

However, even if MPC systems are nowadays seen as a commodity, there is still much to be done, due to the significant gap between the recent MPC technologies development in the academy and those effectively used on industrial plants. Most industrial MPC applications are based on the most traditional approaches: linear algorithms based on step-response models obtained through traditional step tests.

MPC maintenance

MPC performance decay throughout time is a well-known and widely reported fact (figure 3). If no maintenance work is done, the operators end up turning them off. There are many causes for this behaviour:

- Changes in the units operational objectives;
- Equipments efficiency losses (fouling);
- Changes in the feed quality;
- Problems in instruments and in the inferences;
- Lacks of qualified personnel for the controller's maintenance.

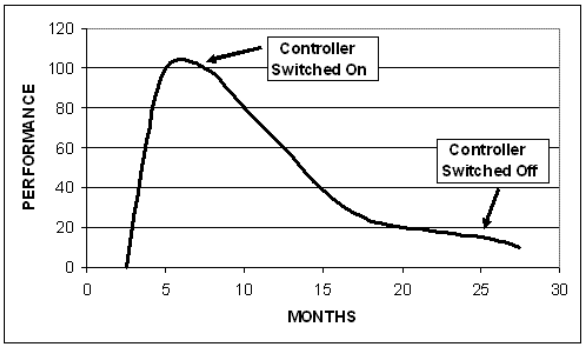

Figure 3 – Advanced Control Performance during the time.

Therefore, the first great challenge associated with MPC control is to have reliable tools to keep performance and diagnose problems. So, industry needs better tools to help maintenance personnel to answer the following questions:

Is advanced control system accomplishing their objectives? What is its performance? Is the process optimized? What are the benefits? How is the level of disturbances? What is operational factor of the controller? How are the operators adjusting the limits of the manipulated variables? Are manipulated variables very limited? What is the variability of the main controlled variable? Is the process operating close to the constraints?

It is necessary a tool not only to answer these questions, but the system point out the causes of the bad performance: bad models, bad controller tuning, inference problems, non-linearities, frequent changes in the operation point, new constraints not considered in the design?

Nonlinear models, Identification and Model mismatch

Many different and even sophisticated approaches have been proposed in order to allow MPC algorithms to cope with process nonlinearity, see Bequette (2007) for a recent review on the subject. However, despite all this effort, industrial NMPC applications are relatively few, and most of these are based on the simplest approaches.

One possible reason for that might be simply that the nonlinear behaviour is not known, and any lack of performance is seen as a typical model mismatch.

Another possibility might be that the nonlinear behaviour is known, but can not be easily determined with traditional plant tests. One way to overcome these problems might be the use of rigorous dynamic simulators, to improve the understanding of the process behaviour. Information obtained with dynamic simulation could be combined to the existing linear model in order to provide a reliable nonlinear one. Dynamic simulation might be useful also to find out the best way to characterize the observed nonlinearity. Once more, although there is availability of dynamic simulators, there is not much use of them in industrial applications.

Process identification of complex processes is still a hard task, where a significant part of the effort on MPC implementation is spent.

In order to address this problem, some commercial tools have been conceived in this decade for closed-loop identification. These tools are based on efficient ways to perform step tests allied to modelling strategies for minimization of the model order. While this approach has proved to be useful and promising, it is still a hard task to apply these techniques to complex processes, especially when dealing with noisy data. It seems to be a lot of space for development in this area.

Another interesting way to reduce implementation time can be the use of algorithms for automation of the plant test.

Tuning

MPC tuning is another interesting issue, where new technologies might help to reduce implementation time and also on the maintenance task.

Some interesting ideas have been proposed by Trierweiller and Farina (2003) that try to combine desired and achievable performances. However, the controller tuning still consume time and is critical points for controller performance. Normally, all MPC tuning methods consider a square controlled variables x manipulated variables matrix, but, in fact all controller has a rectangular matrix that means different tuning scenarios depending on which constraints is active.

Another big challenge is to reduce the application time and maintenance time. For this, it is believed that the main critical points are:

- Tools for the development of inferences:
  - Use of rigorous dynamic simulators, or statistical methods for better inferences using less laboratory analysis data.
- Dynamic models identification:
  - Automation of the identification tests, minimizing problems and loss of data;
  - Efficient tools for closed loop identification;
  - Characterization and identification of the non linearities of the process.
- Better tools for tuning the predictive controller:

- How to define the priorities in the several operating points of the controller and change automatically the tuning parameters. This activity is still done by trial and error in many industrial cases.

New advanced controllers that contemplate these aspects will help the users to implement and maintain these industrial systems.

4. Conclusions

This article has discussed some ideas about the improvement of MPC implementation, monitoring and maintenance. The first important issue to be taken into account is the requirement of expert tools regarding the regulatory control level. Aspects related to the MPC model identification and updating, and the conception of new tools for MPC tuning generation and assessment are seen as key points to help the users on implementation and maintenance tasks.

An Industrial Perspective on Pharmaceutical PSE

Peter Crafts

Principal Process Engineering, AstraZeneca Pharmaceuticals, Global Process R&D, Macclesfield, UK.

Abstract

If we, or one of our loved ones, become ill then access to safe and effective drugs to treat disease, alleviate pain and enable surgery becomes a high priority. AstraZeneca's business model is to discover, produce and market new pharmaceutical compounds that best meet these needs.

The industry average success rate for taking a new pharmaceutical compound through the clinical trials process and into the market is only ~8% however. This translates to a process development environment where many new processes compete for limited resource in stop-start projects, driven by the clinical trials programme. Within this environment PSE is most beneficial in focusing laboratory effort to areas most likely to succeed. Extrapolating small data sets to design sustainable and optimised processes is highly prized.

This paper explores the current role of PSE in AstraZeneca. Contemporary case studies are presented to illustrate both successes and areas where current knowledge and technology are insufficient. The examples cover:

- Solvent selection for reactions;
- Batch distillation for the exchange of process solvents;
- Crystallisation process design, solubility prediction and phase diagrams;
- The prediction of oiling-out during crystallization.

A common theme running through all these cases is the requirement for accurate phase equilibrium models, and this area will be explored in more detail.

Incorporating Molecular Signature Descriptors in Reverse Problem Formulations

Nishanth G. Chemmangattuvalappil, Charles C. Solvason,
Susilpa Bommareddy, Mario R. Eden
Department of Chemical Engineering, Auburn University, Auburn, AL 36849, USA

Abstract

The recently introduced concept of reverse problem formulation has been helpful for the solution of integrated process and product design problems from a properties perspective. A new algorithm has been developed that utilizes molecular property operators based on molecular signatures to obtain the molecular structures corresponding to the property targets estimated during the process design step. The algorithm allows property models based on different Topological indices (TI) and group contribution models to be represented on the same property platform.

Keywords: Molecular design, Signature description, Reverse problem.

1. Theoretical background

1.1. Reverse problem formulation

Reverse problem formulation (RPF) is a technique used to reduce the complexity of integrated process and product design problems. The application of RPF for identifying the property targets corresponding to optimum process performance can be found in the work published by Eden et al. (2004). In RPF, the integrated problem is broken down into two reverse problems. The first reverse problem provides the property targets to achieve optimum process performance and the second reverse problem is used to generate the molecular structures that meet the property targets. However, the current algorithms used for solving the second reverse problem are limited to very few properties which can be predicted using group contribution methods (GCM). Therefore, there is a need for an algorithm which is more general and can be extended to property models beyond group contribution methods.

1.2. Molecular signature descriptors

Molecular signature is a molecular descriptor used for representing the atoms in a molecule using the extended valancies to a pre-defined height (Visco *et al.,* 2002, Faulon *et al.,* 2003a). If G is a molecular graph and x is an atom of G, the atomic signature of height h of x is a canonical representation of the sub graph of G containing all atoms that are at a distance h from x. The signature of a molecule is defined as the linear combination of its atomic signatures. The detailed procedure for generating signature can be found in the work published by Visco *et al.* (2002) and Faulon *et al.* (2003a). Faulon *et al.,* (2003a) identified the relationship between TIs and signatures. If k is a constant, ${}^{h}\alpha_{G}$ is the vector of occurrences of atomic signature of height h and TI (root (${}^{h}\Sigma$)) is the vector of TI values calculated for each root of atomic signature:

$$TI(G) = k \cdot {}^{h}\alpha_{G} \cdot TI(root({}^{h}\Sigma)) \qquad (1)$$

2. Reverse problem formulation using molecular signatures

Since many existing QSPR expressions can be reformulated in terms of molecular signatures, algorithms based on signatures will be able to track a wide variety of property targets. In this approach, the property targets identified in the first RPF will form the input to the molecular design problem.

2.1. General problem statement

Identify the molecules with the best dominant property, which also satisfy a set of property constraints. The first step is to identify the QSAR/QSPR expressions corresponding to all the given properties/activities. In the next step, identify the heights of molecular signature corresponding to the TIs used in QSPR. If θ is the property function of property *P,* the property operator corresponding to *P* is estimated as follows. The property operator of a property is a function of the actual property which obeys linear mixing rules (Shelley and El-Halwagi, 2000):

$$\theta = f(TI) \tag{2}$$

$$TI = \sum_{i=1}^{N} {}^{h}\alpha_i \cdot TI(root({}^{h}\Sigma)) = \sum_{i=1}^{N} {}^{h}\alpha_i L_i \tag{3}$$

$$\Omega(P) = \sum_{i=1}^{N} x_i L_i \tag{4}$$

The dominant property, which is expressed in terms of the occurrences of atomic signatures, can be optimized subject to the property constraints. If Ω_j is the property operator corresponding to the dominant property and Ω_{ij} is the normalized property operator of molecule *i*, an optimization problem can be formulated as follows:

$$Max / Min \ \ \Omega_j \tag{5}$$

$$\Omega_j^{\min} \le \Omega_j \le \Omega_j^{\max} \tag{6}$$

2.2. Structural constraints

The solution of Eqs. 2-6 will provide a collection of signatures that give the best dominant property. However, to ensure that the collection of signatures will form a molecule without any free bonds, the *handshaking lemma* from graph theory is used (Trinajstic, 1992). According to this, in a graph, if *D(i)* is the number of degrees of each vertex *i* and *M* is the total number of edges:

$$\sum_{i=1}^{N} D(i) = 2M \tag{7}$$

In the reverse problem formulation, since the final molecular structure is unknown, it is not possible to know the number of bonds. Therefore, there should be a way to relate the number of signatures to the edges in the structure. Consider a graph without any circuits. If N_i is the total number of signatures, N_{Di}, N_{Mi} and N_{Ti} are the signatures with one double bond, two double bonds and one triple bond in the parent level, the following relationship has been developed between the number of signatures and edges:

$$M = \left[\sum_{i=1}^{N} x_i + \frac{1}{2} \sum_{i=0}^{N_{Di}} x_i + \sum_{i=0}^{N_{Mi}} x_i + \sum_{i=1}^{N_{Ti}} x_i \right] - 1 \qquad (8)$$

If the number of rings in the final structure is N_r, the following relation can be used:

$$M = \left[\sum_{i=1}^{N} x_i + \frac{1}{2} \sum_{i=0}^{N_{Di}} x_i + \sum_{i=0}^{N_{Mi}} x_i + \sum_{i=1}^{N_{Ti}} x_i \right] - 1 + N_r \qquad (9)$$

While designing molecules with both single and multiple bonds, the signatures with single and multiple bonds can form independent structures even with the theoretical potential for connectivity. This situation can be avoided by inserting a constraint which makes the formation of molecules only based on single bonds infeasible. If M_f is the number of edges in the signature combination with only single bonds:

$$M_f \geq 1 \qquad (10)$$

Since Eqs.8 or 9 ensures the entire connectivity of the combination of signatures, the aforementioned constraint will produce a molecular structure with both single and multiple bonds.

In order to differentiate between different types of atoms, vertex coloring has been used. The coloring function has to be selected based on the types of atoms and the nature of the final molecule. For signatures with double and triple bonds, the type of bond also should be the part of the coloring function. The coloring should start from the root atom to all atoms up to level *h-1*. For instance, in the design of an amine molecule, the coloring function is the degree of C or N atoms, the type of bond and the atom type. An example is shown in Figure 1 where the signature of C atom with NH_2 bond is colored:

CH_3-CH_2-C (NH_2) =CH_2 → C (=CC(C) N) → C4 (=C2N1C2)

Figure 1. Coloring of signatures

In a complete molecule, since each edge is shared by two vertices, the colors of the edge that joins the two vertices must be the same for both vertices. However, the order of colors will be different for both the vertices since the reading of color has to start from the root. In addition, the bond type should be consistent in the joined signatures. For instance, consider the signature in Figure 1. Here, the reading of colors are 4→ (=2), 4→N1 and 4→2. It can be seen that these orders are appearing in the reverse order while writing the signatures of attached atoms. The presence of both edges ensures that there is a link between the vertices. If $(l_i \rightarrow l_j)_h$ is one coloring sequence $l_i \rightarrow l_j$ at a level h:

$$\sum (l_i \rightarrow l_j)_h = \sum (l_j \rightarrow l_i)_h \qquad (11)$$

If the color sequence in one signature is $l_i \rightarrow l_j$ with $i=j$, then, there must be another signature present in the set of signatures with the same color sequence to complement the previous one. If η is the number of color sequences $l_i \rightarrow l_j$ on one signature with $i=j$ and x is the number of such color sequences and K is an integer, then:

$$\sum_{i=j} \eta_i x_i = 2K \qquad (12)$$

In order to form a connected tree, it must be ensured that the total number of signatures, where the degree of the vertex at a higher level is more than the degree at a lower level

should be less than the total number of vertices with the higher degree. If n_i is the number of child vertices with a higher degree than the parent vertex, i and j represents the child and parent colors:

$$\sum x_i n_i \leq \sum x_j \tag{13}$$

The dominant property function can be optimized subjected to the constraints. Integer cuts can be used to form other feasible solutions. An algorithm has been developed by Faulon *et al.* (2003b) to enumerate the molecules from the identified signatures.

2.3. Expression of group contribution (GC) models with signatures

In GCM, the property function of a compound is estimated as the sum of property contributions of all the molecular groups present in the molecule. The molecular signatures of sufficient height can be used to re-write GC expressions. This transformation will allow us to solve the property models based on TIs and GC models simultaneously. The height and number of the signatures used to write the molecular groups in the GC model depends on the number of atoms and the nature of the final molecule. Consider the design of a molecule with amine and alkyl groups. The maximum number of amine groups on each alkyl group and attached carbon atom on each amine group is limited to one. The potential groups available in GCM are (Marrero and Gani, 2001):

CH_2 NH_2 CH_2NH_2 $CHNH_2$ CNH_2 CH_3 CH_2 CH C

The root atom on every signature can be colored with two numbers - the first color is the number of neighboring C atoms and the second color is the number of neighboring N atoms. Signature of height 2 is required for complete coloring. All signatures with root N can be used to re-write different amine groups. If the neighboring C atom of an N root has three neighbors, then, the root N atom will be equivalent to a CNH_2 group. Similarly, all N root signatures can be assigned the property contributions of CH_2NH_2 and $CHNH_2$ groups based on the colors of their nearest neighbors. The signatures with root C atoms will form the alkyl groups. Here, the signatures with root C atom having N in any of its nearest neighbor should not be considered as a group since that signature has been taken care of in the amine groups. For the rest of the signatures with root C, property contributions can be assigned based on the numbers of neighboring C atoms.

2.4. Property models with different signature heights

In a molecular design problem with multiple property constraints, different TIs may be describing different properties of interest. It is also possible to have one OSAR/QSPR containing different TIs. If the signature heights of the TIs are different, the signatures corresponding to the largest height have to be enumerated first and the number of signatures of smaller height can be obtained from the higher signatures. Consider the situation where QSPR is based on signatures of heights one and two respectively. The property operator for property Y can be written in terms of signatures as follows:

$$f(Y) = \sum_i L_i{}^1 \alpha_i + \sum_j L_j{}^2 \alpha_j \tag{14}$$

If the height of the largest signature of interest is h and height of the lower signature is h-m, then the total number of each h-m level signatures can be obtained by adding the h level signatures under same color at level h-m. For example, if the signatures of interest are N1(C), N2 (CC) and N3 (CCC) which are signatures with height one. Now, signatures of height two with root vertex N can be divided into three sets S_1, S_2 and S_3.

The elements in these sets are signatures of height two with N vertex and vertex color 1, 2 and 3 respectively. The occurrences of signature N1(C) can be obtained as follows:

$$N(C):\ {}^{1}\alpha_{N(C)} = \sum_{S_1} {}^{2}\alpha_i \qquad (15)$$

The number of occurrences of other signatures of height one is similarly estimated.

3. Case Study: Design of substituent for a fungicide

The optimal substituent selection for dialkyldithiolanylidenemalonate (DD), which was originally solved by Raman and Maranas (1998) has been reworked here. The target properties are affinity (*log* (V_E)), mobility (*log* (μ)) and retention (*log* [*R/(1-R)*]). These properties are correlated to hydrophobic factor (Uchida, 1980), which is correlated to a first order molecular connectivity index (Murray *et al.,* 1975). In this work, an additional property constraint of toxicity (LC_{50}) is included. The GCM is used to predict LC_{50} (Martin and Young, 2001). The property models are shown in Table 1. The objective of this case study is to identify the alkyl substituents of DD that give maximum affinity subject to the constraints based on mobility, retention and toxicity. Here, substituents with multiple bonds are also considered. The first order connectivity index can be re-written in terms of molecular signatures of height two (Visco *et al.,* 2002) according to Eq. 16:

$${}^{1}\chi = \sum_{i=1}^{K_G}\left(\frac{1}{2}\sum_{u\in {}^{l}V_2({}^{h}\chi_i)}\left[\deg(u)\deg({}^{-1}\nu_\sigma(u))\right]^{-\frac{1}{2}}\right)x_i = \sum_{i=1}^{K_G} L_i x_i \qquad (16)$$

It is possible to form 120 signatures of height 2. The property targets and the normalized property operators are shown in Table 1. The molecular design problem can be written in terms of signatures using Eqs. 17-20.

Table 1. Property operators and targets

Property	*Property model*	*Property operator*	*Ref.*	*L.B.*	*U.B.*
Mobility	$-0.6984({}^{1}\chi)+2.0143$	$1.432(2.0143-\log(\mu))$	1	-0.3	0.3
Retention	$0.787({}^{1}\chi)-2$	$1.271\left(\log\left(\frac{R}{1-R}\right)+2\right)$	1	-0.3	1.0
LC50	$\exp\left(-\sum_{i=1}^{N} n_i\alpha_i\right)$	$-\log(LC_{50})$	1	-	0.04
Affinity	$0.5751({}^{1}\chi)-0.2942$	$1.739(\log(V_E)+0.2942)$	1	-	-

$$Max\ \Omega_{V_E} \qquad (17)$$

$$2.455 \le \sum_{i=1}^{120} h_i x_i \le 3.314 \quad \text{(Includes the constraints on mobility and retention)} \qquad (18)$$

$$3.129 \le \sum_{i=1}^{3} c_i x_i \quad \text{(Constraint on LC50)} \qquad (19)$$

$$\sum_{i=1}^{120} D_i x_i = 2\left[\left(\sum_{i=1}^{120} x_i + \frac{1}{2}\sum_{i=66}^{107} x_i + \sum_{i=108}^{120} x_i\right) - 1\right] \text{ (Handshaking lemma)} \qquad (20)$$

The first 65 signatures are the signatures with only single bonds in their parent atom, next 43 signatures have one double bond in their parent atom and the rest of the signatures have either two double bonds or one triple bond in the parent atom.
To differentiate among different types of carbon atoms, the vertices are colored with the degree of each carbon atom. Equations 11-13 are applied to ensure that the signatures will complement each other. For illustration, one of the equations from Eq. 11 is shown. Here, x_{68}, x_{98}, x_{99} *and* x_{100} are the occurrences of the signatures C3(≡C4), C4(≡C3C2), C4(≡C3C3) and C4(≡C3C4). It can be seen that the number of appearances of C3≡C4 is equated to the number of appearances of C4≡C3:

$$x_{68} = x_{98} + x_{99} + x_{100} \qquad (21)$$

Equations 17-21 are solved to obtain the number of appearances of each signature and the molecular structures are enumerated from the signatures using the algorithm provided by Faulon *et al.* (2003b). The best three solutions and the estimated properties are shown in Table 2.

Table 2. Final solution

Affinity	*Mobility*	*Retention*	*Toxicity*	R_1	R_2
				methyl	3-methyl-butyl
1.608	-0.296	0.603	0.035	methyl	2-pentyl
				ethyl	*sec*-butyl
1.598	-0.2833	0.5895	0.018	*Iso*-propyl	3-methyl-1-propenyl
1.5979	-0.2832	0.5893	0.015	Vinyl	4-methyl-2,3-butenyl

4. Conclusions

The newly introduced concept of molecular signature descriptor has been used as tool for the molecular design part of the general reverse problem formulation framework. The ability of signature to represent a wide variety of topological indices allowed the application of RPF into a variety of property targets. Since all property models are expressed as a function of occurrences of signatures, the problem can be solved for a single descriptor even if the TIs are described with signatures of different heights.

Online optimizing control: The link between plant economics and process control

Sebastian Engell

Process Dynamics and Operations Group, Department of Biochemical and Chemical Engineering, TU Dortmund
Emil Figge-Str. 70, 44221 Dortmund, Germany, email s.engell@bci.tu-dortmund.de

Abstract

The idea of direct online optimizing control of chemical production processes is motivated and the handling of plant-model mismatch is discussed in some detail.

Keywords: Online optimizing control, RTO, plant-model mismatch, measurement-based optimization.

1. Introduction

In the design of chemical processing plants, it has become standard practice to employ rigorous stationary models to determine the sizes of the equipment as well as the nominal operating points. But as the models used for plant design do not represent the real process exactly and the processes are subject to a large number of perturbations, e.g. varying raw material compositions and ageing equipment, even if the operating regime was optimized for a rigorous plant model during plant design this will not lead to an optimal operation of the real plant. Moreover, adaptation to varying throughputs or new product specifications has to be performed increasingly often (Backx at al., 2000). This calls for continuous dynamic reactive and proactive adaptation of the operational degrees of freedom of the plant to changing conditions. For process stability and process safety, it is necessary to keep a large number of variables close to their set-points, a task which is usually realized by decentralized low-level PI/PID-controllers. From a process engineering point of view, the main purpose of automatic feedback control is to operate the plant such that the net return is maximized in the presence of disturbances and uncertainties, exploiting the available measurements. This has been pointed out in a number of papers (see e.g. Morari, et al., 1980, Narraway and Perkins, 1991, Skogestad, 2000a). A positive effect of tight feedback control is that the back-off from the operating constraints and product specifications can be reduced, leading to a more profitable operation, but not all process variables need to or should be controlled tightly.

Linear model-predictive control has be become the standard technique in the petrochemical industry to achieve high-performance multivariable control. In recent years, the focus in research has shifted to nonlinear model-predictive control (NMPC) often based upon rigorous dynamic process models. Advances in computer hardware and in numerical algorithms (e.g. Diehl et al., 2002, 2005, Jockenhövel et al., 2003) have rendered the application of NMPC employing high-order first-principles models in real time at real plants feasible. If NMPC controllers are implemented, the cost function can be formulated to represent plant performance rather than tracking performance, see e.g. (Zanin et al., 2000, Toumi and Engell, 2004, Bartusiak, 2005, Abel et al., 2005, Rolandi et al., 2005, Busch et al., 2005). In this paper, we discuss the idea of online optimizing

control with a focus on the issue of plant-model mismatch. We conclude with a discussion of some obstacles for the widespread implementation of this approach.

2. Classical feedback control vs. RTO vs. online optimizing control

The purpose of feedback control is to adapt the operational degrees of freedom of the plant such that the operational constraints and the product specifications are met and the economic performance is optimized. This can, to a certain extent, be achieved by regulating suitably chosen process variables to suitably chosen set-points (Skogestad, 2000a, 2000b). The effect of regulatory feedback control on a profit function J in the stationary situation can measured by the difference of the profit under the influence of disturbances $\underline{d}$ and its nominal value $J(u_{nom}, 0)$(Engell et al., 2005, Engell, 2007):

$$\Delta J = \left(J(\underline{u}_{nom}, 0) - J(\underline{u}_{nom}, \underline{d}_i) \right) + \left(J(\underline{u}_{nom}, \underline{d}_i) - J(\underline{u}_{opt}, \underline{d}_i) \right) + \left(J(\underline{u}_{opt}, \underline{d}_i) - J(\underline{u}_{con}, \underline{d}_i) \right).$$

The first term is the loss (or gain) if the manipulated variables are fixed at their nominal values when disturbances occur, the second term represents the effect of an optimal adaptation of the manipulated variables in the presence of disturbances, and the third term is the difference between the optimal adaptation and the one which is realized by the chosen feedback control structure. If the first term is large compared with the other ones then changing the manipulated variables will have little benefits, neither online optimization nor feedback control is useful here. On the other side, if the third term is large then online optimizing control should be used in addition to regulatory feedback control. Note that the terms appearing in the above formula can be determined, for a given control structure and known disturbances, by an optimization of the degrees of freedom for a stationary process model which is nowadays often available during plant design. This computation reveals the potential of online optimization for a given plant.

Often, the economically optimal operation of a plant is to maximize its throughput (see e.g. Price et al., 2003). The maximum throughput is restricted by the operational constraints of the units and by their ability to meet the constraints on product purities etc. Aske at al. (2008) have recently proposed a control scheme where an optimization of plant throughput is performed based upon the information that is available from the linear models used in local linear MPC controllers. This requires models that are accurate at the steady state while the exact steady-state gain is otherwise not needed to obtain a good control performance, so this may necessitate some additional modeling effort. The scheme was already partly implemented at a large gas treatment plant (Aske, 2009).

If the economic optimum is cannot simply be established by maximizing the throughput, the common approach is to introduce a higher level optimization layer where the operating points are optimized based upon rigorous stationary models, termed RTO – real-time optimization, see (Marlin and Hrymak, 1997) and the references therein. An RTO system is a model-based, upper-level control system that is operated in closed loop and provides set-points to the lower-level control systems in order to maintain the process operation as close as possible to the economic optimum. The general structure of an RTO system is shown in Fig.1. Its hierarchical structure follows the ideas put forward already in the 1970's, see e.g. (Findeisen, et al., 1980). The introduction of an RTO system provides a clear separation of concerns and of time-scales between the RTO system and the process control system. The RTO system optimizes the plant economics on a medium time-scale (shifts to days) while the control system provides tracking and disturbance rejection on shorter time-scales from seconds to hours.

A main disadvantage of this layered approach is the delay of the optimization which is inevitable because of the use of steady-state models. The time between successive RTO steps must be large enough for the plant to reach a new steady state after the last commanded move.

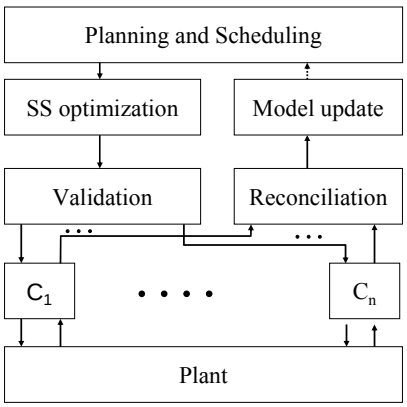

Figure 1: RTO control structure

If a step disturbance occurs in some unmeasured external input to the plant, then first the control system will regulate the plant (to the extent possible) to the set-points that were computed before the disturbance occurred. After all control loops have settled the RTO optimizer can be started, and after the results have been computed and validated, the control layer can start to regulate the plant to the new set-points. Thus it will take several times the settling time of the control layer to drive the plant to the new optimized mode of operation. In the first phase, the control system will try hard to maintain the previously optimal operating conditions even if without fixing the controlled variables to their set-points the operation of the plant would have been more profitable. If the disturbance persists for one sampling period of the RTO system plus one settling time of the regulatory layer, the use of the RTO system on the average recovers about half of the difference between the profit obtained by the regulatory system alone (with fixed set-points) and an online-optimizing controller that implements the optimal set-points within the settling time of the regulatory control layer. The combined RTO-regulatory control structure will work satisfactorily for infrequent step changes of feeds, product specifications or product quantities but it will provide no benefit for changes that occur at time scales below the RTO sampling period.

This situation calls for dynamic model-based online optimization as performed in nonlinear model-predictive control. In NMPC, the cost function is not restricted to a quadratic measure of set-point tracking, but economic goals can be included. This was probably first put forward and implemented at a real plant by Zanin et al. (2000). When dynamic online optimization is introduced, the functions of the RTO layer and of the regulatory control layer can be re-distributed. On the upper layer, key process variables are optimized dynamically over a prediction horizon in order to optimize the economic performance of the process while on the lower layer, these control moves are implemented (e.g. by flow controllers) and inventory-related and other secondary control loops are realized. Implementations at real plants have also been reported by (Toumi and Engell, 2004, Abel et al., 2005) and by Bartusiak (2005) for an industrial application. Recently, Ochoa et al. (2009) compared a direct optimizing control structure for a bioethanol plant to a conventional control structure in simulations and found significant benefits of online optimizing control.

3. Dealing with plant-model mismatch

A key aspect in the application of optimizing control is the effect of plant-model mismatch. The model that is used to dynamically optimize the performance over the prediction horizon never predicts the plant behavior exactly. The ability to cope with plant-model mismatch is one of the most important properties of well-chosen feedback con-

trol structures. In industrial reality, many controllers are implemented based only on very rough plant models but nonetheless function quite well. Feedback is usually introduced into online optimization over moving horizons by the following mechanisms:

- Restart of the optimization with a shifted horizon based upon an update of the estimated states
- Bias correction (extrapolation of the mismatch between the predictions and the measurements).

These two elements of feedback can be considered as relatively weak. The computation of the control moves relies completely on the assumed model of the behavior of the plant that is only shifted to compensate steady-state errors in order to ensure steady-state offset-free regulation. Figure 2 shows an example where an online optimizing control scheme fails temporarily due to plant-model mismatch. The process considered is a combined reaction-separation process, the Hashimoto-SMB process (Borren et al., 2006). The goal of the optimizing controller is to minimize the solvent consumption which dominates the variable production cost under hard constraints of the product purity and of the product recovery. The control scheme minimizes the solvent consumption plus a regularization term over a finite prediction horizon and employs the classical zero order prediction error extrapolation scheme, i.e. the constraints are modified by the difference of the predicted and the measured product purity and recovery at the most recent point in time.

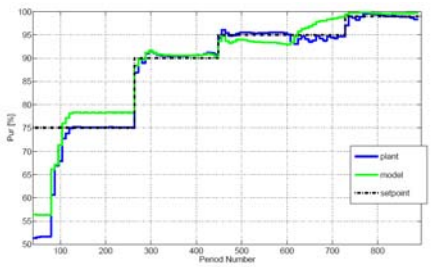

Figure 2: Predicted and measured product purities for the Hashimoto-SMB process with plant-model error mismatch (simulation) (Küpper and Engell, 2008)

It can be seen in Fig. 2 that the assumption of a constant error that results from plant-model mismatch is justified in the first two intervals while in the third interval, the measured purity hardly changes while the predicted purity reacts to the actions of the controller. The prediction error even changes its sign. The controller does not manage to keep the product purity above the constraint in periods 600 - 720.

For the Hashimoto SMB example, a careful analysis of the operating point chosen by the online optimizing controller revealed that the economically optimal operating mode is operation with a breakthrough over the recycle line, in contrast to the standard operation of SMB processes (Mazzotti et al., 1997). This operation mode is more efficient, but less robust than the conventional one. Enforcing the standard operation mode leads to robust control at the expense of an increased solvent consumption (Küpper and Engell, 2008). The example also shows that online optimization may point out opportunities for different operating modes that have not been considered in plant design.

Iterative solution and bias correction does not lead to optimality, because the model used in the optimization is not corrected and the optimality conditions are only satisfied for the model, not for the real plant. Moreover, it cannot be ruled out that due to plant-model mismatch, the plant is driven into a situation where feasibility can no longer be achieved, or the closed-loop system becomes unstable. The next paragraph discusses an approach that avoids these problems without being overly conservative.

3.1. Two-stage optimization for a set of plant models

An extension of moving horizon optimization that takes model errors into account explicitly is to formulate a min-max problem where the controller outputs are computed such that the cost function is minimized and the constraints are met for the worst possible model within a given set. This however may lead to unnecessarily conservative solutions, because in the formulation the presence of feedback that leads to a modification of the control inputs in the future after model errors or disturbances have influenced the system is ignored.

A better way to achieve non-conservative robust nonlinear model predictive control is to employ two-stage stochastic optimization, similar to the approach taken for scheduling problems e.g. in (Sand and Engell, 2004). The model uncertainty is represented by a set of possible plant models. The controlled variables are divided into two sets, *here and now* variables which are applied to all models (the first inputs), and *recourse* variables that can assume different values for each model in the set (the future inputs that will be chosen after additional information has been obtained). In the formulation proposed in (Dadhe, 2006, Dadhe and Engell, 2008), the cost function of the optimization problem is computed for the nominal model only, but the constraints must be met for all models in the set, by a suitable choice of the specific inputs for each model:

$$\min_{\substack{u_k \cdots u_{k+N_p-1} \\ u_k^{*b} \cdots u_{k+N_p-1}^{*b}}} J_k = \min \left(\phi \left(y_{k+N_p|k} \right) + \sum_{j=0}^{N_p-1} \ell \left(y_{k+j|k}, u_{k+j|k} \right) \right)$$

where the first term represents the terminal cost and the second term the incurred cost along the trajectory, under the constraints,

$$\begin{aligned} y_{k+j} &\in \mathcal{Y} \\ u_{k+j-1} &\in \mathcal{U} \\ \Delta u_{k+j-1} &\in \Delta\mathcal{U} \\ 0 &= y_{k+j} - f\left(\theta, y_{k+j-1}, \ldots, u_{k+j-1}, \ldots\right) \\ 0 &= u_{k+i} - u_{k+i}^{*b} \\ y_{k+N_p} &\in W \ominus \mathcal{W}(\alpha) \end{aligned} \qquad \begin{aligned} y_{k+j}^{*b} &\in \mathcal{Y} \\ u_{k+j-1}^{*b} &\in \mathcal{U} \\ \Delta u_{k+j-1}^{*b} &\in \Delta\mathcal{U} \\ 0 &= y_{k+j}^{*b} - f\left(\theta^{*b}, y_{k+j-1}^{*b}, \ldots, u_{k+j-1}^{*b}, \ldots\right) \end{aligned}$$

The upper index "*b" refers to the additional models that reflect the uncertainty about the plant dynamics. The index i assumes values from 0 … N_1, N_1+ 1 being the length of the first stage, and at the end of the prediction horizon, the outputs of all models must be driven to a target region *W* which is shrunk by an estimate of the model uncertainty. The two-stage formulation reflects the presence of feedback in a somewhat optimistic fashion because it is implicitly assumed that the true model will be revealed at a fixed point in time in the future. This robust non-conservative NMPC formulation was applied to sets of bootstrap models for neural net models of nonlinear systems in (Dadhe, 2006) but can be applied to any set of models that characterizes the model uncertainty. For a case study of a bioreactor model which exhibits strong nonlinearities and where the performance of a NMPC controller based upon a nominal model alone is insufficient in certain parts of the operating window, the two-stage multi-model formulation led to satisfactory control (Dadhe, 2006). Instead of considering the model uncertainty only in the constraints, the cost function can also be extended to the expected (average) value of the cost over all plant models or be formulated in a risk-conscious manner.

3.2. Achieving optimality in the presence of model uncertainty

How to use the available measurement information to achieve true optimality in the presence of plant-model mismatch is a challenging problem that has increasingly be

discussed recently (Gao and Engell, 2005, Kadam et al., 2007, Chachuat et al., 2008). The classical solution is to include a (usually small) set of model parameters into the estimation of the plant states and to adapt the model to the observations. This is efficient if the uncertainty can be tied to a limited number of crucial model parameters. If the plant-model mismatch can be eliminated by parameter estimation, optimality can be achieved for the real plant. However, if there is structural plant-model mismatch, then parameter adaption in a structurally incorrect model may make things worse, as demonstrated in (Chachuat et al., 2008).

If plant-model mismatch cannot be eliminated completely, there is a very promising scheme that addresses the issues of optimality and of feasibility: gradient adaptation (Tatjewski, 2002, Gao and Engell, 2005). The idea of Tatjewski that simplifies the Integrated System Optimization and Parameter Estimation Strategy first proposed by Roberts (1979) is to correct not only the bias but also the gradient of the cost function. The strategy requires the knowledge of the gradient of the real performance function (which is assumed to depend only on variables which are measured) with respect to the optimization parameters. Then convergence to the optimum can be assured without adaptation of model parameters. Gao and Engell (2005) extended this idea to the case where uncertainties are also present in the functions that relate the constraints to the degrees of freedom, e.g. product purity or conversion constraints. The drawback of the scheme is that the gradients of the performance indicator and of the constraints with respect to the controls have to be estimated online which may require additional control moves. Various schemes and for this are also discussed in (Gao and Engell, 2005).

4. Further critical issues

Lack of space prevents a detailed discussion of the many open issues in online optimizing control with economic cost functions here. Clearly stability is an issue, as discussed e.g. by Rawlings and Amrit (2008). From a practical point of view, modeling is the major bottleneck. To formulate, parameterize and validate dynamic models requires a major effort that has to be justified by the expected economic advantages. The recent trend towards building training simulators for all major new plants yields dynamic models for control almost for free, but then the simplification of these overly detailed models is a challenging problem.

A second practically very important limiting issue is that of reliability and transparency. It is hard, if not impossible to rule out that a nonlinear optimizer does not provide a solution which at least satisfies the constraints and gives a reasonable performance. While for RTO an inspection of the commanded set-points by the operators usually will be feasible, this is less likely in a dynamic situation. Hence automatic result filters are necessary as well as a backup scheme that stabilizes the process in the case where the result of the optimization is not considered safe. But the operators will still have to supervise the operation of the plant, so a control scheme with optimizing control should be structured into modules which are not too complex. Distributed online optimization has become an increasingly active research area recently (e.g. Venkat et al., 2008, Rawlings and Stuart, 2008, Gunnerud et al., 2009). Good interfaces to the operators that display the predicted moves and the predicted reaction of the plant and enable comparisons with their intuitive strategies are certainly essential for practical success. Other aspects are discussed in (Engell, 2007).

Integration of Planning and Scheduling and Consideration of Uncertainty in Process Operations

Zukui Li, Marianthi Ierapetritou

Department of Chemical and Biochemical Engineering, Rutgers University
98 Brett Road, Piscataway,NJ 08854, USA

Abstract

In the process industry, integration of planning and scheduling and addressing uncertainty have been identified as two of the most important factors that affect the efficient implementation of planning and scheduling operations for the production systems. In this paper, we review the existing work towards the integration of planning and scheduling and different methodologies of addressing uncertainty for planning and process scheduling decision making. The major challenges in planning and scheduling toward effective process operations are also presented throughout the paper.

Keywords: planning, process scheduling, integration, uncertainty.

1. Introduction

Production planning and scheduling are important subjects for modern industry, especially in the situation of facing major new challenges through increased global competition, greater regulatory pressures and uncertain prices of energy, raw materials and products. Although it has received wide research in planning and scheduling, there still exist very important and urgent needs in addressing the following two important issues for realistic application of production planning and scheduling systems. First, the traditionally strategy of generating planning and scheduling tasks separately often causes infeasible and suboptimal decisions, so it is of great necessity to integrate the planning and scheduling so as to generate really good operation decision for the production systems. Second, uncertainty appears in all the different levels of the industry from the detailed process description to multi-site manufacturing, it is necessary to systematically consider uncertainty so as to validate the use of mathematical models and preserve plant feasibility and viability during operations.
In this paper, we give a review of the existing work in the area of integration of planning and scheduling and in considering uncertainty in process operations. Different solution strategies for the integration of planning and scheduling is presented in section 2, followed by a detail description of uncertainty considerations for process scheduling and planning in section 3. Throughout the paper we present the major challenges towards effective implementation of planning and scheduling.

2. Integration of Planning and Scheduling

Production planning and scheduling belong to different decision making levels in process operations, they are also closely related since the result of planning problem is the production target of scheduling problem. The planning problem deals with longer term issues compared to scheduling with the emphasis being on the optimization of production capacity minimizing cost. In the process industry, the most commonly used

planning and scheduling decision making strategy follows a hierarchical approach, in which the planning problem is solved first to define the production targets and the scheduling problem is solved next to meet these targets. However, the main issue with this traditional strategy is the lack of communication between the two decision levels, i.e., the planning decisions generated might cause infeasible schedule subproblems. Thus at the planning level, the effects of changeovers and daily inventories are neglected, which tends to produce optimistic estimates that can not be realized at the scheduling level, i.e., a solution determined at the planning level does not necessarily lead to feasible schedules. Moreover, the optimality of the planning solution cannot be ensured because the planning level problem might not provide an accurate estimation of the production cost, which should be calculated based on the details of the scheduling problem.

Therefore, it is important and necessary to develop methodologies that can effectively integrate production planning and scheduling. However, since production planning and scheduling are dealing with different time scales, the major challenge towards the integration is dealing with the big computational complexity associated with the resulted optimization problem. To overcome the above difficulty, most of the work appeared in the literature aim at decreasing the problem scale through different types of problem reduction methodologies and developing efficient solution strategies as summarized by Grossmann et al. (2002) and Maravelias and Sung (2008). In this paper, we are aiming of reviewing the existing work in the area of planning and scheduling integration as classified in the following subsections.

2.1. Solving the Integration Problem through Hierarchical Decomposition

The first type of methods is based on decomposition in a hierarchical way through iterative solution procedure. In hierarchical decomposition of the integration problem, information is passed from the aggregate planning problem to a set of detailed scheduling problems which are solved independently using temporal decomposition. Thus, the problems that need to be solved include a relative simple planning problem and a series of scheduling subproblems. To ensure the feasibility and optimality of the solution, it is further necessary to develop effective algorithms to improve the solution using additional cuts in the planning level within an iterative solution framework (Papageorgiou and Pantelides, 1996; Bassett et al. 1996; Munawar and Gudi, 2005; Dogan and Grossmann, 2006).

2.2. Rolling Horizon Based Framework

The second type of methods, which is also called rolling horizon approach, consider a relative rough model for the far future planning periods in the integrated planning and scheduling model, whereas detailed scheduling models are only used for a few early periods and aggregate models are used for later periods. The production targets for the early periods are directly implemented, while the production targets for the later periods are updated along with the rolling horizon. Applications of this kind of strategy can be found in (Dimitriadis et al., 1997; Sand et al., 2000; Wu and Ierapetritou, 2007; Verderame and Floudas, 2008).

2.3. Campaign Planning Integrated with Periodic Scheduling

For the cases where there is no plant and market variability, campaign mode can be applied to generate an easy to implement and profitable process operations plan. In a periodic scheduling framework, the planning and scheduling integration problem is replaced by establishing an operation schedule and executing it repeatedly (Zhu and Majozi, 2001; Castro et al., 2003; Wu and Ierapetritou, 2004).

2.4. Integration with Surrogate Scheduling Model through Offline Analysis

Other than using the detailed scheduling model in the integrated planning, surrogate methods aim at deriving the scheduling feasibility and production cost function first and then incorporating them into the integrated problem. This avoids the disadvantage of large scale and complex model which directly incorporate the detailed scheduling model into aggregating planning model as shown in (Sung and Maravelias, 2007).

2.5. Mathematical Programming Based Decomposition of the Simultaneous Model

Except the different methods for the integrated planning and scheduling as summarized above, another approach is based on the study of the special structure of the mathematical programming model for the integration problem and aims at developing efficient decomposition techniques to solve the optimization problem directly. It is intuitive that the direct way for addressing the integrated planning and scheduling problems is to formulate a single simultaneous planning and scheduling model that spans the entire planning horizon of interest. However, when typical planning horizons are considered, the size of this detailed model becomes intractable, because of the potential exponential increase in the computation. Lagrangian relaxation is an approach that is often applied to models with a block diagonal structure as shown in Figure 1. In such models, distinct blocks of variables and constraints can be identified that are linked with a few "linking" constraints and variables. The major drawback of Lagrangian relaxation method is that there is duality gap between the solution of the Lagrangian dual problem and the solution of original problem, and the feasibility of the solution needs to be recovered through heuristic steps. Thus it is often only used as the bounding step in the branch and bound framework. However, the disadvantage of Lagrangian relaxation can be avoided by augmented Lagrangian relaxation (ALR) method, which has retrieved several applications in areas such as multidisciplinary optimization (Tosserams et al., 2008), power generation scheduling (Carpentier et al., 1996).

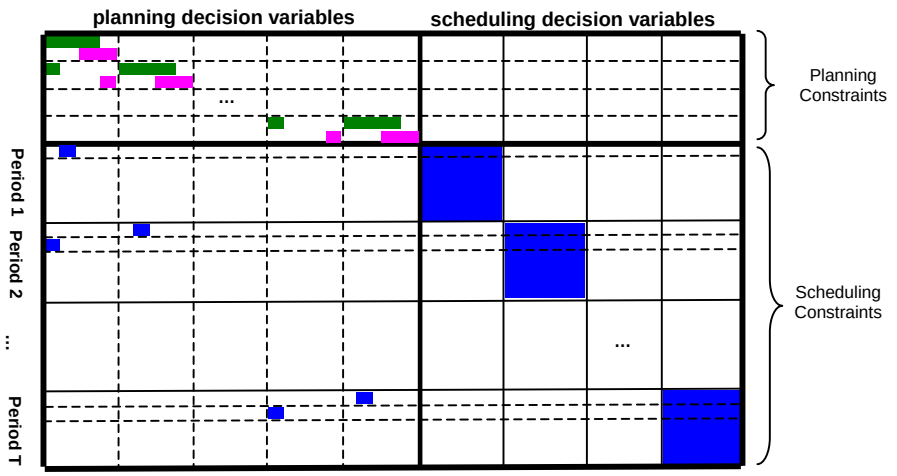

Figure 1. Structure of the constraint matrix of the simultaneous model

3. Planning and Scheduling Under Uncertainty

Traditionally, most of the work in the area of process operations deals with the deterministic optimization model where all the parameters are considered known. Along with the studies in deterministic planning and scheduling, consideration of uncertainties in these problems has got more attention in recent yeas because the inability of many

existing planning and scheduling systems to address general issue of uncertainty has been cited as a major reason for the lack of influence of planning especially scheduling research in industrial practice. It has also been recognized that having ways to systematically consider uncertainty is as important as having the deterministic model itself. Thus to achieve effective process operations, it is necessary to consider uncertainty that appears in all the different levels of the industry from the detailed process description to multi-site manufacturing.

In real plants, uncertainty is coupled with the planning and especially scheduling process since many of the parameters that are associated with these problems are not known exactly. Major uncertainties may exist in the planning and scheduling data including (Schnelle and Bassett, 2006): (i) sales and marketing (changes in product orders or order priority, changes of demand and pricing from forecasts); (ii) process (batch cycle times variability, yields, changeover times, recipe variations); (iii) production (e.g., batch or equipment failures, unavailable raw material, resource changes); (iv) new processes and products (ramp-up rates for cycle times and unit ratios). Uncertainty in those parameters are described using bounded interval form, probability distribution functions (continuous or discrete), and fuzzy description. Following the alternative description methods for uncertainty in process operations, different models and optimization approaches have been developed.

3.1. Process Scheduling Under Uncertainty

Methodologies for process scheduling under uncertainty aim at producing feasible, robust and optimal schedules. According to the different treatment of uncertainty, process scheduling methods can be classified into two groups: preventive scheduling and reactive scheduling.

3.1.1. Preventive Scheduling

Preventive scheduling generates scheduling policies before uncertainty occurs. Detail classification of preventive scheduling includes: stochastic scheduling, robust optimization method, fuzzy programming method and sensitivity analysis method. Stochastic scheduling is the most commonly used approach in the literature for preventive scheduling, in which the original deterministic scheduling model is transformed into stochastic model treating the uncertainties as stochastic parameters. Within the stochastic programming models we can distinguish the following categories: two-stage/multi-stage stochastic programming and chance constraint programming based approach (Orçun et al., 1996; Petkov and Maranas, 1997; Balasubramanian and Grossmann, 2002; Bonfill et al., 2004). Robust scheduling aims at building the preventive schedule to minimize the effects of disruptions on a performance measure. It tries to ensure that the predictive and realized schedules do not differ drastically while maintaining a high level of schedule performance (Vin and Ierapetritou, 2001; Lin et al., 2004; Janak et al., 2007; Jia and Ierapetritou, 2007). Fuzzy programming based method can be used in the case where probabilistic information is not available. Fuzzy set theory and interval arithmetic are used to describe the imprecision and uncertainties in process parameters (Balasubramanian and Grossmann, 2003; Wang, 2004; Petrovic and Duenas, 2006). An alternative way in preventive scheduling is using MILP sensitivity analysis, which is used to determine how a given model output depends upon the input parameters (Jia and Ierapetritou, 2004).

3.1.2. Reactive Scheduling

Reactive scheduling is a process of modifying the existing schedule during the process operation to adapt to changes (uncertainty) in production environment, such as disruptive events, rush order arrivals, order cancellations or machine breakdowns. For

this type of uncertainty there is not enough information prior to realization of the uncertain parameters that will allow a preventive action. There are a number of papers in the literature that focus on this kind of methodology (Huercio et al., 1995; Sanmarti et al., 1996; Honkomp et al., 1999; Vin and Ierapetritou, 2000; Ruiz et al., 2001; Méndez and Cerdá, 2003; Janak and Floudas, 2006). However, a major limitation of the existing reactive scheduling techniques is the response time, which might cause significant delay while the generation of a new schedule takes place. In Li and Ierapetritou (2008), a novel approach based on parametric programming is proposed to improve the efficiency of reactive scheduling and avoid the resolution of a complex optimization problem when uncertain event occurs during the scheduling period. Parametric programming serves as an analytic tool by mapping the uncertainties in the optimization problem to optimal solution alternatives. From this point of view, parametric programming provides the exact mathematical solution of the optimization problem under uncertainty. In the proposed method, reactive schedule is obtained from the solution of multiparametric programming problem which is solved ahead of time and covers all possible outcomes of future uncertainty as shown in Figure 2. The multiparametric programming problem is derived from a reactive scheduling formulation which integrates disruptive events (rush order and machine breakdown) as uncertain parameters in the process modeling. A restriction of the parametric method is that the computational complexity increases tremendously with the number of uncertain parameters, and thus it is appropriate for the problem with relative small number of uncertain parameters.

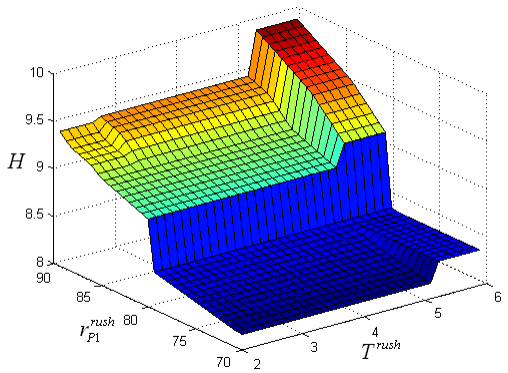

Figure 2. Parametric solution of the reactive scheduling problem, which gives the exact relationship between the new makespan and rush order information (new order amount, order arrival time)

3.2. Planning Under Uncertainty

For production and supply chain planning level problems, uncertainty is usually associated with product demand, which may lead to either unsatisfied customer demands or loss of market share or excessive inventory costs. Gupta and Maranas (2000) utilize a two-stage stochastic programming approach, where production is chosen here-and-now while distribution decisions are optimized in a wait-and-see fashion. This makes sense, since production tends to be the main contributor to lead times. Gupta et al. (2000) further investigate the trade-offs between customer demand satisfaction and production costs using a chance-constrained approach. Ryu and Pistikopoulos (2003) aim to deal with two problematic features in supply chain planning: (i) hierarchical decision structures with interdependence of the decisions of different agents and (ii) uncertainty in data. They develop a bi-level approach, which

captures the interdependence of the solutions and solve the problem using a parametric programming approach. Wenkai et al. (2003) describe a large refinery scheduling and inventory management model and introduce the concept of marginal value analysis, which identifies critical streams and operations. Neiro and Pinto (2003) extend this work to a set of refinery complexes, and also add scenarios to account for uncertainty in product prices. They demonstrate that nonlinear models reflecting process unit conditions and mixture property prediction can be used in multi-site planning models and that there is significant cost benefit in solving for the complex together rather than for the individual refineries separately. Wu and Ierapetritou (2007) address the simultaneous solution of production planning and scheduling problem through a hierarchical framework. The planning problem aggregates orders in the planning period and considers uncertainty utilizing a multi-stage stochastic programming formulation where three stages are considered with increasing level of uncertainty. The planning model includes material balances and time horizon constraints which involve a sequence factor to reflect the recipe complexity. Using a rolling horizon strategy, the production for the current stage is provided to the scheduling problem, which is solved using a continuous-time formulation. Finally, although very few work have addressed the problem of the uncertainty in integrated planning and scheduling problem (Dogan and Grossmann, 2006), it is still a great challenge since the deterministic integration of these two decision making stages is still a primarily unsolved problem for realistic cases.

4. Conclusions

In the existing planning and scheduling systems, there are few generic packages which can support the integration of planning and scheduling, and furthermore, the problem of the uncertainty is so far not well addressed in commercial systems. To achieve realistic and effective application of planning and scheduling decision making in process industry, the systematic consideration of integration and uncertainty issue is a necessary. Based on our experience, challenges towards effective implementation of planning and scheduling in the process industry include: a) the development of effective solution methods for integrated planning and scheduling problem; a) the development of new reactive scheduling methods; b) theoretical and algorithmic studies of methods for scheduling under uncertainty which can address a large number of uncertain parameters; c) the development of novel uncertainty analysis and optimization algorithms which can be applied in realistic large scale problems; d) the development of unified frameworks for integrated planning and scheduling under uncertainty. In summary, the integration of different decision making stages and the systematic consideration of uncertainty will have a tremendous impact on industrial sector increasing their production flexibility in the current dynamic and uncertain economic environment.

Abstract

Mathematical programming techniques to predict cerebrospinal fluid (CSF) flow fields and drug transport in the human brain are presented. In addition, advantageous use of distributed mathematical models to accelerate design and development of a novel volume sensor for hydrocephalus treatment is demonstrated. CSF flow in the brain can be measured analytically in three dimensions, but quantitative interpretation requires a distributed inversion problem. In the example of a volume sensor, medical imaging and rigorous mathematical analysis lead to optimal sensor design and optimal placement for highest sensitivity. Finally, prediction of drug transport in the brain leads to improved treatment options for patients suffering from neurodegenerative disorders such as Parkinson's and Alzheimer's. Infusion parameters such as flow rate and drug catheter position need to be optimized in three dimensions to achieve maximal therapeutic thresholds in the desired target area of the soft brain tissue. This example constitutes a three dimensional design problem with partial differential equation constraints. Our systematic modeling approach may improve the simulation and design of disease treatment options.

Keywords: brain physics, medical imaging, convection enhanced drug delivery.

1. Introduction

Recently in the process systems engineering community there is a trend towards analyzing biological systems or harnessing their capability for technical processes. Examples include energy systems based on algae or biomass, conversion of sunlight with biological organisms, or the integration of novel materials and processes into life sciences. In many of those processes the design challenges involve complex biological domains that are different from traditional process system engineering approaches. A specific challenge for mathematical models is the distributed nature of biological systems as observed in discrete parts of cell organelles, or the aggregation of cells in soft tissue, as well as the distributed nature of bioreactors. Design methods for distributed systems are less well developed than for lumped systems. However, we propose linking experimental data to accurate models of distributed biological systems to address the distributed nature of the process.

A multi-scale modeling approach is proposed to highlight new directions and challenges for distributed systems design with specific attention to biological systems. This method bridges the gap between analysis at the molecular level to the macroscopic level of a continuum. We propose large scale optimization methods to solve distributed

inversion problems. This leads to the discovery of unknown kinetic and molecular transport properties of biological systems.

2. Intracranial Dynamics

The first example of mathematical tools to quantify biological phenomena is the prediction of fluid transport and tissue stresses in the human brain. Intracranial dynamics describes the interactions of blood flow, CSF flow, and the deformation of porous brain tissue. While specific data about viscosity, density, and porosity about the brain and its fluids are known, there currently exists no comprehensive mathematical description of blood flow or its interaction with CSF and the flow field that results from the pulsating vasculature. While detailed aspects of normal pulsatile deformations of brain tissue can be quantified using existing medical imaging techniques, the complete picture of cause and effect is missing. Quantification of force interactions between blood, CSF, and the brain is necessary to understand normal dynamics as well as pathological conditions affecting the human brain.

With the advancement in imaging and computational analysis, understanding the complex interactions between vasculature and the soft brain tissue is feasible. Recently, our group has reconstructed the arteries and veins of a specific patient. This was achieved by manual segmentation of 1200 computer tomography (CT) images using Mimics 12.11. A precise three-dimensional surface of the main arterial system was obtained and is shown in Figure 1. A detailed description of our patient-specific image reconstruction methodology is discussed elsewhere (Linninger et al., 2007). In future work, the model of the cerebral vasculature will be used to predict blood pressures and vessel wall expansion.

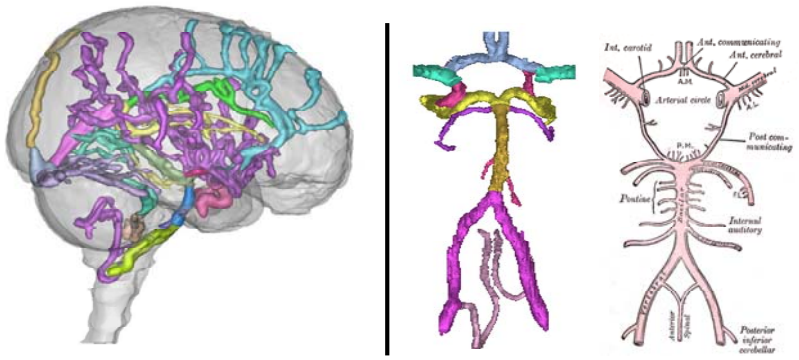

Figure 1. (Left) CT angiography images and Mimics were used to reconstruct a patient's cranial arteries/veins. (Right) Detailed view of reconstructed Circle of Willis and vertebral arteries juxtaposed with artist sketch (Gray, 1918).

Mimics was also used to develop a three-dimensional distributed model of brain tissue and CSF spaces. Reconstructed surfaces and volumes were meshed in ADINA 8.5, yielding a computational domain composed of tetrahedral balance envelopes. Boundary conditions such as constant CSF production and vasculature expansion in the brain parenchyma were included in the model. Linearized Navier-Stokes equations were solved numerically in ADINA-FSI 8.5. The three-dimensional model of CSF and brain tissue is used to predict CSF flow due to changes in cranial volume throughout each cardiac cycle. The model explains subtle changes in the flow field and quantifies other symptoms associated with pathologies of intracranial dynamics. Specific indicators we

discovered include the decrease in the prepontine stroke volume and the increase in the aqueductal flow as shown in Figure 2. We believe comprehensive models such as these will lend greater insight into normal intracranial dynamics and help us understand causes of certain brain disorders including idiopathic hydrocephalus. Future work will refine the model in the spirit of hierarchal decomposition to accurately capture the cerebral capillary network, which in the current models is grossly simplified. In a step by step process, it is believed that mathematical modeling will be able to uncover the functionality of the physical brain which to date is still elusive. More detail regarding the modeling approach and transport mechanisms are explained in Somayaji et al. (2008).

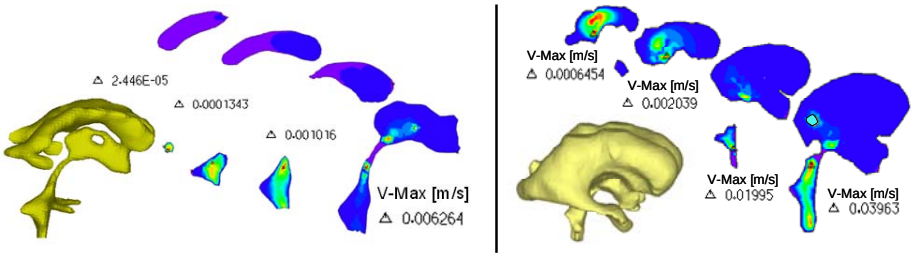

Figure 2. CSF velocity field in the cerebral ventricular system of normal subject (left) and patient with communicating hydrocephalus (right). The velocity field is displayed in sagittal cross-sections of 5 mm increments from the mid-sagittal plane. In hydrocephalus, aqueductal flow increases.

3. Computer Aided Design of a Volume Sensor

In classical biological research, there is a tendency to perform design optimization directly on animal models in an iterative trial and error process. Parameters are improved in several stages, scaling up from small animals to larger ones until a device or treatment for humans has been generated. Modeling of distributed systems accelerates the scaling procedure and design decisions typically achieved with animal experimentation. In this example, the implementation of these design decisions to fabricate a ventricular volume sensor is discussed.

Hydrocephalus, a disease associated with enlarged cerebral ventricles, may cause nausea, severe headaches, and possible death. To improve current treatment of this disease a sensor to measure ventricular volume is proposed. The proposed sensor is based on an impedance measurement system. This system renders a correlation between ventricular volume and the potential drop across sensor electrodes. The measured potential drop is due to a small electromagnetic field induced by two excitatory electrodes (Linninger, 2008c). We have shown that the potential drop is a function of the ventricular size according to the distribution of current within the cerebrospinal fluid and the adjacent volume (Linninger et al., 2008a). Due to the contrast in electrical conductance of brain tissue and CSF, the expansion of the cavity directly affects the voltage drop detected on the measurement electrodes. Sensor parameters such as electromagnetic field strength, electrode quantity, electrode spacing, catheter positioning, instrumentation frequency and gain, and biocompatibility are part of a large design problem. Instead of simultaneously optimizing all these parameters for each animal simultaneously in realistic conditions, the development process can be accelerated using image reconstruction and computational methods.

The proposed catheter is integrated into a computer model to predict ideal sensor measurements according to Maxwell's equations. The *in silico* model is used as a

virtual laboratory to test different catheter parameters such as spacing and position. The simulations help maximize device sensitivity and catheter position with respect to the enlarging ventricles. Once ideal sensor parameters are determined using computer simulations, the sensor is fabricated with microfabrication techniques. Figure 3 shows the design of an optimal sensor, a simulation to test sensor parameters, and the microfabricated sensor.

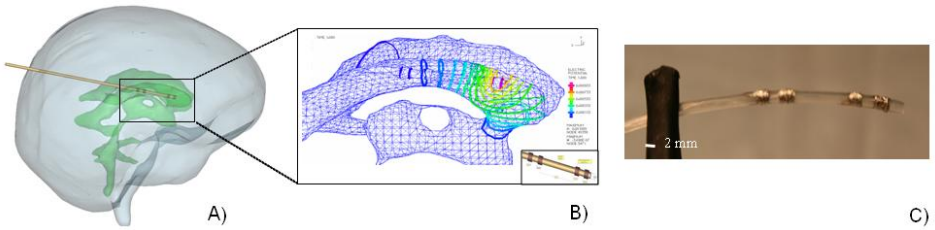

Figure 3. Computer Aided Sensor Design utilizing MRI reconstruction is shown in frame A. Simulations are done with Finite Element Analysis in frame B, and the microfabrication of the sensor is displayed in frame C.

4. Applications in Drug Delivery

4.1. Catheter Placement

The next case demonstrates the large potential of mathematical programming for rational therapy design in biomedical research. The objective is to maximize chemo-toxic agents in tumors. High concentrations of the chemotherapeutic agents in the brain can destroy the tumor and prevent reoccurrence. At the same time, the drug concentration should be low in other areas to spare critical regions in the cortex that would otherwise lead to detrimental side effects. A conceptual therapy plan given by the physician is depicted in Figure 4. The problem we wish to address with rigorous optimization is to precisely locate the optimal catheter position and design for administering the cytotoxin. Three catheter designs were available to choose from: single port, two-port, and a three-port catheter (Linninger et al., 2008b).

The distributed optimal drug delivery problem was solved with mathematical programming methods. Figure 4 compares achievable concentration profiles and distribution volumes in different brain regions with various port configurations. The best single-port catheter solution suggests an infusion site positioned near the tumor as expected. However, the single outlet configuration cannot deliver the desired therapeutic dosage to the white matter. The treatment only reached 46% of targeted volumes, I1, and I2, in sufficiently high concentration so that the risk for recurrence is unacceptable. A two-hole catheter distributes the drug over a wider range with two peak concentrations, the first near the tumor and the second inside the white matter. The program also determined the optimal distance between the outlet ports as 39 mm. Unfortunately, therapeutic thresholds were reached in 72% of the targeted tissue only. The optimal three-port catheter doses the tumor at therapeutic concentrations, I1, and simultaneously delivered effective drug concentrations into the white matter, I2. The chemotherapy delivered by a three-hole catheter dosed the tumor region as well as the adjacent white matter tracts (100% distribution volume). At the same time, toxic levels remained safe in the cortex (V1, V2). This illustration shows the viability of our optimization approach to provide pre-operative decision support to the physician to determine optimal infusion parameters such as catheter design and placement.

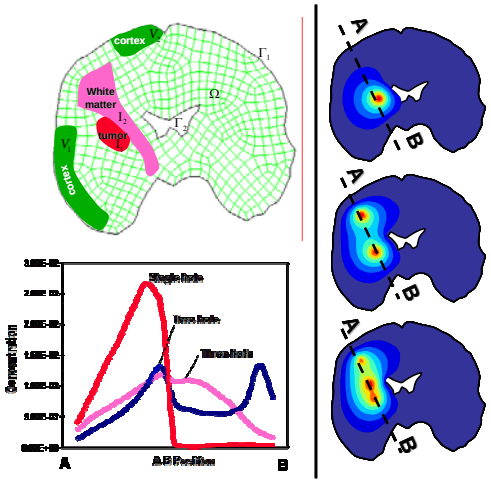

Figure 4. (Left) The conceptual treatment plan for glioblastoma targets the tumor (I1) and adjacent white matter (I2), without exceeding toxicity limits in the cortex (V1, V2). (Right) The optimal drug delivery plans with single, two- and three-port catheters.

4.2. Anisotropy of Brain

Molecular transport mechanism varies greatly in different regions of the brain. The effective diffusivity in the gray matter is essentially isotropic, whereas in white matter diffusion is anisotropic and heterogeneous (Linninger et al., 2008d). The difference in the transport properties are attributed to different properties of gray and white matter and can be quantified using diffusion tensor imaging (DTI) data of the brain tissue. DTI measures the apparent water diffusion coefficients in the brain tissue. Quantitative maps developed from DTI data can be used to characterize the degree of heterogeneity and anisotropy of the brain tissue.

Previously, data from DTI was primarily used to trace white matter tracts in the brain (Lebihan et al., 2001; Cao et al., 2003). In our work, we incorporate the three dimensional tensor quantities from the DTI data with first principles transport equations to predict drug distribution. The apparent water diffusion tensors are calculated by fitting the crude DTI data into a three-dimensional symmetric, positive-definite, second order tensor. For each voxel in the imaging plane, eigenvalues and eigenvectors of the corresponding diffusion tensor are calculated and visualized as hyper-ellipsoids with principal axes; the principle axes correspond to the lengths and orientations of the three eigenvectors as shown in Figure 5a. At each grid point in the brain mesh, six independent diffusion tensor elements are obtained by interpolation with the nearest neighbor. Simulations of drug distribution with anisotropic and heterogeneous brain models were performed using Fluent software. The drug concentration field and bulk flow field in an isotropic brain model were compared with an anisotropic brain model, visualized in Figure 5. Predicted drug distribution patterns in the anisotropic model were asymmetric and followed directional influences of the brain tissue.

5. Conclusions

This overview article highlights several applications of mathematical modeling for advancing biomedical research. We have shown three case studies in which rigorous mathematical modeling has led to insight into pathological conditions, design of

medical devices, and design of rational therapy parameters. These examples and the underlying systems methodologies provide a scientific approach for discovery about complex brain functions and is a contribution to a true interdisciplinary research effort. We hope that this overview provides a motivation for process systems engineers to venture into the field of biomedical research with methods that have been proven successful in the chemical industry and hold enormous potential to advance knowledge in biomedical research.

Hybrid System Descriptions for Chemical Engineering Processes

Luís C. Oliveira-Lopes

FEQUI/UFU – School of Chemical Engineering, Federal University of Uberlandia, Av. João Naves de Ávila, 2121, Santa Mônica, CEP 38408-902, Uberlândia – MG , Brazil

Abstract

The hybrid description for process modeling has the advantage of allowing a more flexible description for dynamic models in the presence of state jumps and logical decisions. This work presents hybrid descriptions for processes of interest in Chemical Engineering, therefore, phenomena such as change in the number of stages/phases, processes failures, tolerant control, procedures or arrangements between stages, and jump on variables may be assessed by the verification of computational hybrid models. Cases of interest of process modeling, simulation, control and analysis are discussed.

Keywords: Hybrid systems, Modeling, Simulation, Control.

There are several entities, called model, which are able to mimic relevant features of a process or a situation one is interested in studying. A mathematical model is a simplified and abstract representation of part of the reality one desires to describe with a specific purpose. There is always a trade-off between the complexity of the description and the degree of accuracy it is designed to handle. Each different model assumes different hypothesis and in general, " it is not possible to maximize simultaneously generality, realism and precision."(Levis, 1968). A prediction that depends on very specific assumptions for validity of a model is called *fragile*, a prediction of a model is *robust* if it can be derived from a different model or from a general broader description. Besides that, in addition to make prediction, a model may be required to explain a certain phenomenon or even to incorporate knowledge in a no classical way. Many times it is necessary to combine approaches for a process representation in order to do that. For instance, the combination of a neural network model within a fuzzy framework (the neuro-fuzzy model) is often seen in the literature (Jin, 2000).

A model that presents a combination of approaches is often called as hybrid model. Nevertheless, the term hybrid system was originally proposed by Witsenhausen (1966) to describe a combination of continuous dynamical systems and discrete event systems. Hybrid Systems description comes from coupling between digital controllers, computers and subsystems built as finite-state machines, and plants modeled by differential or difference equations (Lazar, 2006). Therefore, it consists of a unified framework for describing processes evolving according to continuous, discrete dynamics, and logic rules. Hybrid systems are capable of selecting the activation of a specific mode when a discrete event occurs, handling discontinuities.

The term *hybrid* refers basically to a combination of two or more methods or objects. The expression *hybrid system* was proposed by Witsenhausen (1966) aiming to describe a combination between continuous dynamical systems and discrete event systems. Hybrid Systems come from coupling between digital controllers, computers

and subsystems built as finite-state machines, and plants modeled by partial or ordinary differential equations, or difference equations (Lazar, 2006). They can express continuous and discrete-time dynamics, jump discontinuity and transitions driven by logical commands. Hybrid systems can be composed by several operating modes, allowing them to show complex dynamical behaviors simultaneously. An ordinary general form of a hybrid model, describing a parameter concentrated model, can be represented by:

$$\frac{dx}{dt} = \psi_1\big(x(t), q^+(k), u(k)\big),$$
$$\psi_2\big(x(t), q^+(k), u(k)\big) \leq 0, \tag{1}$$

where, $x(t)$ is a continuous real-valued set, $q^+(k)$, and $u(k)$ are discrete real-valued variables.

Hybrid systems are a natural approach to formulate computer-controlled systems since they involve a physical process and a computer (controller). The classical approach to deal with computer-controlled systems has been through the use of sampled-data theory. However, this scheme can be encoded using a hybrid model. The hybrid model also captures a more general formulation, which is sometimes closer to real-time implementations in embedded control systems.

Hybrid systems are capable to retain an appreciable variety of dynamic behaviors. However, a hybrid system general formulation introduces high complexity for analysis purposes, application of techniques to design of controllers, simulation and validation. This fact led the research in hybrid systems to follow a particular path: instead of a general formalism, specific classes of systems are adopted to represent the process of interest.

To represent hybrid systems, one needs a description that is able to capture different types of continuous and discrete dynamics, is capable of modeling different ways in which discrete evolution affects and is affected by continuous evolution. In addition, it has to be composable and abstractable (Lygeros, 2004). Different description place more emphasis on different aspects, depending on the applications and problems they are designed to address. In this work, several classes of hybrid systems description are discussed and evaluated in chemical processes:

(a) *Piecewise affine systems*, PWA (Sontag, 1981, Johansson and Rantzer, 1998, Ferrari-Trecate et al., 2002) are described by:

$$\begin{cases} x(k+1) = A_i x(k) + B_i u(k) + f_i \\ y(k) = C_i x(k) + D_i u(k) + g_i \end{cases} \quad \text{for} \quad \begin{bmatrix} x(k) \in \mathbb{R}^m \\ u(k) \in \mathbb{R}^n \end{bmatrix} \in \Omega_i \tag{2}$$

where Ω_i are convex polyhedral in the input-state space, the variables: $y(k) \in \mathbb{R}^p$ denotes the output, $x(k)$ is the state, and $u(k)$ is the input set, at time k. PWA is a commonly used extension of linear systems to represent nonlinear and non-smooth processes.

(b) *Mixed-logical dynamical systems*, MLD. (Bemporad, 2004). This class of model was introduced by Bemporad and Morari (1999).

Mixed-logical dynamical systems are described by:

$$x\ k+1 = A_k x\ k + B_{1k} u\ k + B_{2k}\delta\ k + B_{3k} z\ k \quad (2.a)$$

$$y\ k = C_k x\ k + D_{1k} u\ k + D_{2k}\delta\ k + D_{3k} z\ k \quad (2.b)$$

$$E_{2k}\delta\ k + E_{3k} z\ k \geq E_{1k} u\ k + E_{4k} x\ k + E_{5k} \quad (2.c)$$

where $k \in \mathbb{Z}$; A_k, $B_{1k,2k,3k}$, C_k, $D_{1k,2k,3k}$, $E_{1k,2k,3k,4k,5k}$ are matrixes with appropriate dimensions. The domains are defined by:

$$\begin{aligned} x &= [\,x_c\ x_l\,]^T, x_c \in \mathbb{R}^{n_c}, x_l \in \{0,1\}^{n_l}, n = n_c + n_l \\ y &= [\,y_c\ y_l\,]^T, y_c \in \mathbb{R}^{p_c}, y_l \in \{0,1\}^{p_l}, p = p_c + p_l \\ u &= [\,u_c\ u_l\,]^T, u_c \in \mathbb{R}^{m_c}, u_l \in \{0,1\}^{m_l}, m = m_c + m_l \end{aligned} \quad (3)$$

Vector **x** denotes the states, which are composed with continuous states ("c" index), and logical binary states, 0-1 ("l" index). The vector **y** represents the model output data. The input vector **u** encloses continuous commands ("c" index) and binary commands, 0-1 ("l" index). The MLD system is said to be well posed if **δ**(k) and **z**(k) are uniquely defined in its domain, once **x**(k) and **u**(k) are specified. An interesting advantage is, in certain conditions, MLD systems can be equivalent to other model classes. This fact means that systems modeled by other classes can be converted into MLD systems that possess well definite techniques that favor its use for optimal and predictive control purposes.

In addition, in the MLD framework, logical propositions can be rewritten in the format of linear inequalities by means of the transformation of Boolean variables in binary integer variables. Previous operational knowledge of a process can also be added systematically under the form of inequalities, which form the set of constraints of an optimization problem that is base for optimal control problem synthesis (Krilavicius, 2006).

(c) *Linear complementarity systems*, LC (van der Schaft and Schumacher, 1998; Heemels et al., 2000).

In discrete time, this description uses a set of nonnegative orthogonal vectors (complementarity variables), $v(k), w(k) \in \mathbb{R}^q;\ 0 \leq v(k) \perp w(k) \geq 0$ and is given by:

$$\begin{aligned} x(k+1) &= Ax(k) + B_1 u(k) + B_2 w(k), \\ y(k) &= Cx(k) + D_1 u(k) + D_2 w(k), \\ v(k) &= E_1 x(k) + E_2 u(k) + E_3 w(k) + \xi \end{aligned} \quad (4)$$

(d) Extended *linear complementarity systems*, ELC (de Moor, 1999).

In this description one has an auxiliary variable $\varpi(k) \in \mathbb{R}^r$, and,

$$\begin{aligned} &x(k+1) = Ax(k) + B_1 u(k) + B_2 \varpi(k), \\ &y(k) = Cx(k) + D_1 u(k) + D_2 \varpi(k), \\ &E_1 x(k) + E_2 u(k) + E_3 \varpi(k) \leq \xi \\ &\prod_{j \in \phi_i} [\xi - E_1 x(k) - E_2 u(k) - E_3 \varpi(k)]_j = 0 \ \text{ for } \forall i \in \{1,2,\dots,p\} \end{aligned} \quad (5)$$

(e) *Max-min-plus-scaling* systems (MMPS) (De Schutter and van den Boom, 2001).

In this class of model, discrete event systems can be modeled by

$$x(k+1) = \mathcal{M}_x\big(x(k), u(k), \varpi(k)\big),$$
$$y(k) = \mathcal{M}_y\big(x(k), u(k), \varpi(k)\big), \quad (6)$$
$$\mathcal{M}_c\big(x(k), u(k), \varpi(k)\big) \leq c$$

where $\mathcal{M}_x, \mathcal{M}_y$ and $\mathcal{M}_c$ are MMPS expressions (i.e., expressions defined by the composition of max and min functions, sum, and multiplication by a scalar) in terms of the state *x*(k), the input *u*(k), and the auxiliary variables $\varpi(k)$, which are all real-valued.

Figure 1 shows the relationship between the model classes introduced up to this point in the work.

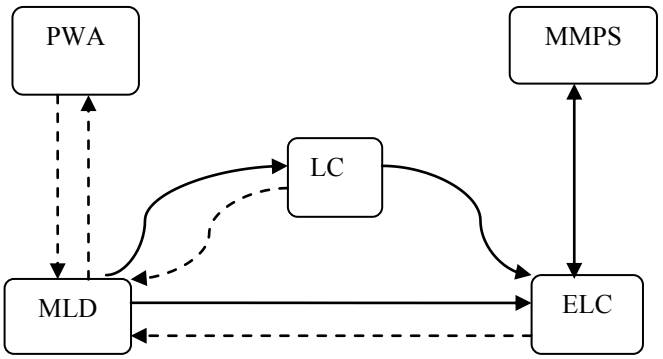

Figure 1 – Representation of links between a few classes of hybrid system descriptions. The arrow indicates that the class or origin is a subset of the model target class. Dashed line only indicates that special conditions need to be imposed to have that condition satisfied.

(f) *Switched Systems* (Liberzon, 2003)

The idea of switching system consists of a number of modes represented by differential equations and a set of switching rules. These systems arise in processes with variable structure and may represent networked control systems, in which information shared by continuous subsystems is updated in a discrete fashion, and embedded systems, in which computer software interacts with physical devices. A switched system is a particular kind of hybrid system that consists of several subsystems and a switching logic among them. The feature that distinguishes a switched system from a general hybrid system is that its continuous state does not exhibit jumps at the switching instants. Figure 2 shows the usual trajectory for a switched system with three switching instants.

Most approaches for representing hybrid systems use combinatorial or finite techniques such as graphs or automata extended by the capability to handle continuous elements. The continuous elements are *embedded* into a discrete dynamic structure. Examples of these descriptions are: hybrid automata, hybrid Petri Nets, and differential-algebraic models.

(d) *Hybrid automata* (Branicky et al., 1998).

Hybrid automata can model a large class of hybrid systems as they consider a discrete event system where the continuous dynamics in each discrete state are modeled by an arbitrary differential (difference) equation. A hybrid automaton is a dynamical system representation that is a collection of a set of discrete states, a set of continuous states, a vector field, a set of initial states, a domain, a set of edges, a guard condition, and a reset map. A usual way of representing this model is a directed graph.

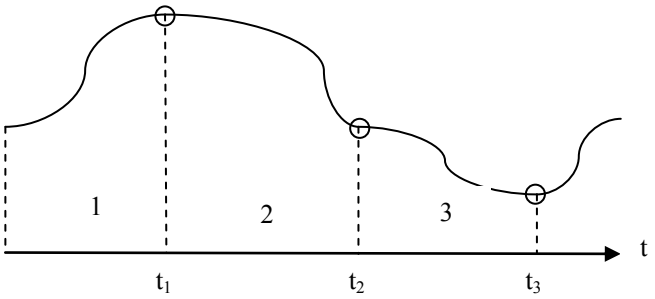

Figure 2 – Trajectory of a switched system. The indicated time instants are the discrete instant there is a change in the switching signal.

(e) Hybrid Petri Nets (Ghomria and Allab, 2007)

Petri nets were originally developed for modeling sequences of finite automata and they have been found to be useful for simulation and analysis of resource allocation problems of discrete event dynamic systems with both sequential and parallel elements. There is a number of extensions to the original concept of Petri nets in the literature including timed, hierarchical, multi-valued logical as well as stochastic elements. Figure 3 shows a simple Petri net description of a control valve.

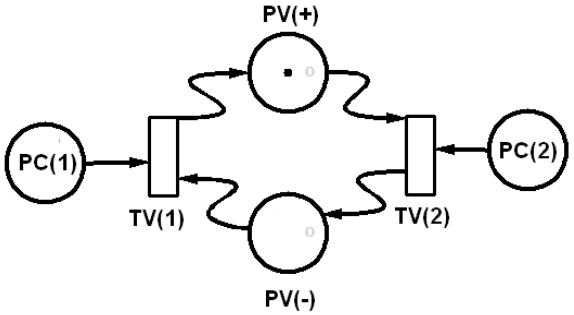

Figure 3 – Petri nets for input/output relationship in a process valve.

All these classes of hybrid systems introduced herein will be presented and discussed with examples of Chemical Engineering in the keynote session. Modeling and simulation of industrial plants with a hybrid description are investigated, tolerant control and fault propagation analysis will be presented and evaluated in this context, process control of hybrid process including logical decisions will be also evaluated by hybrid model based control strategies.

Integrating Refining to Petrochemical

Marcus Vinicius de Oliveira Magalhães

PETROBRAS, Av. República do Chile, 65, room 904, Rio de Janeiro, 20720-350, RJ, Brazil

Abstract

By definition petrochemical plants are integrated to refineries, since the most important feedstock for a petrochemical complex (i.e. naphtha) is produced at an oil refinery. Even when the petrochemical plant is natural gas based, a refinery must be in place to separate ethane and propane (and eventually butane), which are the actual raw materials for the steam cracking furnaces of the natural-gas-fed petrochemical plant. Although integration is an implied requirement between the two businesses, because one is downstream of the other, further integration is desirable for both of them. This work describes the potential benefits and challenges faced by this further level of integration.

Keywords: refinery, petrochemical, integration, benefits, challenges

1. Overview

The integration of refinery operations and production of petrochemicals can lead to a framework that adds value for both businesses. Substantial savings can be achieved, either for existing plants or new ones, by properly designing and/or operating a refinery and a petrochemical plant. These savings are derived from sharing common infrastructure (tank farm, utilities, terminals, pipelines …), leading to reduction in capital investments, or reduced inventories and energy/utility requirements if both sites are close enough to benefit from an integrated operation.

Low value components/products from one side, which are burned or sold at low prices, can be valuable raw material or blend stock component at the other side. This shipment of products entitles the increase of the aggregate margin due to the sourcing and security of feedstock supply and optimization of refined and petrochemical products slate, capturing synergies throughout the value chain.

Petrochemical industry often operates under cycles of profitability, with these cycles repeating every seven to ten years. Petrochemicals margins follow closely these cycles according to the operating rates. When the supply capacity is about to be met by the demand, operating rates are high and so are margins. Conversely, when operating rates are low, most likely due to the buildup of additional capacity, margins drop. Refinery profitability follows a different time and severity pattern, pretty much dependent on crude oil price. Hence, another beneficial aspect of refinery petrochemical integration is the potential enhanced profitability stability, which may be achieved with an integrated complex.

2. Benefits

The benefits of integrating refinery operations and petrochemicals production will be analyzed under the following standpoints: capital investments, operating costs, additional savings and environmental benefits.

2.1. Capital Investments

When setting up a new business unit, except for the case where processing steps can be eliminated with the integrated approach, it is not expected any major savings for the ISBL (Inside Battery Limits) class of costs. So, integration would not lead to any substantial savings at ISBL, when compared to the standalone situation.

On the other hand, integration can offer significant capital investment savings for the OSBL (Outside Battery Limit) class of costs. Typically, fewer tanks will be required, as opposed to the standalone situation, as the two plants may operate in a coordinated manner, implying that feedstock or byproduct will be pumped directly from one facility to the other. A direct consequence of a configuration with fewer tanks is the reduced inventory levels, thus enabling reduced working capital.

Refineries are typically large producers of utilities (e.g. cooling water, steam, electricity, fuel gas, flare, water and waste treatments etc). If some spare capacity is found for any of these utilities at the refinery side, substantial savings can be achieved by avoiding the construction of such a utility generator, when building a new petrochemical business unit integrated to a refinery.

Finally, additional savings can be made if the new business unit can operate sharing with the existing one several buildings, such as, administrative buildings, laboratory, control room, warehouses, workshops, and so on.

2.2. Operating Costs

Since raw material inventory to a downstream unit (or recycle to an upstream unit) can be drastically reduced or even eliminated, inventory costs can be substantially lowered if these products can be pumped directly between the integrated plants.

If the plants are in close proximity, some heat integration may also lead to potential energy savings, reducing utilities requirements and costs in both sides, and potentially, reducing CO_2 emissions (contributing to reduce impact on global warming). However, a high level of integration would require careful coordination from the control to the planning levels.

The two sites must plan their production on a collaborative manner in order to avoid shortage or surplus of feedstock and products on a short term basis, and also capture benefits from normal operations and spot opportunities. That implies the two business units must share sensitive information related to their operations to run their businesses smoothly and profitably under unplanned market disturbances, of either the supply of crude oil or products' (refinery fuels or petrochemical) demands.

Integration can also lead to significant reduction in maintenance costs. However, maintenance needs to be planned with care to minimize its possible greater impact on the profitability of integrated plants compared with standalone facilities. If the

shutdowns for maintenance of the two plants are not properly scheduled, upstream (downstream) unit's throughput may face reduction, or even worse, the unit may have to shut down, because the downstream (upstream) unit is not operating and the available storage space (inventory) may not be able to cope with the planned feed flowrate for the maintenance period.

Moreover, if both plants rely on the same labor resources to carry out the turnaround, it is likely that the maintenance costs will be higher, if the local market does not have the capacity to perform larger scope of maintenance tasks in parallel.

Finally, if staff can be shared, significant savings can be realized in administrative, operational (mainly OSBL) and technical services.

2.3. Additional Savings

Though sometimes not easy to quantify, integrated facilities, as opposed to stand-alone ones, may benefit from sharing common:

- Best practices related to engineering, operations, safety, environmental, reliability, automation, training and management;
- Fire fighting and medical crews, and;
- Purchase of goods and services.

2.4. Environmental Benefits

In addition, according to a study from AMEC assessing the benefits of industrial integration for facilities in Alberta, Canada, the environmental impact of integrated plants is significantly smaller than that of stand-alone counterparts, as listed below:

- 1.5 to 5.1 times lower air emissions (SO_2, NO_x, CO, CO_2 and PM);
- 1.4 to 2.2 times lower the ecological footprint;
- 1.1 to 1.6 times lower water consumption.

3. Enabling Raw Materials and Technologies

Some low value chemicals/streams available at one side may be of high value and interest at the other side. Two classical examples are cat-cracker off-gas and propylene produced at a refinery FCC (Fluid Catalytic Cracking). The off-gas is typically sent to the refinery fuel gas ring and burned at boilers and/or heating/reaction furnaces. The ethylene and ethane contents of this gas are around 15% to 20% vol. each. Ethylene is a petrochemical product itself and ethane a good quality feedstock for a steam cracking furnace, as it enables high ethylene yield. To extract both ethylene and ethane from the refinery off-gas there must be in place a gas plant (with cryogenic circuit) similar to the ones found downstream of pyrolysis furnaces.

Propylene, also produced at a refinery FCC, normally leaves the refinery in the LPG stream However propylene can be used in the manufacture of many petrochemical products (e.g. polypropylene, propylene oxide, cumene, acrylic acid, and so on). To extract the propylene out of the LPG one needs to rely on a sequence of distillation columns (splitters).

On the way back, from the petrochemical to the refinery, one can easily find other two classical examples of products, Hydrogen and Pygas (Pyrolysis gasoline) which are

valuable at the refinery side and not that much at a petrochemical plant. Pygas, if it is low benzene and olefins contents, is normally a very good component for gasoline blending that improves octane number.

In today's world refiners are facing tight environmental regulations imposing very low sulphur content in its fuels products. In order to cope with this never ending trend to make cleaner fuels, refineries must rely on hydrotreating processes, which require hydrogen as raw material, to reduce sulphur content down to the allowed limits. Although refineries normally have hydrogen generation capabilities in place, the trend is a growing demand for this ingredient. So, even if the hydrogen available at the petrochemical plant needs some further processing to meet purity requirements for use at refinery, it is clear that integration can offer a good opportunity to utilize the hydrogen, often burned at the petrochemical site.

In Brazil, the hydrogen consumption in five years time is estimated to exceed the current one by more than four times to meet the strict environmental specifications of the next generation of automotive fuels, mainly diesel and gasoline. Hence, the increased demand for hydrogen is likely to become a very attractive integration opportunity providing refineries with a supply framework of consuming excess hydrogen, if at low cost, from petrochemical plants combined with in-house production from hydrogen generation units.

Many other chemicals can play a more valuable role at the other side of fence, thus improving profitability of the integrated business. In general, olefins and aromatics, normally produced at a refinery FCC or Reforming unit, respectively, are of interest in a petrochemical plant. Petrochemical FCC, a specialized FCC suited to the production of petrochemicals, operating at higher severity and with a catalyst with higher ZSM-5 content than a conventional FCC, is becoming very popular technology these days as it is geared towards producing more petrochemicals at the expense of gasoline. Any technologies devised to increase the yield of light olefins and aromatics, and extract them, are more than welcome for both petrochemical and refinery businesses.

4. Challenges

As clearly indicated in the previous section, the integration of refinery and petrochemical facilities introduces a fertile terrain for the search of solutions which are good for both businesses. The purpose of this section is to highlight a few challenges of such integration.

The first challenge is related to devising a proper sequence of available technologies to produce petrochemicals from a C4 stream. The next two challenges are related to the development of cost-effective process technologies to recover valuable petrochemical building blocks (CO and ammonia) from refinery waste streams. The last challenge, that involves no actual molecules, has to do with the development of a mathematical tool to support the complex optimization of an integrated refinery petrochemical portfolio.

4.1. C4 Challenge

The C4 stream produced at an FCC encompasses a rich potential for petrochemical application. The table below shows typical composition and possible use of each component as a raw material.

Component	Application	Typical Composition (%)
Butadiene 1-3	PBR, ABS, SBR	1
Butene 1	Hexene 1	13
Butene 2	Propylene	26
Isobutene	ETBE, Isooctane	15
Isobutane	Alkylate	33
N-Butane	Maleic Anhydride	12

Although butadiene is a valuable petrochemical building block, as it plays the role of monomer or co-monomer of important polymers, its content in a typical FCC C4 stream is very low. The remaining components are found in significant composition and if they can be efficiently extracted from the bulk of the C4 they can be used as valuable raw material for a suitable process.

Given the very narrow range of the boiling points (from +3 ºC to -11 ºC) of the C4 components, separating them using a straightforward sequence of distillation columns is just not feasible in practical terms, since it is not economically viable. The challenge posed here is to design a suitable sequence of processes to recover, extract or transform each of the C4 components in a profitable manner, considering that for some processes, only one of the components is important, whereas the others are inert.

4.2. CO Challenge

Carbon monoxide is also a very important petrochemical building block. It can be used to produce many important chemicals, such as methanol, acetic or formic acid and n-butanol. CO can be obtained in a cost-effective manner, from an SMR (Steam Methane Reforming) unit, if a cheap source of natural gas is available. The search for cheap CO sources will ever be a key business driver for competitive production of chemical products derived from CO.

The exhaust gas from an FCC regenerator contains CO in low concentration, although the overall flowrate is large. This gas is normally destined to a CO boiler, where the CO is further oxidized to CO_2, producing additional steam, before finally vented to atmosphere. It sounds economically very promising to use this stream as a source of CO. However, the stream is typically found at very high temperature around (700 ºC) and very low pressure (slightly above atmospheric), and. it contains particulates and is also rich in N_2 and CO_2. Hence, recovering CO from this cheap source in a cheap manner is another challenge to refinery and petrochemical integration.

This particular challenge, once overcome, may be environmental beneficial, because CO_2 emissions will be reduced at this part of the plant.

4.3. Ammonia Challenge

Likewise, the development of cost effective process to recover ammonia from sour waters, largely produced in all refineries, will enable a cheap source of this important raw material for the petrochemical and fertilizer industry.

4.4. Modeling Challenge

The integration imposes many difficulties to deal with different cultures, requiring high degree of coordination and communication. Also, start-ups, shut-downs and normal operations are all more difficult compared with stand-alone facilities, and require more complex planning, scheduling, optimization and process control tools defined over much larger envelopes.

Due to the extensive range of petrochemical products and the very nature of the oil products and refinery processes, to devise an integrated business in an optimum manner will require a powerful modeling tool to support the selection process of the strategic opportunities in the long term horizon.

5. Conclusions

Refining and petrochemicals are faced with increasingly stringent environmental and regulatory constraints and fierce competition that have impacts on the profitability and sustainability of both industries. Integration across the supply chain will be a key factor to remain competitive and profitable, and to overcome the threats posed by the ever challenging market environment. In the new integrated context, the two industries will need to encourage the exchange of products, raw materials and utilities in an optimal way to make the best of all opportunities from both industries.

Using systems engineering to reconstruct, analyze and redesign metabolism

Patrick F. Suthers[a], Vinay Satish Kumar[b], Alireza Zomorrodi[a], Sridhar Ranganathan[c] and Costas D. Maranas[a]

[a]Department of Chemical Engineering, [b]Department of Industrial Engineering, [c]Huck Institute of Life Sciences, The Pennsylvania State University, Department of Chemical Engineering, University Park, PA 16802-440, USA

Systems engineering computational techniques and in particular mathematical programming are increasingly being used to not only optimize metabolism for targeted overproductions but also for streamlining the process of metabolic model creation and curation. Key challenges in strain optimization include the selection of genes to eliminate (i.e., knock-out), add (i.e., knock-in) or modulate their expression levels in pursue of an overproduction target (e.g., a biofuel compound). Similarly, in metabolic model reconstruction and curation we seek to make model modifications so as agreement with experimental data is maximized. In both cases, this leads to the formulation of large mixed-integer, and in some case bilevel, formulations not very different from the ones encountered in process systems engineering.

Currently, there exists about twenty different microbial and eukaryotic metabolic reconstructions (e.g., *Escherichia coli, Saccharomyces cerevisiae*, *Bacillus subtilis*) with many more under development. All of these reconstructions are inherently incomplete with some functionalities missing or erroneously added due to the lack of experimental and/or homology information. Our group has introduced optimization-based procedures (i.e., GapFind and GapFill) to identify and eliminate network gaps in these reconstructions (Satish Kumar et al., 2007). These gaps are manifested as metabolites that are lacking either production and/or consumption pathways. Under steady-state conditions these metabolites form isolated parts of the model that cannot carry any metabolic flow. We repair these inconsistencies by allowing more reactions to operate reversibly and/or by expanding the list of cytosolic/transport reactions in the model. We demonstrated this procedure for the genome-scale reconstructions of *Escherichia coli* (Reed et al., 2003) *a*nd *Saccharomyces cerevisiae* (Duarte et al., 2004).

In addition to connectivity, genome-scale metabolic reconstructions are generally validated by comparing *in silico* growth predictions for different single gene deletion mutants under different carbon substrates with *in vivo* growth data. These comparisons results in two types of model-prediction inconsistencies; either the model predicts growth when no growth is observed in the experiment (GNG inconsistencies) or the model predicts no growth when the experiment reveals growth (NGG inconsistencies). We recently introduced the optimization-based framework, GrowMatch (Kumar and Maranas, 2009), to automatically reconcile GNG predictions (by suppressing functionalities in the model) and NGG predictions (by adding functionalities to the model). We used GrowMatch to resolve inconsistencies between the predictions of the latest *in silico Escherichia coli* (*i*AF1260) model (Feist et al., 2007) and the *in vivo* data available in the Keio collection (Baba et al., 2006). This led to an improvement in the

consistency of *in silico* vs. *in vivo* predictions from 90.6% to 96.7%. Specifically, we were able to suggest consistency-restoring hypotheses for 56/72 GNG mutants and 13/38 NGG mutants. For many cases, GrowMatch identified fairly non-intuitive model modification hypotheses that would have been difficult to pinpoint through inspection alone.

Armed with GapFill and GrowMatch, we explored their application during the generation phase of a new genome-scale model, as opposed to *a posteriori* improving existing ones. We applied these frameworks during the reconstruction of the genome-scale metabolic model of *Mycoplasma genitalium*. *i*PS189 (Suthers et al., 2009). *M. genitalium* has received extensive attention in the literature as it is widely used as a model organism in many minimal genome studies. Key challenges for *M. genitalium* included estimation of biomass composition, handling of enzymes with broad specificities and the lack of a defined medium. Our computational tools were employed to identify and resolve connectivity gaps in the model (*i.e.*, GapFind and GapFill) as well as growth prediction inconsistencies with gene essentiality experimental data (*i.e.*, GrowMatch). The resulting curated model, *M. genitalium* *i*PS189 (262 reactions, 274 metabolites) was 87% accurate in recapitulating *in vivo* gene essentiality results for *M. genitalium*. Specifically, we found that the model correctly identified 149 out of a total of 171 essential genes (i.e., specificity of 87%) and 16 out of a total of 18 non-essential genes (i.e., sensitivity of 89%). This level of agreement not only meets, but exceeds thresholds for metabolic model quality put forth in the literature. Additional *in vivo* gene essentiality studies using a fully defined medium could usher a more accurate elucidation of the true metabolic capabilities of *M. genitalium*, as well as suggest improvements to the model.

Motivated by the paucity of single-gene deletion data for metabolic model curation we explored the generation of model predictions for multiple-gene deletion mutants. Note that essential genes are defined as genes whose deletion is lethal. By analogy, synthetic lethals refer to pairs of non-essential genes whose simultaneous deletion is lethal (i.e., no biomass formation). One can extend the concept of lethality by considering gene groups of increasing size where only the simultaneous elimination of all genes is lethal while individual gene deletions are not. We developed an optimization-based framework for the targeted enumeration of multi-gene (and by extension multi-reaction) lethals for genome-scale metabolic models (Zomorrodi et al., 2009). Specifically, these frameworks are applied to the latest *i*AF1260 model of *E. coli* (Feist et al., 2007) leading to the exhaustive identification of all double and triple lethals as well as targeted identification of higher-order ones. Graph representations of these synthetic lethals revealed a variety of motifs ranging from hub-like to highly connected sub-graphs. These results provided a birds-eye view of the redundant mechanisms available for redirecting metabolism and revealed complex patterns of gene utilization and interdependence. The procedure also opened the door for the use of falsely predicted synthetic lethals as guidelines for metabolic model testing and curation. By analyzing the functional classifications of the genes involved in synthetic lethals (such as carbohydrate or nucleotide metabolism) we uncovered trends in connectivity within and between classifications.

Recently, we exploited the same mathematical concepts used to exhaustively explore multi-gene lethality, to classify all fluxes in the metabolic model depending upon whether or not they must increase, decrease, or become equal to zero to meet a pre-

specified overproduction target (Ranganathan et al., 2009). This classification is not limited to individual reactions but is extended for pairs, triplets, etc. while making use of all flux data available for the strain before engineering though metabolic flux analysis (MFA). The final output of this analysis is a map that spans all possible sets of engineering interventions capable of meeting a pre-specified overproduction target. The developed methodology was tested by exhaustively identifying all engineering interventions for a variety of bioproducts ranging from hub metabolites (e.g., succinate) to biofuels (e.g., isobutanol) and many others. The method recapitulated known engineering targets but also revealed new non-intuitive ones that boost productivity by performing coordinated changes on distal pathways

Integration of Production Planning and Scheduling

Christos T. Maravelias

Univeristy of Wisconsin, Madison, WI 53706, USA

Abstract

We start our presentation with an overview of supply chain management, the associated planning problems, and a motivation for the integration of medium-term production planning and short-term scheduling decisions (Maravelias and Sung, 2008). We briefly review existing modeling and solution methods and then present four new approaches to this integrated problem.

First, we discuss how lot-sizing problems can be extended to address features often found in process networks (Sung and Maravelias, 2008). Specifically, we discuss the problem where a) multiple items can be produced in each planning period, b) sequence-independent setups can *carry over* from previous periods, c) setups can *cross over* planning period boundaries, and d) setups can be longer than one period. We develop a mixed-integer programming (MIP) formulation for this generalized problem and derive a number of optimality properties that can be used to tighten the formulation. We also discuss a network representation and the resulting MIP formulation. We present examples that illustrate how the proposed model can be used to address medium –size single- and multi-unit problems.

Second, we develop polyhedral results for a discrete-time state-task network (STN) formulation for the production planning of multi-stage continuous processes (Maravelias and Papalamprou, 2009). Specifically, we express the feasible region of the LP-relaxation as the intersection of two sets. We show that the constraints describing the first set yield the convex hull of its integer points. For the second set, we show that for integral data the constraint matrix is κ-regular, and that the corresponding polyhedron is integral if the length of the planning period is selected appropriately. We use this result to prove that for rational data, integer variables assume integral values at the vertices of the polyhedron. We also discuss special cases of this problem, for which we derive stronger results. We illustrate how these results can be used to effectively address large-scale production planning problems.

Third, we present a projection-based method where a detailed MIP scheduling model is used off-line to obtain a convex approximation of feasible production levels and a convex underestimation of total production cost as a function of production levels (Sung and Maravelias, 2007). These approximations involve only planning variables yet provide all the relevant scheduling information necessary to solve the integrated problem with high quality. We then develop two MIP formulations for the representation of nonconvex regions: the first expresses non-convex regions as unions of polytopes, while the second as difference of polytopes. We use these formulations to generate a non-convex projection of the scheduling feasible region onto the space of production level variables (Sung and Maravelias, 2009). We discuss how this method can be used in a rolling-horizon manner to address hard planning-scheduling problems, as well as a process design tool.

Finally, we discuss methods for the decomposition of planning-scheduling problems in multi-stage batch processes (Ferris et al., 2009). We generate subproblems based on fixing: a) batching decisions, b) batch-unit assignment variables in a bottlenecking

stage, c) the last batch in the sequence on each unit of the bottlenecking stage, and d) strong branching. We discuss how the above methods can be combined and carried out in a dynamic fashion exploiting the natural hierarchy of decisions (batching → unit-task assignment → sequencing). We also discuss the implementation of this dynamic decomposition algorithm within GAMS using the master-worker paradigm: the master processor generates and spawns all the tasks to worker processors, collects the results, and communicates information among workers; worker processors are part of a computational grid. We present computational results on a collection of six instances of varying difficulty.

Keywords: Production planning; scheduling; mixed-integer programming.

Robust Integration of RTO and MPC

Darci Odloak

University of São Paulo - Department of Chemical Engineering, Av. Prof. Luciano Gualberto, n. 380, trav. 3, CEP 05508-900, São Paulo - SP, Brazil. Brazil.
E-mail: odloak@usp.br

Abstract

Here, it is studied the stable integration of real time optimization (RTO) and model predictive control (MPC) for the case where the controller has a two layer structure. Stability is also obtained when model uncertainty is considered in both the target calculation and dynamic layers.

Keywords: Real Time Optimization, Model Predictive Control, Robust Stability.

1. Introduction

The usual approach of integrating real time optimization (RTO) and model predictive control (MPC) is through a three layer structure (Ying & Joseph, 1999) where in the upper layer we have the real time optimization, which is based on a rigorous nonlinear steady state model of the process. The RTO layer solves an optimization problem that defines the optimal operating conditions subject to equipment constraints and product specifications. As represented in Figure 1, the optimal inputs and outputs of the system are then passed to an intermediary layer where, based on the estimation of the disturbances $d(k)$, feasible targets for the inputs and outputs are re-computed through the solution of a QP based on the linear static model of the system.

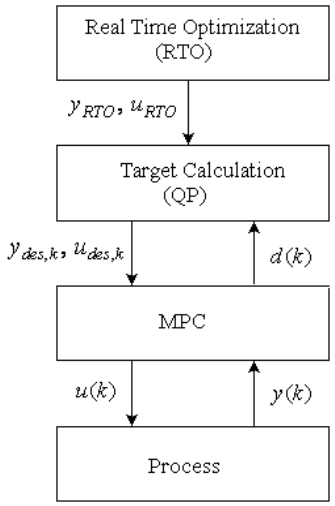

Figure 1- Control structure with RTO and the two-layer MPC.

Finally, in the MPC level, the optimizing targets are dynamically implemented. Since the optimization problem that is solved in the RTO layer is executed with a time period of hours and the target calculation and MPC problem are executed with a time period of minutes, one can consider that the RTO layer is dynamically decoupled from the other two layers. Consequently, the stability of the RTO and MPC integration will depend on the interaction between the target calculation and dynamic layers. Thus, the scope of this work is to propose a QP/MPC strategy that is stable to large excursions of the optimal operating conditions of the process system. Along the trajectory followed by the process operating point, one may expect a significant change in the parameters of the linear model on which the target calculation and dynamic layers are based. Here, it is proposed stable QP/MPC strategies for the case where the model of the process system is well known and for the case where we have a certain class of uncertainty in the process model.

2. The stable QP/MPC for the nominal system

Suppose that we have a stable system with *nu* inputs and *ny* outputs and consider the structure represented in Figure 1, where the solution of the RTO problem produces optimal values for the system outputs $y_{RTO,i=1,\ldots,ny_t}$ and for the system inputs $u_{RTO,i=1,\ldots,nu_t}$. In this system ny_t is the number of outputs that are selected to have optimizing targets and nu_t is the number of inputs that have optimizing targets. It is also assumed that $ny_t + nu_t = nu$, which is the number of available degrees of freedom of the system. Then, at time step *k*, assuming that the linear model considered in the QP and MPC layers is perfectly known, the target calculation layer of the structure represented in Figure 1 solves the following problem:

$$\min_{y_{des}(k),u_{des}(k),\varepsilon(k)} V_{k,a} = \left(y_{des}(k) - y_{RTO}\right)^T C_y \left(y_{des}(k) - y_{RTO}\right) + \left(u_{des}(k) - u_{RTO}\right)^T C_u \left(u_{des}(k) - u_{RTO}\right) + \varepsilon^T(k) C_\varepsilon \varepsilon(k) \tag{1}$$

subject to

$$y_{des}(k) - x^s(k) = D^0\left(u_{des}(k) - u(k-1)\right) \tag{2}$$

$$y_{\min} - \varepsilon(k) \le y_{des}(k) \le y_{\max} + \varepsilon(k), \quad \varepsilon(k) \ge 0 \tag{3}$$

$$-m\,\Delta u_{\max} \le u_{des}(k) - u(k-1) \le m\,\Delta u_{\max} \tag{4}$$

$$u_{\min} \le u_{des}(k) \le u_{\max} \tag{5}$$

where

C_y, C_u and C_ε are positive definite weighting matrices; $x^s(k)$ represents the predicted output of the process system at steady state as defined in the dynamic layer of the control structure; $u(k-1)$ is the control action applied to the real system at the previous time step and *m* is the control horizon of the controller corresponding to the dynamic layer of the control structure represented in Figure 1.

The optimal solution to the problem defined in (1) is then passed to the dynamic layer where a constrained infinite horizon MPC is implemented. This controller is based on the works of Odloak (2004) and González and Odloak (2009), but with some modifications to accommodate the integration of the controller with RTO and the target

calculation stage. This controller, which has the same sampling period as the QP stage, solves the following optimization problem:

$$\min_{\Delta u_k, y_{sp}(k), \delta_y(k)} V_{k,b} = \sum_{j=0}^{\infty} \left(y(k+j|k) - y_{sp,k} - \delta_{y,k} \right)^T Q_y \left(y(k+j|k) - y_{sp,k} - \delta_{y,k} \right)$$
$$+ \sum_{j=0}^{\infty} \left(u(k+j|k) - u_{des,k} \right)^T Q_u \left(u(k+j|k) - u_{des,k} \right) + \sum_{j=0}^{m-1} \Delta u(k+j|k)^T R \Delta u(k+j|k) + \delta_y^T(k) S_y \delta_y(k)$$

(6)

subject to

$$-\Delta u_{\max} \le \Delta u(k+j|k) \le \Delta u_{\max}; \qquad u_{\min} \le u(k+j|k) \le u_{\max}, \quad j = 0,...,m-1$$

$$x^s(k) + \tilde{D}^0 \Delta u_k - y_{sp}(k) - \delta_y(k) = 0$$

$$\begin{cases} y_{sp}(k) = y_{des}(k) \\ \delta_y(k) = \varepsilon(k) \end{cases} \text{ (only for those outputs that have optimizing targets)}$$

$$y_{\min} \le y_{sp}(k) \le y_{\max}$$

$$u(k-1) + \tilde{I} \Delta u_k - u_{des}(k) = 0 \text{ (only for those inputs that have optimizing targets)} \qquad (7)$$

where

Q_y, Q_u, R, S_y and S_u are weighting matrices of appropriate dimensions

$\tilde{D}^0 = \left[\underbrace{D^0 \quad \cdots \quad D^0}_{m} \right]$, $\tilde{I} = \left[\underbrace{I_{nu} \quad \cdots \quad I_{nu}}_{m} \right]$, I_{nu} is the identity matrix with dimension *nu*, D^0 corresponds to the process gain and

$$\Delta u_k = \left[\Delta u(k)^T \quad \Delta u(k+1)^T \quad \cdots \quad \Delta u(k+m-1)^T \right]^T$$

Following the same steps as in Odloak (2004), we can prove that the controller produced by the solution of problem (6) at successive time steps is asymptotically stable in the sense that if $y_{des}(k)$ and $u_{des}(k)$ remain fixed, then the outputs and inputs of the system that have targets will converge to the targets and the remaining outputs and inputs of the system will converge to steady state values inside their respective bounds.

Remark 1

The problem defined in (6) is based on a dynamic model of the process system. In the nominal case, it is assumed that a single model is able to represent adequately the system near the operating point being considered. For a system with *nu* inputs and *ny* outputs, a state space model that is suitable to the implementation of an offset free MPC can be represented in the following form (Odloak, 2004):

$$\begin{bmatrix} x^s(k+1) \\ x^d(k+1) \end{bmatrix} = \begin{bmatrix} I_{ny} & 0 \\ 0 & F \end{bmatrix} \begin{bmatrix} x^s(k) \\ x^d(k) \end{bmatrix} + \begin{bmatrix} D^0 \\ D^d \end{bmatrix} \Delta u(k) \qquad (8)$$

$$y(k) = \begin{bmatrix} I_{ny} & \Psi \end{bmatrix} \begin{bmatrix} x^s(k) \\ x^d(k) \end{bmatrix}$$

where

$x^s = \begin{bmatrix} x_1 & \cdots & x_{ny} \end{bmatrix}^T$, $x^s \in \Re^{ny}$, $x^d = \begin{bmatrix} x_{ny+1} & x_{ny+2} & \cdots & x_{ny+nd} \end{bmatrix}^T$, $x^d \in \Re^{nd}$,

$F \in \Re^{nd \times nd}$, $\Delta u(k) = u(k) - u(k-1)$

In the state space model defined in (8), the state component x^s corresponds to the integrating poles produced by the incremental form of the model, and x^d corresponds to the system modes. For stable systems, it is easy to show that when the system approaches steady state, component x^d tends to zero. F is a diagonal matrix with components corresponding to the poles of the system. The system has *nd* stable poles. Matrix D^0 is the static gain of the system.
If the model defined in (8) is used to represent the system, there is no need to include the estimation of the unmeasured disturbances (represented as *d* in Fig.1) in order to eliminate offset in the system outputs.

Remark 2
If the nominal undisturbed system starts from a steady state and, at a given time *k*, the RTO layer produces a step change in y_{RTO} and u_{RTO}, and the new steady-state defined by (y_{RTO}, u_{RTO}) is reachable, then the sequential solution of the problems defined in (1) and (6) results in the convergence of $y_{des}(k)$ to y_{RTO} and $u_{des}(k)$ to u_{RTO}.
To prove this property, suppose that the problem defined in (1) is solved at time *k* and the optimal solution corresponds to $\left(y^*_{des}(k), u^*_{des}(k), \varepsilon^*(k)\right)$ that is passed to the lower level of the control structure where the problem defined in (6) should be solved at the same time step considering the new targets. Also, let the corresponding optimal value of the objective function of problem (1) be designated $V^*_{k,a}$. Now, observe that we can find a feasible solution to problem (6) by adopting $\Delta u_k = 0$, $y_{sp}(k) = y^*_{des}(k)$ (for those outputs that have targets), $y_{sp}(k) = 0$ and $\delta_y(k) = x^s(k) - y_{sp}(k)$ (for the other outputs). Note also that constraint (7) is certainly feasible because of (4). So, this problem is always feasible and from its solution we obtain the vector of optimal control sequence Δu^*_k. Then, the first component of Δu^*_k is injected in the true process and we wait until time step *k*+1 where problem (1) is solved again. Now, we can show that a feasible solution to problem (1) at time *k*+1 is given by $\left(\tilde{y}_{des,k+1}, \tilde{u}_{des,k+1}, \tilde{\varepsilon}_{k+1}\right) = \left(y^*_{des,k}, u^*_{des,k}, \varepsilon^*_k\right)$. It is easy to see that this solution satisfies constraints (3-5) and we need only to show that it also satisfies (2). For this purpose let us write the left hand side of (2) for the proposed solution as follows

$$LHS = \tilde{y}_{des,k+1} - x^s(k+1) = y^*_{des,k} - x^s(k) - D^0 \Delta u^*(k)$$

Now using (2) at time *k*, we have

$$LHS = D^0 \left(u_{des,k} - u(k-1)\right) - D^0 \Delta u(k)$$

Analogously, the right hand side of (2) for the proposed solution at time k+1 can be written as follows

$$RHS = D^0\left[\tilde{u}_{des,k+1} - u(k)\right] = D^0\left[u_{des,k} - u(k-1) - \Delta u(k)\right]$$

and it is clear that *LHS*=*RHS* and consequently (2) is satisfied by the proposed solution.

If the value of the objective function defined in (1) corresponding to the feasible solution $\left(\tilde{y}_{des,k+1}, \tilde{u}_{des,k+1}, \tilde{\varepsilon}_{k+1}\right)$ is designated $\tilde{V}_{k+1,a}$, then it is clear that $\tilde{V}_{k+1,a} = V^*_{k,a}$ and consequently $V^*_{k+1,a} \le V^*_{k,a}$, which means that the objective function of problem (1) is converging. Then, if the optimal steady state defined by $\left(y_{RTO}, u_{RTO}\right)$ is feasible, $V_{k,a}$ will converge to zero and the system inputs and outputs will converge to the their targets.

3. The robust QP/MPC for the uncertain system

Depending on the market conditions, product specifications, feedstock quality, etc, the RTO layer may define optimizing targets that correspond to quite different operating conditions, which means that a MPC controller, based on the nominal linear model, can result in poor performance or instability of the closed loop system. So, model uncertainty should be considered in the target calculation and dynamic layers of the MPC controller. For instance, suppose that the true gain matrix D^0_t of the process model, lies in a convex polytope defined by L vertices $D^0_1, D^0_2, ..., D^0_L$, which means that

$$D^0_t = \sum_{i=1}^{L} \lambda_i D^0_i, \;\; \sum_{i=1}^{L} \lambda_i = 1, \;\; \lambda_i \ge 0 \tag{9}$$

Now, we may define the objective function of the target calculation layer for each of the vertices of the polytope that characterizes the uncertain system defined in (9) as follows

$$V_{k,a}(D^0_i) = \left(y_{des,i}(k) - y_{RTO}\right)^T C_y \left(y_{des,i}(k) - y_{RTO}\right) + \left(u_{des}(k) - u_{RTO}\right)^T C_u \left(u_{des}(k) - u_{RTO}\right) + \varepsilon_i(k)^T C_\varepsilon \varepsilon_i(k) \qquad i = 1, ..., L \tag{10}$$

Then, the optimization problem to be solved in the QP layer to calculate the targets for the MPC controller is defined, for the uncertain system, as follows

$$\min_{\substack{y_{des,i}(k), u_{des}(k), \varepsilon_i(k) \\ i=1,...,L}} V_{k,a}(D^0_n) \tag{11}$$

subject to

(4), (5), and

$$V_{k,a}(D^0_i) \le \tilde{V}_{k,a}(D^0_i), \quad i = 1, ..., L \tag{12}$$

$$y_{\min} - \varepsilon_i(k) \le y_{des,i}(k) \le y_{\max} + \varepsilon_i(k), \quad \varepsilon_i(k) \ge 0, \quad i = 1, ..., L \tag{13}$$

$$y_{des,i}(k) - x^s(k) = D^0_i\left[u_{des}(k) - u(k-1)\right], \quad i = 1, ..., L \tag{14}$$

where

- D_n^0 is the gain matrix of the nominal or most probable model of the process system.
- $\tilde{V}_{k,a}(D_i^0)$ is computed with $\left(\tilde{y}_{des,i}(k), u_{des}^*(k-1), \varepsilon_i^*(k-1)\right)$ where $\tilde{y}_{des,i}(k-1)$ satisfies the equation: $\tilde{y}_{des,i}(k) - x^s(k) + D_i^0\,\Delta u(k-1) = D_i^0\left(u_{des}^*(k-1) - u(k-2)\right)$ (15)

Remark 3

Problem (11) is always feasible, because $\left(\tilde{y}_{des,i}(k), u_{des}^*(k-1), \varepsilon_i^*(k-1),\ i=1,...,L\right)$ is a feasible solution to the problem (11). Also, if at time *k*, $\left(y_{des,i}^*(k), u_{des}^*(k), \varepsilon_i^*(k),\ i=1,...,L\right)$ is the optimal solution to the problem defined in (11), then, the solution that corresponds to the true process model whose gain matrix is $D_t^0 = \sum_{i=1}^{L} \lambda_i D_i^0$ is given by

$$\left(y_{des,t}^*(k),\, u_{des}^*(k), \varepsilon_t^*(k)\right) = \left(\sum_{i=1}^{L} \lambda_i y_{des,i}^*(k),\, u_{des}^*(k),\, \sum_{i=1}^{L} \lambda_i \varepsilon_i^*(k)\right)$$

It is easy to show that this solution satisfies contraints (4-5) and (13-14). To show that it also satisfies constraint (12), we write this inequality explicitly for the optimal solution and for each vertex of the polytope that charcterizes the model uncertainty:

$$\begin{aligned}
&\left(y_{des,i}^*(k) - y_{RTO}\right)^T C_y \left(y_{des,i}^*(k) - y_{RTO}\right) + \left(u_{des}^*(k) - u_{RTO}\right)^T C_u \left(u_{des}^*(k) - u_{RTO}\right) + \varepsilon_i^*(k)^T C_\varepsilon \varepsilon_i^*(k) \\
&\le \left(\tilde{y}_{des,i}(k-1) - y_{RTO}\right)^T C_y \left(\tilde{y}_{des,i}(k-1) - y_{RTO}\right) + \left(u_{des}^*(k-1) - u_{RTO}\right)^T C_u \left(u_{des}^*(k-1) - u_{RTO}\right) \\
&\qquad + \varepsilon_i^*(k-1)^T C_\varepsilon \varepsilon_i^*(k-1), \qquad i = 1,...,L
\end{aligned} \tag{16}$$

Using the Schur complement, it is possible to show that (16) is equivalent to

$$\begin{bmatrix}
C_y^{-1} & 0 & 0 & 0 & \left(y_{des,i}^*(k) - y_{RTO}\right) \\
0 & C_\varepsilon^{-1} & 0 & 0 & \varepsilon_i^*(k)^T \\
0 & 0 & -C_y^{-1} & 0 & \left(\tilde{y}_{des,i}(k) - y_{RTO}\right) \\
0 & 0 & 0 & -C_\varepsilon^{-1} & \varepsilon_i^*(k-1) \\
\left(y_{des,i}^*(k) - y_{RTO}\right)^T & \varepsilon_i^*(k)^T & \left(\tilde{y}_{des,i}(k) - y_{RTO}\right)^T & \varepsilon_i^*(k-1)^T & \begin{array}{l} -\left(u_{des}^*(k) - u_{RTO}\right)^T C_u \left(u_{des}^*(k) - u_{RTO}\right) \\ +\left(u_{des}^*(k-1) - u_{RTO}\right)^T C_u \left(u_{des}^*(k-1) - u_{RTO}\right) \end{array}
\end{bmatrix} \ge 0$$

$$i = 1,...,L \tag{17}$$

Now, since (17) is a linear matrix inequality, any linear combination of the corresponding process models will produce a similar combination of the inequalities represented in (17), and consequently (12) is satisfied for the true model. So, $V_k(D_t^0)$ is decreasing and will converge to zero if the steady state corresponding to $\left(y_{RTO}, u_{RTO}\right)$ is reachable by the true plant.

Before defining the optimization problem that is solved in the dynamic layer of the control structure defined in Figure 1, for the case where there is model uncertainty, let

us characterize the type of uncertainty of the dynamic model considered in the MPC. Let any dynamic model be represented by the following set of parameters: $\theta = \left[D^0, D^d, F \right]$. Here, we assume that the true model of the process system is represented as $\theta_t = \left[D_t^0, D_t^d, F_t \right]$, where $\left(D_t^0, D_t^d \right) = \sum_{i=1}^{L} \lambda_i (D_i^0, D_i^d)$, $\sum_{i=1}^{L} \lambda_i = 1$, $\lambda_i \geq 0$ and $F_t = F_{j=1,\ldots,L}$. We should observe that the uncertainty is not polytopic in terms of the parameters related to the dynamics of the system. This means that the gain of the true system is a convex combination of a finite of possible gains, while the dynamics of the system is defined by one element of a finite set of possible dynamics.

Based on the works of Odloak (2004) and González et al. (2007) that propose robust MPC controllers for the type of uncertainty described above, the problem that is solved in the dynamic layer of the control structure of the uncertain system is the following

$$\min_{\Delta u_k, y_{sp,i}(k), \delta_{y,i}(k)} V_{b,k}(\theta_n) =$$

$$\sum_{j=0}^{\infty} \left[y_n(k+j|k) - y_{sp,n}(k) - \delta_{y,n}(k) \right]^T Q_y \left[y_n(k+j|k) - y_{sp,n}(k) - \delta_{y,n}(k) \right]$$

$$+ \sum_{j=0}^{\infty} \left[u(k+j|k) - u_{des}(k) \right]^T Q_u \left[u(k+j|k) - u_{des}(k) \right] + \sum_{j=0}^{m-1} \Delta u(k+j|k)^T R \, \Delta u(k+j|k)$$

$$+ \delta_{y,1}^T(k) S_y \delta_{y,1}(k) + \cdots + \delta_{y,L}^T(k) S_y \delta_{y,L}(k) \tag{18}$$

subject to

$-\Delta u_{\max} \leq \Delta u(k+j|k) \leq \Delta u_{\max}, \quad j = 0, \ldots, m-1;$

$u_{\min} \leq u(k+j|k) \leq u_{\max}, \quad j = 0, \ldots, m-1$

$y_{sp,i}(k) = y_{des,i}; \quad i = 1, \ldots, L$ (for those outputs that have optimizing targets)

$y_{\min} \leq y_{sp,i}(k) \leq y_{\max}, \quad i = 1, \ldots, L$

$x^s(k) + \tilde{D}_i^0 \Delta u_k - y_{sp,i}(k) - \delta_{y,i}(k) = 0; \; i = 1, \ldots, L$

$u(k-1) + \tilde{I} \Delta u_k - u_{des}(k) = 0$ (only for those inputs that have optimizing targets)

$V\left(\Delta u_k, \delta_{y,i}(k), y_{sp,i}(k) \right) \leq V\left(\Delta \tilde{u}_k, \tilde{\delta}_{y,i}(k), \tilde{y}_{sp,i}(k) \right), \; i = 1, \ldots, L$

where

$$V\left(\Delta u_k, \delta_{y,i}(k), y_{sp,i}(k) \right) = \sum_{j=0}^{\infty} \left[y_i(k+j|k) - y_{sp,i}(k) - \delta_{y,i}(k) \right]^T Q_y$$

$$\times \left[y_i(k+j|k) - y_{sp,i}(k) - \delta_{y,i}(k) \right] + \sum_{j=0}^{\infty} \left[u(k+j|k) - u_{des}(k) \right]^T Q_u \left[u(k+j|k) - u_{des}(k) \right]$$

$$+ \sum_{j=0}^{m-1} \Delta u(k+j|k)^T R \, \Delta u(k+j|k) + \delta_{y,i}^T(k) S_y \delta_{y,i}(k)$$

$\Delta \tilde{u}_k = \left[\Delta u^*(k|k-1)^T \quad \cdots \quad \Delta u^*(k+m-2|k-1)^T \quad 0 \right]^T$; $\tilde{y}_{sp,i}(k) = y_{sp,i}^*(k-1)$

$\tilde{\delta}_{y,i}(k)$ is such that $x^s(k) + \tilde{D}_i^0 \, \Delta \tilde{u}_k - y_{sp,i}(k) - \tilde{\delta}_{y,i}(k) = 0, \; i = 1, \ldots, L$

Note that the problem defined in (18) is always feasible because $\left(\Delta\tilde{u}_k, \tilde{y}_{sp,i}(k), \tilde{\delta}_{y,i}(k), i=1,...,L\right)$ is a feasible solution to this problem.

Assuming that the problem defined in (11) has converged, that is $y_{des,i}(k) = y_{RTO,i}$ and $u_{des}(k) = u_{RTO}$ for a finite *k*, then, it can be shown that $\left(\Delta\tilde{u}_k, \sum_{i=1}^{L}\lambda_i \tilde{y}_{sp,i}(k), \sum_{i=1}^{L}\lambda_i \tilde{\delta}_{y,i}(k)\right)$ is a feasible solution to problem (18) for the true system and, corresponding to this solution, we have $V_{b,k+1}\left(\Delta\tilde{u}_{k+1}, \tilde{\delta}_{y,t}(k+1), \tilde{y}_{sp,t}(k+1)\right) = V_{b,k}\left(\Delta u_k^*, \delta_{y,t}^*(k), y_{sp,t}^*(k)\right)$ and consequently $V_{b,k}(\theta_t)$ is decreasing and the closed loop system is stable.

4. Conclusion

Here, it was proposed a two step algorithm to the robust stable integration of real time optimization and multivariable control of a process system in the control structure of the process plant. The first step consists of a target calculation layer based on an optimization problem where convergence of the computed targets to the set points defined by the RTO layer is assured. The second step of the algorithm is based on an extended infinite horizon MPC where the errors on the inputs that have targets are penalized and the outputs are controlled at the desired targets or inside zones. An extension of the method is presented to the case where we have polytopic uncertainty in the model parameters associated to the gains of the process system. Uncertainty in the dynamic parameters can be included by considering a finite set of possible dynamics.

Sustainable Supply Chains: Key Challenges

Ana Paula Barbosa-Póvoa

Centro de Estudos de Gestão do-IST, CEG-IST, UTL, Av. Rovisco Pais 1049–001 Lisboa, Portugal, apovoa@ist.utl.ptl

Abstract

In the new economic context the long term success of any organization is built not only on profits and profitability but also on its contribution to the future of people and the future of the planet. Being supply chains a key cornerstone in any organization the consideration of sustainability at the supply chain level is recognized as an emerging area that needs to be studied in a systematic way. The concept of sustainable supply chain is raising both in the industry and academic communities and studies have been reported on this new supply chain management concept. An overview of some of these works is performed along this paper and some major issues that should form a future research agenda on the area are identified.

Keywords: Sustainability, Supply Chains, Energy Efficiency, Life Cycle Analysis.

1. Introduction

Supply Chain Management as a concept was introduced back in the early 1980s (Oliver and Webber, 1982) but received most attention from 1990 onwards. Nowadays, supply chains are the foundation of any organization that wants to act in the current global competitive economy. Conventionally, supply chains have been seen as operational structures responsible for the production and distribution of products to different markets disperse around the globe, whose main objective was the satisfaction of costumers at a minimum cost. Supply chain research communities tended to focus on sub-sets of the supply chain management decisions instead of looking in a cross-functional and co-coordinated way to the different existent levels of decisions (Varma et al., 2007). This paradigm is however changing and advances in global competition with a parallel exhaustion of natural resources and an increased society awareness towards environment, created a new way of thinking when managing supply chains.

The need of seriously exploring the concept of sustainable supply chains within a collaborative perspective is seen as a goal to improve companies' revenue growth and costumer's recognition (Kleindorfer, et al., 2005). As stated by the New Zealand World Business Council for Sustainable Development, supply chains need to be seen as operational structures that manage the raw materials and services from suppliers to manufactures/service providers and back with improvement of the social and environmental impacts explicitly considered (NZBCSD, 2003). To respond to this challenge enterprises´ must invest on the design, planning and operation of their logistic structures while considering the minimization of their global energy consumption (Grossmann, 2004). As reported by Côte et al. (2008) supply chain management can significantly influence environmental performance, both positively and negatively. Substantial opportunities thus exist, along the supply chain, to reduce company's energy consumption. The extension of the traditional supply chain to consider the reserve flows where waste management is incorporated and a better rationalization of resources is

achieved, reduction of greenhouse gases emissions through the use of less polluted production and transportation modes; substitution of chemicals that might reduce the generation and management of hazardous waste or the reduction of the packaging waste are only some of the options that companies should consider.
Along this paper sustainable supply chains are being addressed. Some major works considering this new supply chain paradigm are analyzed and some of the key challenges that should to be considered in a future research agenda on sustainable supply chains are identified.

2. Sustainability and Supply Chains

Sustainable Supply Chains Management has its roots in both Sustainability and Supply Chain Management literature and involves a broadened approach of the supply chain management. Sustainability as defined by the World Commission on Environment and Development (WCED, 1987) is the use of resources to meet needs of the present without comprising the ability of future generations to meet their own needs. On the other hand, Supply Chain Management can be viewed as a systems approach to manage the entire flow of information, materials, and services from raw materials suppliers through factories and warehouses to customers and back. A focus on supply chains is therefore a step towards the adoption of a growth on sustainability. As stated by Linton et al. (2007) sustainability must integrate issues and flows that go beyond the core of the supply chain management such as: product design, production, distribution, end of life products and recovery processes.

Product design: should look into methodologies to assess environmental implications at the product design level. These can assist in the determination on how to design a product so as to minimize its environmental impact over its usable life afterwards. The integration between the product design and the processing phase should be explored so as to diminish environmental impacts and guarantee the long-term sustainability.

Production: research at the process level should concentrate efforts in the development of cleaner process aiming at reducing by-products that might damage the environment and human health. Process technologies should be designed and operated to easily incorporated reusable products aligning in this way with the need of decreasing the use of resources.

Distribution: transportation appears as one of the main contributors to the supply chain footprint. The reduction of greenhouse gases through the use of cleaner transportation modes coupled with an optimal definition of the supply chains structures will contribute positively towards sustainability.

End-of-life products and Recovery processes: how to effectively recycle end-of-life products by using a reserve chain is an area that has become a field of rapidly growing importance. The initial product design has a great influence on to each degree a product can be re-used, remanufactured, recycled, incinerated or disposed of. Work on how to capture the value remaining in products at the end of its life should be extended.

The in-breath in each one of these areas is out of the scope of the supply chain management but their study is definitely related to the supply chains systems. Efforts on both sides will support the goal of responsible care as stated by Grossmann (2004). Process Systems Engineering play an important role in any of the above areas and its contribution towards a global life cycle assessment will contribute to the achievement of

such goal. The development of systematic methods and tools that guarantee the design of environmental benign products and processes coupled with sustainable supply chains is therefore the goal to accomplish.

3. Sustainable Supply Chain Management

Adding the Sustainability component to supply chain management implies considering the influence and relationships between supply chain management and the environment as well as the social aspects of the business practices. As a major challenge the research on the area needs to develop adequate measures for the environment supply chains impacts and should taken as basis the engagement of all the supply chain activities in the triple bottom line (3BL), the threes P´s, people, profit and planet (Kleindorfer, et al., 2005). Such concern has been identified by different authors during the present decade and different approaches have been followed. Some looked only to the forward supply chains while others explored the reverse logistics as a way to deal with the environmental and social pressures. The closed-loop supply chain concept emerged where both flows, forward and reserve, are considered simultaneously. As referred by Guide and Van Wassenhove (2002) the companies that have been most successful with their reverse supply chains are those that closely coordinate them with the forward supply chains, creating the closed-loop supply chain. These aim to contribute towards the sustainable development by defining and operating the right systems that guarantee a reduction of resources by recycling and recovery end of life products back into the chain. As stated by Salema et al. (2007) the literature on closed-loop supply chains, has been slowly building, but remains sparse.

Jayaraman et al. (1999) developed a mixed integer programming formulation to model a closed-loop supply chain. The model was tested on a set of problems based on the parameters of an existing electronic equipments remanufacture firm. Fleischmann et al. (2001) proposed a model for the location of logistic facilities. Their work was the first to propose a general model formulation (Mixed Integer Linear Programming Model, MILP) that simultaneously optimizes the reverse and the forward networks. Two case studies were used to explore the model application. Krikke et al. (2003) also proposed a MILP model for the design of a closed-loop supply chain where both location-allocation decisions and product design are considered. The objective function includes both supply chain costs and environmental impacts using a performance indicator (based on LCA approach). As product design is involved, an assembly and disassembly of products is explicitly modelled. Beamon and Fernandes (2004), presented a model for a single product closed-loop supply chain design. Fandel and Stammen (2004) propose a strategic model for the supply chain design. Salema et al. (2006, 2007, 2008) study the problem of designing simultaneously the forward and reverse networks. In these works the models evolved along time and different aspects of the closed-loop supply chains have been considered. The proposed models are fairly general as they incorporate facility capacity limits, multi-product flows and uncertainty under a dynamic context. Strategic versus tactical decisions were considered. The final networks structures as well as the planning of materials along the chain are obtained. Quarasigui Frota Neto et al. (2008), developed a framework for the design of logistics structures in which profitability and environmental impacts are balanced. A multi-objective model was developed. An European pulp and paper industry case-study was solved.

All the above works focused essentially on the strategic and at most on the planning contexts. At the operational level fewer works appeared that dealt with the closed-loop supply chains. Amaro and Barbosa-Póvoa (2008a) looked into the detailed scheduling

of supply chains with reverse flows where different product recovery policies are analysed. A real case-study of the pharmaceutical industry has been solved. Later on, the same authors (Amaro and Barbosa-Póvoa, 2008b) presented a generic approach where the integration between the planning and the scheduling level was proposed. The model also contemplated the reserve flows where management of end-of-life products was considered.

On the reserve logistic structures several works have also appeared. A review, on the characteristics of the research on reserve logistics, is presented by Rubio et al (2008). Ammons et al. (2000) developed a MILP model for the design and planning of reverse production systems. The State-Task Network (STN) was used as representation methodology. The model was applied to the recycling of a network router from an Original Equipment Manufacturer. The same problem was addressed by Realff et al. (2000) through a different approach where a robust optimization framework was used. Duque et al. (2007), using the maximal State-Task Network proposed a optimization model for the design and operation of a recovery route for residual industrial products with uncertain demands. The final model is able to suggest the optimal processing and transport routes, while optimizing a given objective function and meeting design and environmental constraints. This work was extended in Duque et al. (2009) where the eco-indicator 99 was used to quantify the environmental impact of the chain. Quarasiguasi Frita Neto et al. (2009) studied the eco-efficiency methodology and proposed a multi-objective linear problem with three objectives: minimize costs, cumulative energy demand and waste in a reserve logistics network.

On the forward chains the sustainability concept has been mainly associated with the quantification of the environmental impacts. As referred by Papageorgiou (2008), on its review on supply chain optimization for the process industries, Zhou et al. (2000) developed a goal programming model to account for sustainability aspects on the supply chains of continuous processes. Hagelaar et al. (2002) explore the concept of Life Cycle Analysis (LCA) when applied to a supply chain context and concluded that no guidelines exist for an integration of these two strategies. Turkay at al. (2004) explored the problem of multi-company collaborative supply chain management where not only economical goals where considered but also environmental aspects where incorporated. Later on, Hugo and Pistikopoulos (2005) looked into the supply chains planning problem where environmental concerns were accounted for. A mathematical formulation was developed which was applied to a bulk chemicals supply chain. In 2006, Soylu et al. (2006) analysed the synergies that may exist on a collaborative supply chain of energy systems. Matos and Hall (2007) analysed the integration of sustainable development concepts into the supply chains and build up a framework that should guide the utilization of LCA methods into the supply chains. Two case studies were studied, oil sand refining and agriculture biotechnology.

4. Conclusions and Key Challenges

As presented in the reviews published by Kleindorfer, et al. (2005), Srivastava (2007) and Seuring and Muller (2008) and through the analysis presented above it can be said that although a growing interest is observed on the incorporation of sustainability into the supply chain systems, new advances and developments are still required. The footprint of all the supply chain activities needs to be contemplated from the development of new products till the production, storage, transportation and reuse of the current ones. Investment on sustainable technologies, operations and supply chains must exist and an integrate decision over the life cycle of products should characterize

the research on the field. To achieve such target the research community should look into the following key challenges:
1 . What are the good measures for sustainability within the sustainable supply chains? Further work needs to be done on how to measure properly the environmental impacts and its consequences in the social well being of the population.
2. How to defined or redesign the supply chains to facilitate collection, refurshiment, recycling or disposal or returned products? The optimization of the supply chains structures to easily incorporate the end-of-life products is required. Although, several studies appeared in the closed-loop supply chain, general models are still scarce and its application to a large number of supply chains has not yet been done.
3. How to deal with uncertainty? An uncertainty analysis is required. Uncertainty influences the sustainable supply chains both at the supply chain structure definition as well as at the associated planning and scheduling activities. Risk modeling aspects should also be considered. Different decisions lead to different levels of risk that need to be defined so as to take the right decision.
4. How to trade-off the different issues of the 3BL into the supply chains management, profit, people and planet? Multi-objectives approaches need to be explored, which encompass with all the above aspects.

5. Acknowledgments

The author gratefully acknowledge the financial support provided by Fundação para a Ciência e Tecnlogia (FCT), Portugal.

Abstract

Over a period of more than 20 years of experience, deploying industrial projects related to advanced process control and real time optimization in processing industries around the world, many times the following or similar issues have been found:

- A lot of applications of Process Systems Engineering related technologies are extremely successful when used offline by Engineers, in their offices, but only a few of them succeed when transferred to the Operators to be routinely used in real time, tied to online field data, under unsupervised automatic execution.
- The use of certain technologies, deployed under well engineered, successful real time projects, received enthusiastically by Engineers and Operators are not used more than for just a few months after the project completion.
- Real time systems with pretty good up-time figures degrade and finally unused when the Engineer in charge of them is promoted to a new position as a consequence of being so successful with them.
- Very well proven, sound technologies, fail when applied at a given Site while they succeed in a different location owned by the same Company.
- After a failure with one advanced technology, the Site or the Company becomes "immunized" against similar technologies and only after several years, with the renewal of the Engineering staff and young blood that has not been exposed to the past failure, does the technology have a chance to be considered again.

This paper will address some of the root causes for those issues and discuss about the best practices on how to avoid project failures. The range of projects from where experience was acquired range from individual pieces of equipment and isolated Units to whole Areas or Site wide systems (for example, the utilities system comprising the steam, fuels, boiler feed water and electricity networks). All of them were simulated, optimized and/or controlled with real time, online, industrially well established technologies.

Main industrial project steps are explained and critical details to be taken into account when dealing with real time data and online automatic executions. The objective is to help achieve a successful technology deployment avoiding project pitfalls and ensuring the continuous use of the applications based on the proper technology transfer and maintenance.

Keywords: process systems engineering projects, real time optimization, online data

1. Plant Information Systems: An Enabling Technology

DCSs (Distributed Control Systems (DCS) and Plant information (PI) systems are the most widely available data sources in the current industrial context. PI systems usually acquire data from the DCSs and store it in a unique repository. The long term, facility wide PI system based historians constitute what is known as an *enabling technology*, because they became the cornerstone on top of which many other applications can be built. Centralized real-time databases provide access to massive actual and historical process, laboratory and financial data.

Modern PI systems filled the gap from the isolated, customized and proprietary DCS databases and proprietary network protocols to real time applications, by providing a centralized data repository. Moreover, modern open standards allow data to be accessed easily by every application that has a need for it.

Only a few years ago, the interfacing work was a big chunk of any industrial project. Many hours of special programming and integration, requiring detailed knowledge about a lot of proprietary Application Programming Interfaces (APIs) was needed. Nowadays, almost all of the DCS and PI system providers adhere to widely adopted open standards like OPC (OLE for Process Control). Originally built around the Microsoft DCOM technology, OPC standard protocols are nowadays being updated to provide easier ways to deal with data transfer and security issues. Details can be obtained from the OPC Foundation web page (OPC Foundation, 2009).

2. Real Time Process Systems

Control rooms worldwide are facing a shortage of people. Operators are concentrating more and more on the Units under his/her responsibility. DCS screens flourished and hundreds or thousands of tags are available per Unit and a multitude of process diagrams and trends can be projected to the walls and even the ceilings. But only a few employees are available to take care about the process operability and economics. Industrial Sites are becoming increasingly complex and inter-related, not only between Units but also with the power and utilities systems.

Tighter and increasingly restrictive regulations related to emissions are also imposing constraints and adding complexity to their proper management. Deregulated feedstock, electric and fuels markets with varying contracted prices (seasonal or daily) also introduce additional challenges to Operating personnel. Industrial facilities like Refineries and Petrochemicals are becoming increasingly aware that process and utilities systems need to be optimally operated and managed together.

Process systems engineering applications came to the rescue. They have always attempted to produce tools that improve the way industrial production systems were designed, controlled and managed. In the early days, offline applications where the only possibility but the idea was always around about using them in real time.

As explained above, the evolution from having plant information scattered throughout many islands of automation to a unified and centralized Plant Information System was a clear enabling layer for such work.

However, to successfully implement a real time process engineering system there are still several issues and questions that need to be addressed and recommended implementation practices useful to be taken into account.

2.1. Proper Technology Selection

Select the technology that fits with the problem solution rather than force the problem to be solved with an a priori selected technology. For example, if a simple linear regression with two input variables is sufficient enough to infer the needed variable, do

not force the use of a several inputs neural network. But always high rank systems based on sound process engineering principles (i.e., mass and energy balances and thermodynamics) than those based on correlations or non-physical sense solutions (Friedman, 1999).

2.2. Avoid "Computerization"

To solve a given problem, engineers need to apply the ***EBC*** approach suggested by Richalet, 2000, rather than the straight use of ***C***. Follow the ***EBC*** procedure implies:

- First, use your ***E***ye to inspect trends, data, process diagrams, DCS screens...
- Second, use your ***B***rain to carefully understand and design the real time system and select or design the proper software tool.
- Finally, only at the end, use the ***C***omputer to solve the problem.

The enthusiastic but inexperienced engineers tend to go straight to the ***C***omputer, forgetting or minimizing to analyze and perfectly understand the problem to be solved, their real handles and constraints.

2.3. Balance Model Complexity Against Expected Results

Model complexity must be balanced against expected benefits. Remember: "the simplest is generally the best". Engineering judgment and experience plays a key role in this task. Operators and Engineers will appreciate any efforts towards simplification, especially for future re-training and system maintenance.

2.4. Real Time Data Seldom Can be Used "as is"

Carefully designed and engineered "safety envelops" must be built around real time online data, in order to validate all the signals, in and out of the applications. Minimum and maximum limits for each variable, controller windup identification and associated valve openings and controllers statuses must be combined to properly identify and isolate measurement problems. Steady state detection procedures must also be considered to warn Operators or directly skip an optimization run if the Process is unstable.

What should a system do if bad data is detected? If the bad data feeds "critical" variables of the system, then its execution should be suspended and Operators warned. If bad data is related to "noncritical" variables then some kind of backup or default values could be used but such an action needs to be defined on each individual variable. The implementation of data validation procedures is a key activity for every real time project.

2.5. Pricing Information Must be Updated

When economics is the main driver to apply advanced process engineering real time systems, prices used for the optimization or objective function calculations must be diligently updated. When possible, manual data entering should be avoided. Automatic pricing information must be implemented acquiring the prices directly from process information systems or web pages (some examples we have used in the past include the sites of ERCOT in Texas, USA and OMEL in Spain, for electricity market spot prices).

2.6. Have Operators Always in Mind

From the very beginning try to involve Operators, inform them about the project objectives and solve their concerns. A common question is about being replaced by the new system and fired after completion. Second in rank is their worries regarding if the new system will increase their burden. First question is usually outside our control but we never have seen a single Operator being fired due to our projects, most of them very successful. With respect to the second concern, an effort needs to be done to not increase Operator's burden, implementing automatic data updates or procedures to

minimize his/her manual intervention.
Clear and easy operating interfaces need also to be built. Operators must be properly trained and assisted right by the DCS console after being left alone with the new system. It is always a good idea to spend many hours at the DCS console with the Operators to discuss the proposed solutions and technology, explaining to them what is needed so they will accept the introduction of the new technology. Properly designed Operating manuals must be provided and updated as frequently as needed.

2.7. Do not "Prototype" but Deploy Well Engineered Systems

Do not expose Operators nor final users to "interim or prototyping versions" but only to finished, very well built models, including the Operating interface and true handles limits and constraints. Operator's general attitude is to closely adhere to their first impression. There is a single "silver bullet" to use with them: they will never forget if early disappointed or frustrated when trying to use the system for the first time. Moreover, many of them will became "vaccinated" against the technology and refuse to use it, subtle or frontally, any more.

2.8. Document the Application and Maintain it "Forever Green"

Engineering documentation must be provided and updated as soon as changes are implemented in the model or to the Operating interface. The application needs to be maintained "forever green", reflecting continuously the current Process handles and constraints. Changes on the process side must be immediately reflected in the model. Any process change needs to be immediately taken into account because they may impact the way the online variables are considered into the models.
Local resources need to be properly trained and technology providers need to assist and remotely maintain the applications.
As a sidenote it is important to mention the huge impact of remote access capabilities on systems performance. Only a few years ago just a minor model adjustment would take a lot of time for the new information to be exchanged back and forth. Nowadays, VPN or Webex like secure remote access can be easily implemented and solutions can be provided in minutes, instead of hours or even days.

3. Industrial Projects Execution

To cite only a few examples with which the author has been exposed, the following technologies that are widely used in the Process Industry rely heavily on real time data:

- Model Based Predictive Control (MPBC), for example A. Sanz et al., 2005
- Process Monitoring, for example A. Heins et al., 2007
- Real Time Optimization, for example M. Kihn et al. for open loop, 2008 and D. Ruiz et al., 2008 for closed loop applications
- Abnormal Situation Management, for example D. Ruiz et al., 2002

All of them include software where very efficient and robust numerical methods must deal with real time, online data and cope with the unavoidable uncertainties and errors always present in them. But even if the piece of software is implemented soundly this is not a guarantee of success. Only a well executed engineering project, carried on by experienced Application Engineers will guarantee the success.

3.1. Collect the Required Information

A document is submitted to the Site with all the informational requirements for the real time project. It is very important to define a single project owner from the Site side, which will act as a single interface to provide the needed information and coordinate all the project steps.

3.2. Kick-Off Meeting
Prior to the Kick-Off Meeting, the provided information will be reviewed to have a better understanding of the Site process, main constraints and economic position. Additional questions or clarifications are sent to the Site regarding particular issues, as required. The operating procedures, optimization and control strategies should also be discussed. Operators must be introduced to the project goals and to the technology to be deployed.

3.3. Software Installation and Real Time Data Gathering
The software is configured and licensed on the Application server PC. It will also be connected to the OPC data server. Remote access to the model also needs to be configured at this time and needs to be available throughout the rest of the project, including maintenance and sustainability periods.

3.4. Functional Design Specification
Based on the information obtained during the Kick-Off meeting, a Functional Design Specification document is prepared and approved by the Site. This document becomes the blueprint for the entire project.

3.5. Model Building and Configuration
During this stage, the model and the report are built working remotely on the Application server. The model is built and grows with continuous access to online real time data. Eventually, a second trip to the facility would occur during this stage and would be used for mid-term review of the model and optimization.
The real time Application will run routinely, but optimization recommendations will still not be implemented but reviewed by the Engineering staff.
During this stage, a few experienced Operators can help to review the system results.

3.6. Operators Training and Commissioning
Site engineers will train the Operations staff to start and stop the Application, understand issues and potential problems and to implement the recommendations, when applicable. At the end of this period, Engineering and Operations staff begin with the daily use of the Application, which is transferred to its final owners.
Project documentation will be provided and a benefits report should be prepared based on the current results. It should be submitted to the appropriate Management level, to provide the proper feedback about the implemented technology and project execution quality.

3.7. Support and Sustainability
After project completion usually a routine remote check of the health of the online system is performed with the purpose of ensuring the Site continues to benefit from its implementation over time. As a part of the program, a regular review regarding the status of the model and the optimization and simulation solutions is proactively done on a periodic basis. A regular report can then be generated and distributed to the appropriate focal point.

4. Conclusions

Current data availability in the Plant Information systems, widely available at the Process Industries, provides the foundation on top of which you can build Applications to better operate, control and optimize these processes.
Inherent problems of real time data need to be addressed by carefully building a safety net around them, in order to avoid the use of unreliable and bad information.

The success of an industrial real time project deployment can be highly increased by following a set of simple rules and ensuring a proper knowledge transfer to both, Operators and Engineers.
Application maintenance and support helps to sustain the economic benefits after commissioning allowing them to be always in good shape and still used and appreciated by the owners many years after handing the project over to them.

Current trends in parallel computation and the implications for modeling and optimization

John D. Siirola

Sandia National Laboratories, P.O. Box 5800, Albuquerque, NM, 87185

Extended Abstract

Process Systems Engineering (PSE) is built on the application of computational tools to the solution of physical engineering problems. Over the course of its nearly five decade history, advances in PSE have relied roughly equally on advancements in desktop computing technology and developments of new tools and approaches for representing and solving problems (Westerberg, 2004). Just as desktop computing development over that period focused on increasing the net serial instruction rate, tool development in PSE has emphasized creating faster general-purpose *serial* algorithms. However, in recent years the increase in net serial instruction rate has slowed dramatically, with processors first reaching an effective upper limit for clock speed and now approaching apparent limits for microarchitecture efficiency. Current trends in desktop processor development suggest that future performance gains will occur primarily through exploitation of parallelism. For PSE to continue to leverage the "free" advancements from desktop computing technology in the future, the PSE toolset will need to embrace the use of parallelization.

Unfortunately, "parallelization" is more than just identifying multiple things to do at once. Parallel algorithm design has two fundamental challenges: first, to match the characteristics of the parallelizable problem workload to the capabilities of the hardware platform, and second to properly balance parallel computation with the overhead of communication and synchronization on that platform. The performance of any parallel algorithm is thus a strong function of how well the characteristics of the problem and algorithm match those of the hardware platform on which it will run. This has led to a proliferation of highly specialized parallel hardware platforms, each designed around specific problems or problem classes.

While every platform has its own unique characteristics, we can group current approaches into six basic classes: symmetric multiprocessing (SMP), networks of workstations (NOW), massively parallel processing (MPP), specialized coprocessors, multi-threaded shared memory, and hybrids that combine components of the first five classes. Perhaps the most familiar of these is the SMP architecture, which forms the bulk of current the desktop and workstation market. These systems have multiple processing units (processors and/or cores) controlled by a single operating system image and sharing a single common shared memory space. While SMP systems provide only a modest level of parallelism (typically 2-16 processing units), the existence of shared memory and full-featured processing units makes them perhaps the most straightforward development platform. A challenge of SMP platforms is the discrepancy between the speed of the processor and the memory system: both latency and overall memory bandwidth limitations can lead to processors idling waiting for data. Clusters, a generic term for coordinated groups of independent computers (*nodes*) connected with high-speed networks, provide the opportunity for a radically different level of parallelism, with the largest clusters having over 25,000 nodes and 100,000

processing units. The challenge with clusters is memory is distributed across independent nodes. Communication and coordination among nodes must be explicitly managed and occurs over a relatively high latency network interconnect. Efficient use of this architecture requires applications that decompose into pseudo-independent components that run with high computation to communication ratios. The level to which systems utilize commodity components distinguishes the two main types of cluster architectures, with NOW nodes running commodity network interconnects and operating systems and MPP nodes using specialized or proprietary network layers or microkernels. Specialized coprocessors, including graphics processing units (GPU) and the Cell Broadband Engine (Cell), are gaining popularity as scientific computing platforms. These platforms employ non-general purpose dependent processing units to speed fine-grained, repetitive processing. Architecturally, they are reminiscent of vector computing, combining very fast access to a small amount of local memory with processing elements implementing either a single-instruction-multiple-data (SIMD) (GPU) or a pipelined (Cell) model. As application developers must explicitly manage both parallelism on the coprocessor and the movement of data to and from the coprocessor memory space, these architectures can be some of the most challenging to program. Finally, multi-threaded shared memory (MTSM) systems represent a fundamental departure from traditional distributed memory systems like NOW and MPP. Instead of a collection of independent nodes and memory spaces, an MTSM system runs a single system image across all nodes, combining all node memory into a single coherent shared memory space. To a developer, the MTSM appears to be a single very large SMP. However, unlike a SMP that uses caches to *reduce* the latency of a memory access, the MTSM *tolerates* latency by using a large number of concurrent threads. While this architecture lends itself to problems that are not readily decomposable, effective utilization of MTSM systems requires applications to run hundreds – or thousands – of concurrent threads.

The proliferation of specialized parallel computing architectures presents several significant challenges for developers of parallel modeling and optimization applications. Foremost is the challenge of selecting the "appropriate" platform to target when developing the application. While it is clear that architectural characteristics can significantly affect the performance of an algorithm, relatively few rules or heuristics exist for selecting a platform based solely on application characteristics. A contributing challenge is that different architectures employ fundamentally different programming paradigms, libraries, and tools. Knowledge and experience on one platform does not necessarily translate to other platforms. This also complicates the process of directly comparing platform performance, as applications are rarely portable: software designed for one platform rarely compiles on another without modification, and the modifications may require a redesign of the fundamental parallelization approach. A final challenge is effectively communicating parallel results. While the relatively homogenous environment of serial desktop computing facilitated extremely terse descriptions of a test platform, often limited to processor make and clock speed, reporting results for parallel architectures must include not only processor information, but depending on the architecture, also include operating system, network interconnect, coprocessor make, model, and interconnect, and node configuration.

There are numerous examples of algorithms and applications designed explicitly to leverage specific architectural features of parallel systems. While by no means comprehensive, three current representative efforts are the development of parallel branch and bound algorithms, distributed collaborative optimization algorithms, and multithreaded parallel discrete event simulation. PICO, the Parallel Integer and

Combinatorial Optimizer (Eckstein, et al., 2001), is a scalable parallel mixed-integer linear optimizer. Designed explicitly for cluster environments (both NOW and MPP), PICO leverages the synergy between the inherently decomposable branch and bound tree search and the independent nature of the nodes within a cluster by distributing the independent sub-problems for the tree search across the nodes of the cluster. In contrast, agent-based collaborative optimization (Siirola, et al., 2004, 2007) matches traditionally non-decomposable nonlinear programming algorithms to high-latency clusters (e.g. NOWs or Grids) by replicating serial search algorithms intact and unmodified across the independent nodes of the cluster. The system then enforces collaboration through sharing intermediate "solutions" to the common problem. This creates a decomposable artificial meta-algorithm with a high computation to communication ratio that can scale efficiently on large, high latency, low bandwidth cluster environments. For modeling applications, efficiently parallelizing discrete event simulations has presented a longstanding challenge, with several decades of study and literature (Perumalla, 2006). The central challenge in parallelizing discrete event simulations on traditional distributed memory clusters is efficiently synchronizing the simulation time across the processing nodes during a simulation. A promising alternative approach leverages the Cray XMT (formerly called Eldorado; Feo, et al. 2005). The XMT implements an MTSM architecture and provides a single shared memory space across all nodes, greatly simplifying the time synchronization challenge. Further, the fine-grained parallelism provided by the architecture opens new opportunities for additional parallelism beyond simple event parallelization, for example, parallelizing the event queue management.

While these three examples are a small subset of current parallel algorithm design, they demonstrate the impact that parallel architectures have had and will continue to have on future developments for modeling and optimization in PSE.

Keywords: parallel computing, optimization, discrete event simulation

Waste-to-Energy Systems as Examples of Efficient Process Systems Engineering Approach

Petr Stehlík

Institute of Process and Environmental Engineering (VUT-UPEI), Faculty of Mechanical Engineering, Brno University of Technology, Technická 2, 616 69, Brno, Czech Republic

Abstract

Waste-to-energy systems may serve as a relatively simple, but all the more instructive example of industrial processing plant. Their design, operation and control are the subject of significant amount of research efforts worldwide. The present contribution briefly summarizes several recent advances in these areas in the context of respective computing-based methodologies. Practical and sophisticated approaches are demonstrated through industrial examples.

Energy production from contaminated biomass is a subset of waste-to-energy systems, but it is still better viewed as a separate application area. Due to the present rocketing importance of renewable energy sources, contaminated biomass becomes an interesting distributed energy source. Therefore we dedicate part of the paper to computational support in the design of a biomass combustion process.

Keywords: waste to energy, simulation, process design.

1. Introduction

Basic systems of the unit for the thermal processing of waste – incineration itself, heat recovery system, off-gas cleaning system – are briefly described in the first section as well as control and maintenance. A system for overall performance evaluation of waste-to-energy processes is the subject of the next section. After that, the design of the waste treatment technologies (namely decision support and optimization) is discussed with focus on available computational tools. Finally, computational support in the design of contaminated biomass combustor is presented.

2. Operation control and maintenance

Some types of waste (e.g. municipal solid waste in developed countries) have a high energy potential and it thus seems more appropriate to consider them rather as alternative fuels than waste (Bebar et al. 2005). The waste energy potential may be exploited for example in thermal waste treatment units (municipal and hazardous waste incinerators, see Figure 1), where heat produced by waste combustion is converted to utilizable forms of energy (e.g. steam, electricity, heating of utilities etc.) (European IPPC Bureau 2005). In the design phase of such plants it is advantageous to utilise software tools such as TDW (Puchyr et al. 1998) to make material and energy balances necessary for the selection of appropriate technologies and determination of other important design parameters. Incineration is however a complicated process, which besides useful energy generates also a number of polluting substances that have to be collected and neutralised (Dvorak et al. 2009). These include namely solid particulate matter, nitrogen oxides (NO_x), carbon monoxide, sulphur oxides, hydrogen chloride and

fluoride, volatile organic compounds (VOCs), heavy metals (Cd, Hg, Cr, Zn, Cu, Pb) and also persistent organic pollutants (POPs) like PAH, PCB and PCDD/F.

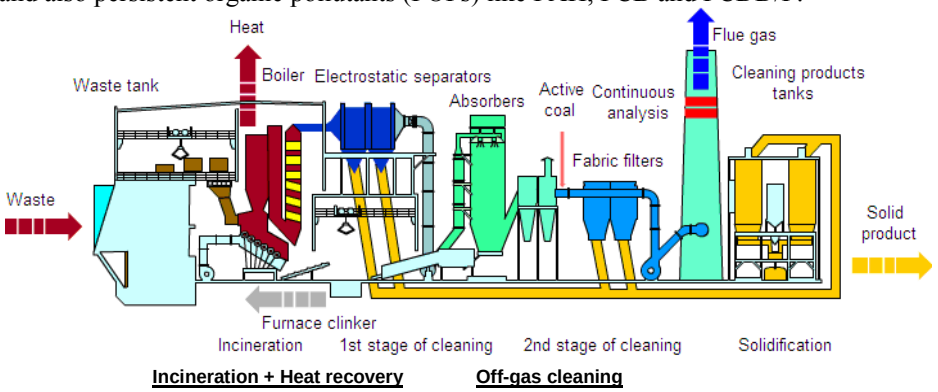

Figure 1 Schematic layout of typical unit for the thermal processing of waste

During the combustion process itself it is necessary mainly to keep temperature in the primary combustion chamber above 850°C, while in the secondary combustion chamber (afterburner) the required temperature is 1100°C and a 2 s residence time (Council Directive 2000/76/EC). These measures are designed to reduce mainly carbon monoxide VOCs and POPs. After completing the thermal treatment, the hot flue gas is utilised for preheating of combustion air and for the production of steam in a waste heat boiler (heat recovery steam generator, HRSG). Cooled flue gas after that undergoes mechanical and chemical cleaning, which removes polluting substances down to levels required by the applicable legislation.

Provided that all these steps are performed properly, it is then possible to re-classify waste incineration from a waste disposal technology to waste-to-energy process, as it makes full use of the waste energy potential and generates utilizable forms of energy.

3. Waste-to-energy process simulation

Systems for thermal treatment of waste have developed into complex processes consisting of several subsystems such as incineration section, heat recovery section, etc., as described above. Simulation software systems based on mathematical modelling support the design of up to date units for the thermal processing of waste (Cimini et al. 2005, Grieco and Poggio 2009). However, in order to be able to easily implement innovative processes and equipment it may be beneficial to create customized in-house packages (Friedl et al. 2008, Stehlík et al. 2000).

The author's group has recently developed a so-called W2E (Waste-to-Energy) software, which features such a supporting tool for waste treatment process simulation (Pavlas et al. 2005). It is written in Java and provides user-friendly and intuitive interface. The principle of modelling and simulation is the same as in other similar systems (Felder and Rousseau 1999). The software easily incorporates emerging new technologies, provides computer aid in the research and development of thermal treatment technologies and enables presentation of results on a professional level. Flexibility of the code is provided by its specific architecture ensuring that model modifications consist of few steps and no advanced programming skills are needed. The development of the W2E program is still in progress.

4. Design decision support, optimization

Computing-based methodologies can substantially contribute to improved design and bring together researchers and practitioners. Let us demonstrate this statement through the following examples.

4.1. Hot gas database

Heat recovery is one of the basic systems of units for the thermal processing of waste. Heat recovery system can be generally realized through a wide range of heat exchangers from conventional ones to specialized types. However, in real applications of units for the thermal treatment of waste, special types of heat exchangers are frequently proposed and designed. The selection between conventional and special type of heat exchanger depends mainly on the specific purposes of the heat exchange application in units for the thermal treatment of waste. Energy contained in flue gas is utilized for air pre-heating, steam generation, water heating or technological purposes. Unless due respect is paid to the specific features of process fluids in these processes, serious problems during operation may follow, including excessive fouling, structural damage due to thermal expansion and leakages.

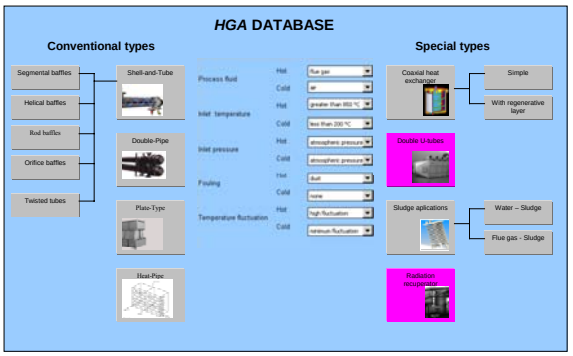

Figure 2 Main user interface window of HGA database

These were the key reasons that led to the development of a multi-purpose computational system equipped with a module featuring database for hot gas applications (HGA Database, see Figure 2), where data concerning both the common and specific types of heat exchangers are contained. HGA database (Kilkovský et al. 2007) is a decision support tool which helps to find optimum design solution as well as to avoid possible serious operating problems. Conventional heat exchangers are given preference in the selection strategy where possible, but in some cases there is no other choice than to select a novel type of heat exchanger (Stehlík 2005).

4.2. SNCR system design

Substantial efforts were recently reported to develop chemical kinetic mechanisms of the SNCR process that would be suitable for coupling with CFD codes e.g. by Cremer et al. 2000 or Saario and Oksanen 2008. Building on these results, successful simulations of industrial units e.g. by Shin et al. 2007 are the natural outcome and a proof that computational support in SNCR system design is both viable and reliable, in spite of the fact that most of such applications naturally do not appear in the open literature.

A comprehensive review of the SNCR technology covering both practical and modelling issues provides a paper by Tayyeb Javed et al. 2007. We may conclude this section by stating that computational analyses of SNCR systems in waste incinerators,

power plants (fired by pulverized coal) and biomass boilers are already applicable in the plant design phase.

4.3. Secondary combustion chamber design

Secondary combustion chambers or afterburners serve typically in hazardous waste incinerators to ensure complete decomposition of the products of the first stage reactor, which may be either a rotary kiln or a gasifier. Their design and operation optimization has been the subject of several experimental and CFD (computational fluid dynamics) studies. Most of them concentrated on the functionality (i.e. pollutant emissions), but some also discussed the possibility to optimize the design with respect to investment costs. There may also be observed a shift from experimental investigations of Watanabe et al. 1996 or Öberg 2003 to computational studies like those by Ficarella and Laforgia 2000 or Hájek et al. 2006.

The most notable difference between the experimental and computational works is that the latter typically examine several alternative design options, whereas all experimental works focused on operational parameters. Thanks to its cost-efficiency the computational approach may thus yield more fundamental improvements than experiments.

5. Design of contaminated biomass combustion unit

A new modern unit for energy production from contaminated biomass and/or alternative fuels, shown in Figure 3, is notable for its efficient integration of proven technological solutions using sophisticated computational support. The newly designed unit reflects present day's needs and the necessity to utilize waste biomass or biomass-based alternative fuels for the production of energy in ways regardful of the environment.

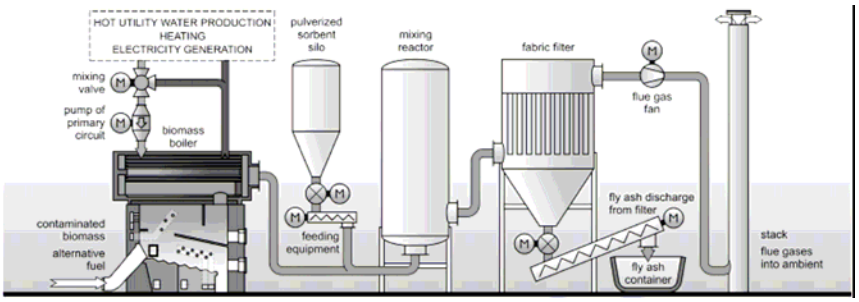

Figure 3 Schematic layout of the new unit for the utilization of contaminated biomass

Key features of the technology include optimized design, maximized heat utilization and minimized pollutant emissions. These features are discussed in some more detail in the following paragraphs.

5.1. Design optimization

During development of the unit, great attention has been paid to the combustion chamber. The locations and number of secondary air ports and flue gas recirculation were optimized using CFD (Computational Fluid Dynamics) modelling. An illustration of the CFD results is included in Figure 3. The issues addressed in the optimization process had a common target – optimum combustion conditions.

5.2. Heat utilization

Configuration of the heat utilization system (the boiler's main heat exchanger and utility extraction system to individual consumers or networks) is governed by specific needs in each individual application.

Condensing stage may be included in the recuperative unit. The heat exchanger is in this case made of stainless steel, with vertical tubes in which flows the flue gas and on the outside is the heated medium. Condensate collected at the outlet is sprayed back into the flue gas at the inlet section of the heat exchanger, thus washing the flue gas side of heat exchanging surfaces and preventing fouling.

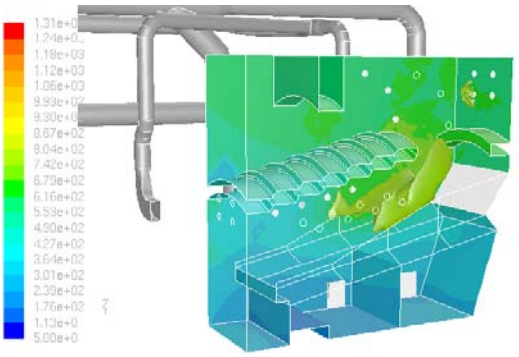

Figure 4 An illustrative display of temperature distribution on inner walls and iso-surface of 800°C in the combustion chamber (at 25% of the nominal firing capacity)

5.3. Flue gas cleaning

Combustion of contaminated biomass produces flue gas, which may contain various harmful compounds. Due to this fact, the unit must be equipped with appropriate flue gas cleaning equipment.

Formation of CO and volatile organic compounds is generally minimised by optimised design and operation of the combustion chamber, as these species are the products of incomplete combustion

Harmful compounds as for example nitrogen oxides, acid compounds (SO2, HCl, HF), heavy metals and fine particulate matter (fly ash) may also be produced by the combustion process. Due to this fact, the unit must be equipped with appropriate flue gas cleaning equipment designed specifically for the collection of those polluting substances that may appear in each individual application (e.g. injection of powder of sodium hydrogen carbonate (NaHCO3) for the removal of acid compounds, adsorption of traces of heavy metals on another pulverised adsorption agent, surface filtration in fabric filter, collecting both agents together with fly ash and products of neutralisation).

6. Conclusion

The present contribution provides a demonstration of up to date efficient and practically proven process system engineering approach in the field of environmental protection. Several examples are shown and novel features are highlighted. Due to limited space, references are provided instead of detailed discussions.

Process Systems Engineering: From Solvay to the 21st Century. A History of Development, Successes and Prospects for the Future

George Stephanopoulos

A.D. Little Professor of Chemical Engineering, Massachusetts Institute of Technology
77 Massachusetts Avenue, Cambridge MA 02139, USA

Abstract

The term Process Systems Engineering (PSE) is relatively recent, but the engineering of processing systems is as old as the beginning of the chemical industry, around the beginning of the 19th century. Initially, the practice of PSE was informal and as time went on it was formalized in progressively increasing degrees. Today, it is solidly founded on engineering sciences and an array of systems theoretical methodologies and approaches. This paper provides an overview of the history of Process Systems Engineering (PSE), i.e. its origin and evolution, a brief illustration of its tremendous accomplishments in the development of modern chemical industry, and an outline of the role it can play in addressing the societal problems that we face today; securing sustainable production of chemicals and materials for the human wellbeing, alternative energy sources, improving the quality of life and of our living environment. Finally, this paper proposes PSE as the foundational underpinning of modern chemical engineering; the only one that ensures the discipline's cohesiveness in the years to come.

Keywords: History of Process Systems Engineering, Process Development, Process Design, Process Control, Process Safety.

Introduction

PSE is the field that encompasses the activities involved in the *Engineering of Systems involving Physical, Chemical, Biological Processing Operations.* These systems, whose variety and purpose are very broad, include but are not limited to the following: Processing plants producing energy, chemicals and materials that societal needs require; manufacturing of a very broad variety of foods and devices that enhance quality of life; therapeutic products and processes to treat human diseases; and systems which ensure the quality of the environment in which humans, plants and animals live.

The approaches of today's formalized PSE are driven by two considerations: (a) The interest is in the "behaviour" of the system as a whole. (b) The emphasis is on studying how the components of the system and their interactions contribute to the overall "behaviour" of the system. The implications are clear: PSE is the integrative complement of all sub-areas of chemical engineering and the one that provides the significance and criticality, or absence thereof, of "local" engineering questions. For example, the operational and economic "behaviour" of a chemical process is the integrated effect of all its unit operations, whose criticality in determining the behaviour of the process can be systematically analyzed. Also, a drug is not just its active

component but a system with three interacting elements; active component, formulation additives, and delivery vehicle. Similar interactions one can easily recognize in the components of a product and associated fabrication lines (e.g. digital processors, LCD or OLED displays, batteries and fuel cells); the components of global production and transportation of energy systems; the constituents of energy and the environment policy-making systems, and others. It is fair to say that no manufacturing process or product reaches the market without the integrative scrutiny of systems engineering.

Mathematical modeling of the components' behaviour and their interactions is the essential tool of modern PSE activities, which along with the parallel development of computers, numerical methods for the solution of mathematical models, optimization theory, and dynamic systems and control theories constitute the formal framework of modern PSE. Consequently, the historical evolution of PSE is very closely related to the evolving needs of the chemical industry, the academic content of chemical engineering and a variety of supporting disciplines.

Today, PSE is well established as core capability in chemical engineering. Unfortunately, its educational foundation remains fragmented and a significant number of educational institutions do not recognize it as foundational component of the chemical engineering curriculum. As chemical engineering tries to redefine its intellectual core and disciplinary cohesiveness, and battles centrifugal forces to the interface with other disciplines, PSE retains its quintessential integrative character and provides the core glue to the development of chemical engineering in the 21st century.

1860s to 1920s: The Formative Period

The chamber and Leblanc processes for the production of sulfuric acid and sodium carbonate, respectively, in mid-18th century England are the most celebrated examples of the early chemical industry. Both were batch, dirty, and rather costly processes, and almost from their inception attracted the interest of businessmen, scientists, and engineers, who were challenged to develop processes with lower unit production cost, cleaner and safer. As people started looking into ways of improving the economics, safety and environmental impact of these processes, two things became clear very early on: (a) The manufacturing system had to be viewed as a system of interconnected operations. (b) The components of the manufacturing system, e.g. the chemistries at the core of the process and the separation units were determining the behavior of the system as a whole, i.e. economics, safety and environmental impact.

These observations set off the period of PSE that I will call the "Formative Period**",** and led to the initial informal delineation of the elements of what later on we would call "Process Development", the core element of PSE. It focused on the essential definition of the processing system, i.e. chemistries, reactors, separators, their integration into a productive whole, and the mechanical design of the equipment where the operations were taking place. The most celebrated example of this attitude is the *Solvay Process*, patented by the Belgian Ernest Solvay in 1861. Solvay may be seen as the first Process Systems Engineer. His 1872 ammonia-based soda production process was a breakthrough. He synthesized the process by interconnecting distinct operations of gas-liquid contacting, reaction with cooling, and separations; he invented new types of equipment for integrating these operations and carrying them out continuously on a large scale. He himself dealt with all aspects of an integrated chemical processing system: the chemistry, the materials handling, and the engineering of an integrated processing system, such as operating conditions and the design of specific equipment. The Solvay process may be seen the model process in which all aspects of PSE are explicitly delineated and directly addressed, in a fairly systematic and more importantly,

system-wide basis. Solvay went beyond the parts to the whole as the essence of the manufacturing system. The result was: a continuous process with careful integration of chemical and physical operations; use of recycles for improved yields and reduction of wasted raw materials; reduction of environmental pollution; and significant cost efficiency. Skip Scriven in his marvelous 1988 paper "On the Emergence and Evolution of Chemical Engineering" declared Solvay as the epitome of what we would later call "chemical engineer". It is therefore fair to argue that the original chemical engineers were in fact process systems engineers.

Over the following 50 years Solvay's essential guidelines for process development were adopted and further improved by many in England and America. Typical examples include: Rudolf Knietz's sulfuric acid process; Herbert Dow's inventive integration of electrochemistry and air-blowing processes that led to processes for bromide products, sodium hydroxide, chlorine, and many of their derivatives ; Charles Hall's production of aluminium; Comprehensive starch processes integrating chemical and fermentation operations; Carl Bosch's historic breakthrough process for ammonia, using Haber's catalytic chemistry; Dubbs' (Universal Oil) continuous thermal cracking process, etc.

By the late 1910s early 1920s, the process development experience of the previous 50 years has set the general scope of the PSE core. A chemical process is a system and its overall behavior is the coordinated effect of basic "Unit Operations"; a concept introduced by George Davis (Manchester Lectures, 1888) and a term coined by Arthur D. Little (MIT, 1915). A certain nascent standardization of the process development process is taking form: focus on cost, environment and safety; evolve from chemistries to processing systems, from batch to continuous processes; introduce material recycles and process system-wide management of energy; recognition that further improvements need better quantitative understanding of the process system at large.

Consequently, during the period 1860s to 1920s, the activities that today we characterize as Process Development (the core activity of PSE) define the central character of what is evolving to become Chemical Engineering. Thus, it is fair to say that during this period a Chemical Engineer is essentially a Process Systems Engineer.

1920s to 1950s: The Waiting Period

The identification of a chemical engineer as a process systems engineer becomes weaker and more tenuous during the ensuing period of 1920s to 1950s, which I call the "Waiting Period". During this period the focus is on the components of a process, i.e. Unit Operations, not the overall process as an integrated system. Continuous deepening in the understanding of the phenomena that take place in basic unit operations, leads to the invention of new unit operations and continuous improvements in the quantitative description of their behaviour. The foundational 1926 book "Principles of Chemical Engineering" by Walker, Lewis and McAdams organizes and provides elementary quantification for physical unit operations, but omits chemical reactors and, more to our subject, an overall view of a chemical process.

With respect to Process Systems Engineering the main developments during the Waiting Period are the following: (a) *Process analysis and design:* rudimentary material and energy balances are introduced and semi-empirical correlations form the basis for the design of unit operations. A gradually increasing quantitative sophistication in estimating reaction rates, transport rates, and thermophysical properties takes hold. (b) *Process Development:* The objective, as exemplified by the Dupont team (Chilton, Colburn) was fast and accurate process design and scale-up. Significant expansion takes place in the number, scope and complexity of new processes; high-

pressure, high-temperature, catalytic, multi-product processes. (c) The complexity of the new processes aggravates the trade-off problems that process designers must solve among cost, operational integrity, environmental emissions, and safety. The need for quantitative modeling of the processes becomes more acute.

In parallel and outside the disciplinary domain of chemical engineering, a series of important developments are taking place and will have a profound effect on the explosive growth of PSE from the late 1950s to today. These developments are: (i) Servo-regulator theory is introduced and addresses the instrumentation needs for monitoring and controlling chemical process operations, which become progressively more complex. This is the period of Bode, Nyquist, Ziegler, Nichols. Books on applied mathematics for engineers started appearing and creating an atmosphere conducive to the development and solution of better models for the description of physical and chemical operations: Sokolnikoff and Sokolnikoff, 1934; Reddick and Miller, 1938; Von Karma and Biot, 1940. Furthermore, the advent of still primitive computational machines is feeding developments on numerical methods for the solution of differential and algebraic equations, along with the introduction of academic courses to prepare the students. The works of Aitken (the δ^2-acceleration method; 1925), Steffensen (1933), and Wegstein (1958) will provide an essential tool for later steady state simulators. The foundations of Mathematical Programming are laid: Linear (Kantorovich,1939; Dantzig, 1947); Nonlinear (Karush, 1939; Kuhn, Tucker, 1951); and Integer (Gomory, 1958); all of which will play a profound role in the next phase of PSE developments.

1960s to Present: The Period of Explosive Expansion and Growth

By the early 1960s three factors are aligned to cause the onset of an explosive growth period for PSE: chemical industry had been growing rapidly, worldwide, for more than 10 years, exerting significant pressure for less costly and processes; a science-based description of the basic phenomena in unit operations is vigorously pursued, producing more reliable quantitative descriptions; the "computer" is entering industrial life in a very rapid determined way and affects all aspects of process systems engineering. The large jumps in energy and petrochemical raw materials, 10 years later, would further accentuate the need for better processes. From the 1960s to today we have witnessed a remarkable growth in the quality and number of PSE activities and practitioners, worldwide. In this article I will briefly overview the most influential developments.

Steady-State Simulators: By the early 60s chemical engineers can put together mathematical descriptions of reactions, their rates, thermophysical properties of pure materials and mixtures, equilibrium and rate processes, and do all of these as functions of equipment design parameters and operating conditions. Numerical methods are engaged to define procedures for the solution of these large sets of equations and computers are called to execute these procedures. The "Sequential Modular Steady State Simulators" come to life and spread very quickly; initially through in-house developments and subsequently supplied by external service companies. The impact of these simulators for the analysis, design and subsequent optimization and control of chemical processes cannot be overestimated. They are credited with 3-fold reductions in capital cost per unit of all commodity chemicals, over a period of 20-30 years.

Process Synthesis: As Dale Rudd observed, "Since World War II, engineering education has moved strongly toward analysis, with courses dealing with individual process operations and phenomena … greatly strengthening engineering education by

showing how things are and how they work. Unfortunately, there was not a parallel development in educational preparation dealing with process synthesis". Starting in late 60s, systematic Process Synthesis ideas allow process engineers to start with given chemistries and end up with quite inventive process flowsheets. Finally, after nearly 100 years the core activity of PSE, i.e. process development can be put into a rational and systematic framework. The impact of this development cannot be underestimated. Now we have a systematic way of "inventing" new processing systems, not simply analyzing existing ones. Eastman Chemical's new methyl acetate process is one of the most celebrated examples. It is a remarkable feat and its success depended on the "ingenious" integration of many elementary chemical engineering tasks.

Process Control: With increasing process complexity the limits of the servo-regulator theory became acutely apparent: strong interactions among control loops; convoluted logic and systems for controlling constraints; ineffective process optimization. In response, process control becomes more "process"-centric and with the following three important developments its practice was revolutionized: digital computers; model-predictive control; and plant-wide focus. Page Buckley's book in 1964 introduced the essential notions for a systematic plant-wide control approach, and was followed by extensive work from the 1970s on. The famous DMC controllers from Shell Development in the1970s took the industry by storm. They truly revolutionized how process control was going to be practiced from that point on: one consistent framework for set-point regulation; satisfaction of operating constraints; steady-state and more recently dynamic optimization of operations in conjunction with the planning and scheduling of operations. The economic impact of MPC was staggering: savings of more than 0.5 billion dollars from its application on 13 Dow Chemical ethylene plants; more than 4,500 deployed systems in major chemical plants over a 15-20 year period.

Optimization: The foundations of optimization theory were in good state at the beginning of the 1960s. During the subsequent 20 years, there was an explosion in the field and significant progress took place in developing effective algorithms for linear, nonlinear, and combinatorial optimization. Chemical engineers in increasing numbers become involved as practitioners and developers of new methodologies. As a result, the practice of optimization spreads very rapidly and is being applied in a large variety of PSE activities: Process Design; Process Synthesis; Process Control; Planning and Scheduling of Process Operations; Supply-chain Management; Development of Models from Data; Product Design; Metabolic Engineering; Oil and Gas Production.

Risk Management and Process Safety: In the 1970s and 1980s a series of environmental devastations (toxic leaks from Love Canal and the meltdown of reactor core in Chernobyl) and high-profile industrial accidents (Bhopal, 3-Mile Island, refineries) sharpened the sensitivities to risk management and process safety. PSE played a central role in addressing these issues. First, it pushed a new mindset in dealing with Process Integrity: from "React and Fix" to "Predict/Detect and Prevent". Second, it fostered the development of a comprehensive Process Safety Management approach with Inherently Safer Process Designs; Advanced Process Safety methodologies and tools; integration of Safety Instrumentation Systems with process control systems; and advanced methods for the design of LOPAs, on-line intelligent diagnostic systems, and others.

Current State and Future Prospects

The Systems-view has been incorporated into an ever increasing number of problems that chemical engineers have been addressing over the last 20 years: product and process design; multi-process and multi-plant integration; supply-chain management; development of pharmaceutical products and biomedical devices; technology and policy for the energy and the environment. Modeling, the core of all PSE activities has advanced to levels of very sophistication: atomic and molecular models; hybrid models with for continuous and discreet real-valued and integer variables. Simulation has followed an equation-oriented path opening up ever increasing possibilities: distributed processes in time and space; processing at the micro-scale; interfacing with statistical mechanics and computational fluid dynamics. Optimization theories and algorithms move in tandem with the increasing sophistication of the models and the size of the applications, while expanding continuously the scope of problems it addresses. Risk management and process safety continue to attract strong attention and support deployment of new technologies and methods. Monitoring, diagnosis, control, planning and scheduling of process operations are being integrated under common theoretical frameworks and computer-based real-time deployments. The results of these efforts have had a deep impact in industrial life and continue to feed new developments.

While efforts towards new improved methodologies and computer-aided tools will continue, the future of PSE activities rests with its ability to continuously renew itself by addressing new classes of problems that the economy faces. The author believes that the following features will characterize PSE activities over the next 10 years:

(a) *Continuous expansion into new areas*: Biology has been one and PSE practitioners have been heavily involved in "Systems Biology" and "Systematized Synthetic Biology", while we have seen the first PSE efforts in the area of materials. Both areas offer a rich variety of important problems to solve.

(b) *Continuous expansion of the boundary that defines the "System"*: Multi-plant sites define the new boundaries; production of different forms of energy, their transportation, and places of energy consumption determine ever expanding boundaries; technology and policy for energy and the environment brings into the system a series of "non-processing" entities. The process of development of pharmaceutical products and the national agenda of Smart Manufacturing require the definition of system whose boundaries include a multitude of other activities.

(c) *Modeling for Discovery and Technological Innovation*: Beyond simulation and design, modeling is at the heart of systematizing experimentation for scientific discoveries and accessing the "risk" in technological innovation.

(d) *From macro- to micro- to nano-scale PSE:* Constructing and operating systems with processing steps at the nano-scale presents a series of problems that present-day PSE has not addressed. Design and operational precision at the nano-scale, the role of shape and geometry, and self-regulation at all levels of the system, are some of the problems that would feed future activities in PSE.

(e) *From "Complicated" to "Complex" Systems Engineering:* The need to understand and model the behavior of self-assembled systems, biological processes based on

few molecules, or the ever expanding scope of classical systems with "humans" as some of their components, pushes PSE to go beyond the scope of well-defined but large and complicated systems, and develop new approaches and methodologies for the so-called "complex" systems.

Acknowledgement

Due to restrictions in the length of the manuscript, this paper is an abridged version of a longer paper currently under preparation with a full list of references. It is mportant though to acknowledge the input that many people have had, either in person or through their writings and presentations that generously shared with me. They are: Paul Barton; Larry Biegler; Jim Davis; Tom Edgar; Ignacio Grossmann; Christos Maravelias; Manfred Morari; Costas Pantelides; John Perkins; Jim Rawlings; Scip Scriven; Jeff Siirola; Jim Trainham; Venkat Venkatasubramanian.

New Opportunities for Process Systems Engineering in Industrial Biotechnology

John M. Woodley

Center for BioProcess Engineering, Department of Chemical and Biochemical Engineering, Technical University of Denmark, 2800 Lyngby, Denmark

Abstract

As industrial biotechnology develops into a mature sector in the coming years, new demands will be placed on evaluating economics and design to retrofit existing plant as well as design new plant. Process systems engineering will also have a major role to play in design of suitable control systems on a rigorous basis. Some new problems will also be forthcoming due to the particular characteristics of biological processing and this too will provide exciting opportunities for process systems engineering.

Keywords: bioprocesses, biocatalysis, fermentation, modeling, simulation.

1. Introduction

Process systems engineering offers many tools for the chemical engineer. Modeling, simulation and process evaluation tools are routinely applied in the bulk chemicals and fuels sector where small process improvements yield significant economic returns. In recent years bioprocesses have become more common. In particular they have found application in the high value products such as pharmaceuticals (and their intermediates). The emphasis in these cases is on rapid process implementation. However in recent years bioprocesses have been applied to bigger volume products such as fine chemicals, bulk chemicals and fuels. In these cases process improvement is the emphasis since this will give significant returns. A range of questions need to be addressed. For example: When should a bioprocess, rather than a chemical process be implemented? If a bioprocess is to be implemented can existing infrastructure be used? How can process plant be adopted for different biomass in different global regions? What is the optimum biorefinery? What options exist for process integration? Quantitative tools are required to solve such problems and process systems engineering has many of these tools currently. In addition, in the case of bioprocesses an extra option available to the engineer is the improvement of the catalyst itself. Hence we are now at the point that process engineering tools need to be applied to the complete set of bioprocesses, including pharmaceuticals, fine chemicals, bulk chemicals and fuels. The main synthetic operations include fermentation, microbial catalysis and enzyme catalysis. Downstream options are dependent on the nature of the product (macromolecular or small molecule). Small molecules are frequently processed in a similar way to other chemical products, although dilute aqueous solutions bring specific problems which need to be addressed. Macromolecules require more specialist operations such as filtration or chromatography. In all cases the molecules are frequently sensitive to extremes of pH and temperature placing specific restrictions and constraints on processing methods. Catalyst recovery (sometimes for recycle) also necessitates filtration and centrifugation. In this paper the specific role of process systems engineering in the development, design and improvement of industrial bioprocesses will be discussed.

2. Scope

Biotechnology is an enormous sector of industry from high value, low volume products (such as pharmaceuticals) to low value, large volume products (such as bio-fuels). To date the majority of implemented processes have focused on the former group. The emphasis here has been on implementing processes effectively to meet the tough regulatory demands placed on such products. Process implementation, rather than optimization, has been the necessary focus of process engineering (e.g. Pollard and Woodley, 2007; Woodley, 2008). In this paper the future processes for biotechnology which fall into the latter category will be discussed. These are the new sectors of industrial (or also called 'white') biotechnology where new opportunities exist for alternative feed-stocks based on renewable resources such as biomass and clean processes with reduced solvent inventories, renewable catalysts and mild conditions for reaction and separation (e.g. Dale, 2003). However this new 'bio-economy' will require the development of a suitable infrastructure and, like the oil-based counterpart will demand very high yield processes meaning that process engineering for the future implementation and development of these process will have an increasingly important role. Given the maturity of the field of process systems engineering it is clear that many new opportunities will be forthcoming.

3. Industrial biotechnology processes

3.1. Fermentation processes

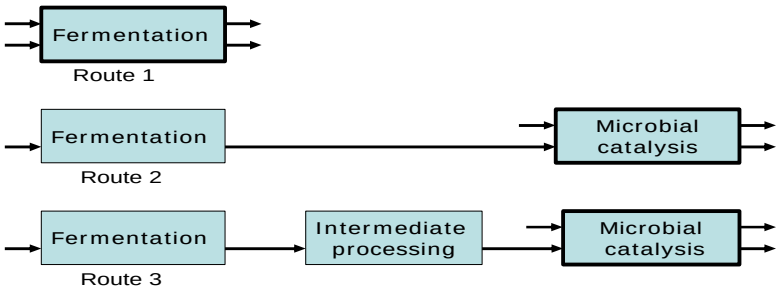
For a significant number of chemicals, the use of fermentation has become a standard alternative to fossil-based feed-stocks and technology. Nevertheless the possibility of growing microbial cells on a variety of sugars (derived from renewable biomass) has re-invigorated interest in this area. The consequence is that fermentation at a large-scale will become more common in the future of the chemical industry. Many fermentation processes can take place in similar process plant which is a significant advantage. The plant is relatively simple and the challenges lie in adequate mixing (sometimes with materials having complex rheology), suitable oxygen input (for aerobic processes) and process control. Downstream, the separation process depends on the product but will nearly always need to avoid high temperatures and extremes of pH. The solvent is water, meaning that the dilute product stream combined with the presence of many other products presents a significant process engineering challenge. Both large molecular weight and low molecular weight products can be made by fermentation. Most industrial biotechnology processes (excluding pharmaceutical processes) focus of low molecular weight products which can subsequently be used as platform chemicals or fuels or enzymes (for application in a range of industries, including detergents, textiles and food ingredients).

3.2. Microbial catalysis

In fermentation processes, by definition, the catalyst is growing during the process. This means that some of the reactant (or substrate) will inevitably be diverted from the product towards the catalyst, lowering the yield. An alternative (for no growth associated products) is to grow the cells first and subsequently carry out the reaction to increase the yield. This also enables the possibility of growth and reaction on different substrates (reactants) or under different conditions in each stage (such as temperature). Likewise the optimal cell concentration for conversion can be selected (Woodley, 2006) and suitable media for effective product recovery chosen. For processes requiring oxygen it can be highly important to select the optimal cell concentration in order to

avoid mass transfer limitations. Several tools are now available for evaluating the oxygen supply issues in such reactions (Baldwin et al, 2006; Law et al, 2006). The three potential routes are shown in Figure 1.

Figure 1: Alternative process scenarios for use of microbial cells for non growth associated biocatalysis. (Route 1 - Combined fermentation and microbial catalysis; Route 2 – Fermentation separated from microbial catalysis; Route 3 – Fermentation separated from microbial catalysis with intermediate processing to change catalyst concentration).



3.3. Immobilized enzyme processes

The presence of so many products is a consequence of the complexity of cells where many enzymes catalyze reactions giving a spectrum of products as well as decreasing the yield of the desired product on the reactant. An alternative, for short pathways, is to isolate the enzymes and then immobilize them on a solid support or behind a membrane or via aggregation, such that they are large enough and have the right properties to be recycled (like a heterogeneous catalyst). In this way a yield of product on the catalyst of around 5 – 10 tonnes / Kg catalyst can be achieved, which enables economic industrial operation. Such an approach has been widely used to assist in the synthesis of high value compounds such as pharmaceuticals and a limited number of well known lower value products such as high fructose corn syrup (HFCS). Many of these processes have been modeled (e.g. Chen *et al*, 2007).

4. The role of process systems engineering

4.1. Evaluation of process options

For some higher value products a bioprocess may in some cases be the only route to a given product (to ensure correct folding of a therapeutic protein for example or the synthesis of an optically pure pharmaceutical intermediate). However, the more usual situation is that there are other competing routes to the same product. Therefore, for now, biotechnology is just one of a number of options for the production of chemicals and fuels. The economic drivers for implementation depend on existing infrastructure, feedstock costs, feedstock availability as well as the efficiency of the relevant (bio)catalyst and (bio)process technology. This presents a fascinating set of alternative

routes and technologies from a given feedstock and/or to a given product(s). Process systems engineering has a particular role to enable such evaluations on a quantitative basis. Process systems engineering also bring the advantages of rapid computational methods such simulations enable alternatives to be quickly evaluated. The answer in a specific case to the problem formulated here will in addition depend on regional factors. Feedstock availability and cost is highly dependent on geographical location. A parallel set of evaluations concerning the need to retrofit existing plant, or build new plant, is also required. Objective functions to be optimized will need to be based not exclusively on economics but increasingly based also on sustainability metrics (e.g. Henderson *et al*, 2008) and integrated with life cycle analysis (to include evaluation of feed-stocks and products as well as processes).

4.2. Evaluation of platform chemicals

While the increasing cost of oil is driving particular interest in the production of new fuels from biomass there is little doubt that today of equal importance is the production of chemicals from biomass. Indeed for the supply of fuels in the future there are many potential sources aside from biomass. In a world with limited (or very expensive) oil it is less clear where the chemicals of the future will originate. There is currently an existing infrastructure based on the use of the 7 established platform chemicals (toluene; benzene; xylene; 1,3-butadiene; propylene; ethene; methane). In the short term one could consider if we can use the same infrastructure and just create the 7 chemicals from alternative sources. However in the longer term it will be necessary to devise new processes based on a different set of platform chemicals. One group will be based around glucose (the hydrolytic product of starch and cellulose and therefore readily available from biomass). In a biorefinery it will be necessary to develop a structure which can manage a range of feed-stocks, a range of technologies and a range of products. This presents a considerable challenge for design and optimization as well as process integration. An interesting example which illustrates the complexity and the challenge that lies ahead is the use of glucose or fructose to produce 5-hydroxymethylfurfural (HMF) or 2,5-furandicarboxylic acid (FDA). Greatest value is obtained by going the whole way from glucose to FDA. However even in this small reaction pathway there are many alternative technologies. Some can be integrated together, some give the required yield and selectivity, some are difficult to implement and others are untested at scale. This illustrates very well the challenge that design engineers face.

4.3. Process integration

The solvent for all bioprocesses, with a few exceptions, is water. Consequently the downstream process is frequently difficult and this is emphasized by the need to carry out separations at moderate temperatures. Given the dilute nature of the streams it is frequently the case that the majority of the costs are therefore in the downstream process. In the case of transport fuels removal of water becomes an essential requirement to reduce costs and avoid transporting large amounts of water. For example, in the case of ethanol which forms an azeotrope, this can be a significant cost. In other cases the product may be integrated within a biorefinery although at some point water will need to be removed. Consequently the integration of water use and reuse via recycle is an essential part of the design of industrial bioprocess facilities. Existing tools such as pinch technology will have an important role. The issue of water use in a biorefinery is in many ways analogous to the issue of heat use in a conventional refinery.

4.4. Biorefinery design

Two major types of biorefinery have been identified for the future, based on lignocellulose biomass utilization to provide a arrange of sugars (for subsequent (bio)catalysis or fermentation) and oil-based material (from biomass). In each case the current research emphasis on biorefineries is to ensure all the fractions of a particular biomass in a given situation are fully exploited. Likewise the development of downstream products is now being explored. For example glycerol (as a byproduct of biodiesel production) can be used as a platform chemical (for example via fermentation to produce 1,3-propanediol). Another interesting example concerns the production of bio-ethanol. This is widely developed as a fuel although there is considerable economic incentive for developing a range of other products (e.g. acetic acid) from ethanol, in other words using it as a platform chemical (Rass-Hansen *et al*, 2003). It is clear that evaluating integration of product and feed streams in this way, as well as use of products as fuels or platform chemicals will be an important role for process systems engineering. There is little doubt that the increasing range of technologies and opportunities as a result of enzyme–based or fermentation-based catalysis will give complex integration problems, which may require new tools (as discussed also in 4.2).

4.5. Biocatalyst design

A particular feature of bioprocesses is the use of biocatalysts, which may exist in several forms as indicated earlier and where options exist for modification. At the simplest level as a protein (isolated enzyme), the options for swapping amino acids via protein engineering exist. New enzymes which have been modified may display new tolerance to reactor conditions such as temperature or pH and may also have improved selectivity of reactivity (activity) on a given (non-natural) substrate or reactant. Order-of-magnitude improvements have been found in a number of cases although understanding the most effective method of making changes to the enzyme depends on past precedent and, to some extent, structural knowledge (e.g. Hibbert *et al*, 2005). In the case of cellular catalysts, individual enzymes can be over-expressed (increasing reaction rate of a given cell) and the regulatory control scheme fixed to direct the carbon to give improved rates and yields (via metabolic engineering). Some start has also been made to the development of pathways where enzymes coming from a variety of sources are cloned into single host to make a new pathway via a combination of genetic engineering and *de-novo* pathway engineering (e.g. Chen *et al*, 2006). In all these areas it is clear that those involved in process systems engineering need to inform the biological engineers about what is required in a given case and set suitable targets. Philosophically it is interesting to note that process implementation may come via process improvements or alternatively via catalyst improvements. In many cases both will be required. Understanding the necessary balance between these areas, as well as their integration with each other will be important for the future development of the field.

5. Future outlook

The development of new bioprocesses as a complement to existing chemical and fuel production is an exciting endeavor that will occupy many process engineers in the future. There will be a particular role for process systems engineers in this developing sector with the advantages of quantitative decision-making tools and rapid simulation that this brings. In the future suitable models will inform developments at the infrastructural level (evaluation of biorefineries, feed-stocks and integration), the process level (evaluation of alternative technologies and process integration) and the

catalyst level (alternatives for protein and metabolic engineering). The further development of process systems engineering tools (including property prediction packages and the development of a database for bio-based molecules) will be required. In addition an increasing dialogue with biochemical engineers and biologists will be necessary to enable the vision of industrial biotechnology to be fully exploited.

The Significance of Experiments on PSE

Günter Wozny, Harvey Arellano-Garcia

Chair of Process Dynamics and Operation, Sekr, KWT-9, Berlin Institute of Technology, Strasse des 17 Juni 135, D-10623, Berlin, Germany

Abstract

Chemical product design, manufacturing and its process imply a spectrum of chemical and physical phenomena over different scales in time and space. An increased use of process simulation in different phases of process life cycle and on different scale makes the information management related to the modeling procedure and practice more relevant. With more complex models also experiments are of increasingly importance for model validation and an improved process understanding. However, the experimental data and meta-data has to be linked simultaneously to the simulation results. Moreover, the requirements for more efficient models, customization, reuse and documentation increase too. The benefit of systematic approaches such as experimental design methods are not sufficiently exploited and should be introduced in the normal process development procedure. Concurrent process development leads to new demands for experimental work beside the process simulation, synthesis and process control. In education new modern and effective standardized and modularized experimental training stations are needed for better understanding and increased students interest. In this work, different aspects of the significance of experiments related to PSE will be presented. For this purpose, different examples are selected and discussed in detail.

Keywords: distillation, ethylene separation, energy saving, process simulation.

1. Introduction

The chemical engineer's work involves a wide range of scales: from molecule in nanometers to plants and enterprises in km and from molecular rotation in picoseconds to life cycle analyses of plants in years. In the last decade several aspects have been investigated in detail and described in literature. Chemical engineering is changing from process design to product design and the integration of both. In the late 19th century till the 1960s the "Unit Operation concepts" including dimensionless group correlation was leading in research and education. Starting form the early 1960s transport phenomena (Bird et al, 1960) became a more and more important branch. Transport phenomena in fluid flows and those related to turbulence, droplets, films, bubbles got more attractive because these methods have helped engineers to get a better insight into the processes. In comparison to Unit Operation scale, transport phenomena were based on a smaller scale. Today, simulation tools like CFD support these methods and a wide range of successful applications in industry and academia have been reported. In the opposite scale direction, aspects of plant wide simulation, plant wide control were considered and investigated starting from the 1980s till today. Nowadays, simulation tools in industrial applications such as Aspen, ChemStation, Simulation Science etc. support engineering work. In fact, PSE methods are currently used in the daily engineers work in process design, optimization and control. Is there anything missing or what can be improved? In

this work, the main focus is not on detailed improvements of any single PSE method. It rather discusses the significance of experiments to PSE. Is there any need to consider these aspects in PSE or can PSE be seen completely separate from experimental research? For an improved understanding of this question, it is helpful, as usual, to take a short look in the literature and discuss definitions and the basics of PSE. For instance, Grossmann and Westerberg (2000) wrote "Process Systems Engineering is concerned with the improvement of decision – making processes for the creation and operation of chemical supply chain. It deals with the discovery, design, manufacture, and distribution of chemical products in the context of many conflicting goals" They continued: "The PSE area can also have validation through experiments for physically existing systems, but, in most cases, PSE has only "virtual" systems in the form of models (e.g. in the conceptual phase of a design). One can test the models, ideally by proving and disproving theorems about them, but, more often, one can only prove mathematically some useful properties or empirically demonstrate that the proposed model works for a set of example problems. So, it seems that experiments are not so important for PSE and there would be only a weak connection. The topic of education is reflected by J. Perkins (2000), he postulated in his article: "Educators have been concerned to develop curricula and courses designed to help students to adopt a "systems approach" to engineering problem solving". He continued: "Design is not only something picked up by experience but is a formal procedure with its own rules which could not only learnt by students but could be taught in a rigorous manner. The Chemical engineer needs to know about a whole range of techniques outside the narrow ever more scientific approach of chemical engineering science." In the attached tables about curricula, the reader will find in the first and also in the second year only one lecture related to experiments from 15 topics like simulation, design. Is that enough? Also, Ziemlewki (2009) summarized aspects in the direction of "Designing the New Global Chemical Engineer". Important topics in this paper are applied mathematics, software implementation, modeling aspects. It is recommended to teach Soft skills and train students in teamwork, leadership aspects, communication, cultural diversity understanding. Nothing about experimental skills is recommended there. Which are the main reasons? Based on our personal experience it is the opposite. Experimental knowledge should be expanded. Students should do different work in laboratory during their studies. Group work should be expanded. Some of the reasons, why experimental work is reduced, are well known. Experiments are expensive and time consuming. How can PSE improve this situation?

Research is, simplified expressed, formulating a hypothesis, observing nature or the real behavior in the plant, in part of the plants, making conclusions and integrating them in a more global context. If we would know all, then no experiments would be necessary. I noticed, once more this is a personal view and experience, an increased uncritically believing what the computer creates by our young students. They like to do computer work by trial and error and stop working after any undesired result happens. They have apparently success very quickly, but often without deep understanding. Because simulation does not support the creation of a mental process model as it does the experiment, there is no critical reflection. How can we change this situation? As we know, methods of Process development are beside the typical PSE methods like simulation and optimization, searching in literature and patents, doing labor experiments (seldom direct usable for equipment design), investigating behavior in Mini-Plants (reducing risk, determination of technical parameters), investigations in pilot-plants (all Unit operations, recycle streams included, cost analysis). Already

Krekel and Siekmann (1985) described important aspects of the role of experiments in process development. Design data for the improvement of existing plants or for the development of new chemical processes are often determined by experiments in laboratories and pilot plants. These frequently expensive test-runs should lower the scale up risk and should ensure its long term functioning and its economy. In this stage, PSE with selected methods like optimal experimental design for an exact planning of experiments can minimize the cost of development. Process simulation, process optimization, control design methods should support the experimental work in parallel. The main aims of experiments are often: determination of reaction data, delivering of first balancing data, production of small charges of products for selected first customers, generation of scale-up data, providing economic data, ensuring long term functioning.

During this stage of process development PSE methods should be used to improve and speed up the design process. An efficient process development can be done by combining Process Simulation and Mini-Plant technique. Moreover, the current economic situation, the international competition and the product life cycles, which are becoming shorter, demand a significant reduction of time from the conception of a product to its market introduction. A significant contribution to rapid and cost effective process design is the combination of PSE methods and experimental methods in different scales. Despite this, it can be noticed very often that PSE methods are used partially or totally independent from experimental work. Often different persons and even different departments are involved solving the postulated problems either in the PSE direction or doing experimental work. A more promising way is to use PSE methods like simulation, optimization and considering control aspects parallel to the experimental investigation from the very beginning. The following selected applications show how some aspects of this approach influences the results.

2. Applications

Changes in process conditions can influence behavior by changing the value of process parameters or by changing the constraints of the model considered. Thus, the dynamic behavior of a process unit will proceed through a series of states, with each state being associated with a different mechanism or model. Although the models are a formalism, the information of such models may offer insight into the considered processes underlying the phenomena being examined, and may be useful in suggestions for new experiments. A common *modus operandi* is to examine the prediction of a number of models, and make out which models are particular good at describing the experimental data, by means of fitting procedures or statistical methods (Faber et al., 2007). Nevertheless, the quality of model predictions for the description of the underlying phenomena depends on the model structure and on the values of the contained parameters which have to be fitted for model validation using experimental data. These measurements are not only used to determine the state variables but also to improve the quality of the process models. Despite increasingly rigorous process modeling, most of the process models use process parameters which have to be determined based on measurement data. As most of these model parameters depend on the actual state of the process and the plant configuration, and therefore, are subject to changes during process operation, it is in many cases reasonable to adjust these parameters using data taken directly from the plant. However, after the estimation, it is important to asses the

reliability and adequacy of the model and of the new parameter estimates again following an iterative procedure. Many relevant processes in bio- and chemical engineering are still not well understood, because the underlying physics is complex. A representative class of processes involved in this contemplation corresponds specifically to catalytic reactions. In these processes several steps could influence the reaction rate (see Fig. 1, for the reaction A→B). First, component **A** has to diffuse from the bulk flow towards the boundary layer (a). Following this, it has to enter into the catalyst pores (b). Then it can be adsorbed on the catalytic surface (c), where the reaction takes place (d).

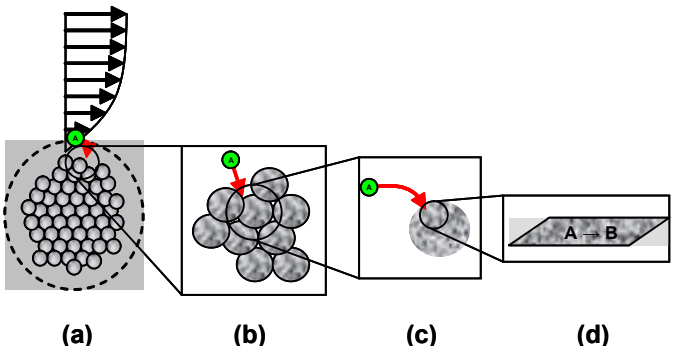

Figure 1 (a) External diffusion; (b) Internal diffusion; (c) Adsorption; (d) Reaction.

These steps are followed by desorption and transport of the product B to the bulk flow. At the steady state operation is though common to work with a rate limiting step (RLS) assuming that only one step dominates the reaction resistance. In most of the cases it is the reaction step (d). However, each step can be described with a set of model equations. The question is whether it is possible to identify process states, in which other steps dominate the process. This may occur, for example, due to catalyst decay. With this knowledge suitable counteractive measures can be initiated. A so-called Automated Mechanism Recognition (AMR) approach has been developed, which is based on the recognition of current dominant mechanisms (Arellano-Garcia et al., 2008).

Another application of interest on this issue represents the **fluidized bed reactor** for the OCM (oxidative coupling of methane) process. This suggestion is based on the fact that gas-phase reactions occurring in the bubbles are significantly slower than the catalytic reactions, which are very sensitive to the presence of oxygen. Oxygen is necessary for the reaction to occur, but unfortunately excess of oxygen or it's high availability to catalyst can cause combustion reactions to be dominating in comparison to selective – methane coupling reactions. Therefore so called "distributed feed of oxygen" is needed in order to control the combustion reactions and achieve higher selectivity.

This is possible with either **membrane reactors**, reactors with oxygen co-feed or with fluidized bed reactors for very fast catalytic reactions. The "co-feed" principle can only occur in fluidized bed reactors if reaction is significantly faster than mass-transport between bubbles and emulsion, and therefore controls the overall reaction rate. In this case, working conditions with excess of methane will ensure low oxygen concentration in the emulsion phase, and therefore increase the rate of selective reactions compared to combustion reactions. For getting a qualitative overview of the problem, model-based and experimental analysis of the reactor are needed.

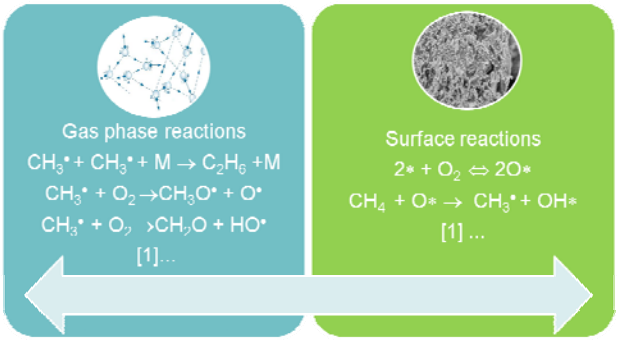

Figure 2 Gas phase and surface reactions in the OCM Process.

Another application in this work is given by a dynamic model for a **catalytic fixed bed reactor** (FBR) based on partial differential equations (PDE), which is discussed and used for the identification of reaction mechanisms taking place during the oxidation of sulphur dioxide over a vanadium pentoxid catalyst. The measured data is collected from a pilot plant, which uses commercial sized catalyst particles. In order to reduce the experimental effort a developed framework based on the methods of nonlinear optimal experimental design is applied using a steady state FBR model (Schöneberger et al., 2008, 2009). The systematic procedure is improved using a dynamic reactor model. This makes the time dependent measurement data valuable for the identification procedure.

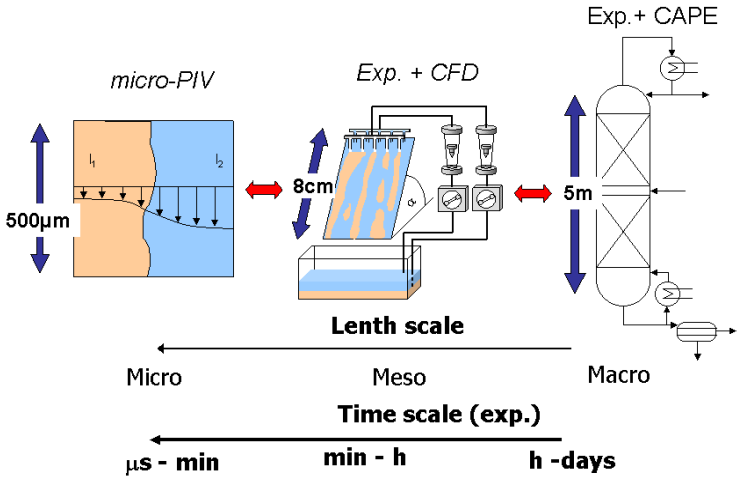

Figure 3 Combination of PSE method and experiments to understand flow behavior and separation efficiency of three phase distillation column.

In **three phase distillation** a counter current vapor flow influences the liquid flow additionally. Since the interfacial area between all phases is significant for mass and heat transfer, the determination of the interfacial area is necessary (Hoffmann et al., 2005). For this purpose, experimental setup for optical measurement methods, like particle tracking velocimetry (PTV), light induced fluorescence (LIF) and µ-PIV (Micro Particle induced velocimetry) are employed. To use the µ-PIV for investigating the flow velocity in packing expenditure is necessary. Normally a transparent plate is used and

the measurements are done from the back side. For this application the measurement technique has to be expanded to non transparent materials. With this modification usage of the experimental data for model validation is possible. Comparison of the experimental results with CFD simulation will be shown. The investigation of three phase distillations shows that the analysis of different scales from m up to μm and from minutes and hours up to μs is necessary for an improved understanding and description of the physical behavior of chemical processes (see Fig. 3). Using only one single PSE method (e.g. process simulation or parameter identification or CFD simulation) is not sufficient. On the track of understanding three phases (two liquid, one vapor phase) in one packed tower a detailed knowledge about the complex fluid dynamics on the packing surface is required. New measurements methods and the parallel use of different PSE methods as experimental design, parameter identification, CFD simulation would increase the efficiency and the speed of development.

3. Conclusions

For process design and development PSE methods and experimental investigations should be combined from the early state. By this means, risks of scale-up such as temperature distribution in the reactor, cooking of the catalyst, mechanical stability, different flow patterns leads to different yields and selectivity, foaming in columns, reboiler and so on can be reduced. Some of these problems can be solved by simulation. Parallel good planned experiments are necessary.

A Review of Sustainable Energy – Recent Development and Future Prospects of Dimethyl Ether (DME)

En Sup Yoon, Chonghun Han

School of Chemical and Biological Engineering, Seoul National University
Shillim-dong, Gwanak-gu, Seoul, Republic of Korea.

Abstract

DME can be synthesized from natural gas, coal, biomass, and/or coal seam, and is a sulfur-free, near-zero aromatics synthetic fuel which is considered as an excellent substitute for conventional diesel and liquefied petroleum gas. Currently, various production technologies are developed and many commercial projects are actively being progressed. This paper presents recent development and future prospect of Dimethyl Ether (DME) as an alternative energy and simple review for biomass energy.

Keywords: dimethyl ether, sustainable energy, alternative fuel

1. Introduction

Sustainable energy resources are fundamental to economic stability and development. The threat of climate change, the erosion of energy security, and the growing energy needs of the developing world, all pose major challenges to energy decision makers. Innovation of new energy technologies and a better use of existing technologies will be required to meet these challenges. Environmental pollution and the greenhouse effect, resulting from high dependency on petroleum based energy resources, cause special concern and threaten energy security. As a result, greater efforts and attention are given to the development of non-petroleum based energy resources.

Among the candidates for the non-petroleum based energy resources, solar, geothermal, wind, and tidal energies have received much attention as green energy sources, while biomass energy, hydrogen and fuel cells, and gas-to-liquid coal gasification have been the subject of intense study as synthetic sources. Recently, synthetic energy sources have been in the lead among alternatives to petroleum based energy for their environmental friendliness, high energy density, and potential for commercialization. This paper deals with one of the synthetic energy challenges, dimethyl ether (DME). DME can be synthesized from natural gas, coal, biomass, and/or coal seam, and is a sulfur-free, near-zero aromatics synthetic fuel which is considered an excellent substitute for conventional diesel and liquefied petroleum gas (LPG). In this paper, we introduce recent studies and review the technological and economic aspects of DME manufacture and its prospective use as an alternative fuel. Also, we will review the biomass energy that can be used as feedstock for various synthetic energies as well as DME in the presentation.

2. Properties of DME

The properties of DME suggest that it could be a substitute for petroleum based energy with much better environmental performance. DME is a sweet nontoxic chemical with an ether-like odor and is liquefied at 6 atm or -25□. The characteristics of DME are

similar to liquefied petroleum gas (LPG), which can be used in replacement of LPG for domestic heating, clean combustion automobiles and for exploitation of existing land-based and ocean-based LPG infrastructures with minor modifications.
With a cetane number of 55-60, DME is also considered a substitute for diesel fuel (cetane number 55). The cetane number is a measurement of the combustion quality of diesel fuel during compression ignition. It is a significant expression of diesel fuel quality among a number of other measurements that determine overall diesel fuel quality. Notably, when compared with diesel fuel in CIDI engine tests, the combustion of DME produced much less pollutants than diesel (e.g., hydrocarbons, carbon monoxide, nitrogen oxides, and particulates).

3. Production Technology

3.1. Chemistry

DME is produced in a minimum of two steps. First, hydrocarbons from natural gas, coal, or biomass are converted into synthesis gas (syngas), a combination of carbon monoxide and hydrogen. Second, the syngas is then converted into DME in two different ways. One way is a conventional two-step process which consists of methanol synthesis and dehydration; the other is a one-step process which directly produces DME from syngas. The reactions are shown below.

Table 1. DME synthesis chemistry

Partial oxidation reforming	$CH4+1/2O2 \rightarrow CO+2H2$
Steam reforming	$CH4+H2O \rightarrow CO+3H2$
Gas/water shift reation	$CO+H2O \leftrightarrow CO2+H2$
Methanol synthesis	$2CO+4H2 \rightarrow 2CH3OH$
	$CO2+3H2 \rightarrow CH3OH$
Methanol dehydration	$2CH3OH \rightarrow CH3OCH3+H2O$
DME direct synthesis	$4H2+2CO \rightarrow CH3OCH3+H2O$

3.2. Process Technology

Regardless of the reaction route, the reforming technology for syngas production is fundamentally necessary for DME production but is not included in this review because it is a well-defined technology. The main process technologies for producing DME are classified according to reaction chemistry. Two step technologies, i.e. indirect synthesis, employ two reactors because the reactions must take place in separate reactors. Toyo, MGC, Lurgi and Udhe have their own indirect processes for DME production. On the other hand, one step technologies, without the intermediate production and purification of methanol, include Haldor Topsoe, JFE Holdings, Korea Gas Corporation. Air Products and Chemicals has also developed a different one-step process for direct synthesis in the liquid phase. Distinguishing features of the various technologies will be given in the following section.

3.2.1. Two Step Technology

The process licensed by Toyo has two distinguishing characteristics. First, the highly active steam-reforming catalyst developed by Toyo (ISOP catalyst) is applied to the reforming unit in the syngas generation process to make the facilities more compact. Second, the high performance MRF-Z™ reactor developed by Toyo, which has the features of multi-stage indirect cooling and radial flow to the methanol synthesis unit,

allows the construction of a unit upto the capacity of 6,000 ton/day in a single train. The process is composed of single train methanol synthesis and single train DME synthesis without using an oxygen generator even in a large capacity DME plant of 3,500 tons per day. Toyo successfully operated a fuel-use DME production plant in Sichuan Province in China in 2003. In the summer of 2008, the fifth fuel-use DME plant is to start operation at Shanxi Lanhua Clean Energy CO., Ltd. in Shanxi province in China.

3.2.2. One Step Technology

Korea Gas Corporation (KOGAS) has developed a process for DME direct synthesis from natural gas, CBM and bio gas. This process consists of reformer section, CO2 removal section, methanol regeneration section, DME reactor section and DME purification section. The tri-reforming process, using natural gas that contains 10 mol% CO2, was developed for the syngas process. A new catalyst was developed by KOGAS for DME synthesis. KOGAS demonstrated a 50~100-kg/day pilot plant in 2003 and a 10-ton/day pilot plant on 2008.

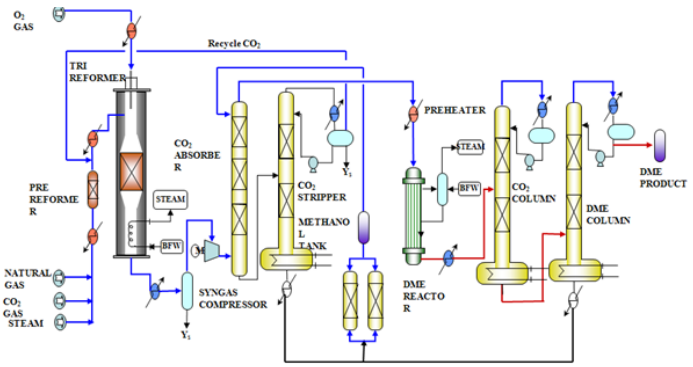

Fig. 1. The direct DME synthesis process developed by KOGAS

3.3. Related Research Works

Research on technologies for DME production has included improving catalyst activities for one-step and two-step reactions, studying reactor types such as fixed-bed reactor, slurry reactor, and fluidized-bed reactor for effectively removing reaction heat, studying the process operation, and improving optimization and scale up, and so on.

The fluidized-bed reactor is at the initial stage of laboratory testing, and its feasibility has not been yet established. Investigators are studying two different reactor types for the commercialization of DME synthesis: bubbling slurry reactor and fixed bed reactor. In a slurry reactor, fine catalyst particles are suspended in a solvent and the feed gas enters as bubbles from below. Controlling the reactor temperature is manageable, thanks to the large heat capacity of the solvent that is cooled by heat exchange tubes in the reactor. However the reactant should be transferred from gas bubbles to liquid phase solvent and then to catalyst particles for the synthesis reaction. Low diffusivity in the liquid phase can slow down the overall reaction rate. Loss of fine catalyst particles from the reactor could also be a problem. Much more data from further experiments would be needed for scale-up of the process. The fixed-bed DME process can potentially solve those problems. Therefore, our research group has developed a shell-and-tube type fixed-bed reactor with KOGAS. In a fixed bed reactor, operations are difficult, and the control of exothermic heat within the DME synthesis reactor is a primary problem.

Catalysts can be irreversibly deactivated when exposed to high temperatures (330^{o}C). Therefore, it is necessary to understand and predict reactor behaviors, including temperature profiles, under various conditions for design and scale-up. It is not feasible to gather all the data experimentally, however, and numerical simulations are highly valuable in the development of such a process.

4. Analysis of Economics

4.1. Markets

As described previously, DME presents many possibilities as a substitute of LPG, a source for power generation, and fuel for vehicle. For example, DME/LPG mixture is being used as fuel in China. We have also tested a DME/LPG mixture, rather than the complete replacement of LPG, as a possible energy source. Because the liquefaction conditions for DME are weaker than those for LPG (-42 or 7atm), DME mixed with 20% LPG can be used in the current facilities without any modifications as a residential and commercial fuel. Actual proof studies are being conducted by Korea Gas Safety Corporation, LPG Center of Japan, Jiutai Chemical of China and ENN Test results from the Korea Gas Safety Corporation show that all existing facilities (e.g. vessels, high-pressure hoses, pressure regulators, gas meters, fuse-cock, low-pressure hoses) can be used immediately at 10% price reduction.

DME as fuel for power generation produces less carbon dioxide emissions than coal or oil and has similar performances to gas. All experimental results from MHI, Hitachi and GE show that power generation using DME-containing fuel allows a safe and highly efficient operation of a dry low NOx combustion system while minimizing the generation of NOx and carbon monoxide. DME has a bright market prospect as a substitute of diesel used in automobiles. Further research and technical developments can lead to a rapid progress for DME.

Japan has developed nine types of prototype DME vehicles and installed 4 DME gas stations at various places. Japan is also trying test driving to prove actual performance. Shanghai Jiao Tong University in China has also set a goal to show DME vehicles at Shanghai in the 2010 world exhibition. In the EU, VOLVO, BUCKSHOW, and others have already finished the development and tests of DME trucks. Korea Institute of Energy Research has completed the development of DME fuel supply technology. At the present, they are operating test-runs of a 1.5-ton DME truck. They will soon complete the development of a 33-seater DME bus, and they plan to operate it in the middle of November, 2009.

DME is very valuable as an alternative to diesel thanks to its environmental factors. Measured against the enforced California ULEV (Ultra Low Emission Vehicle) Standard, DME vehicle emission satisfies numerical values of checklists (NOx, CO, HC, PM Etc.). CO and PM values for DME are remarkably lower than those required for ULEV values. Additionally, DME vehicle emission values checked against the 2009 Japan regulations showed satisfying results for the whole list (NOx, CO, HC, PM, etc).

4.2. Economics Analysis

According to SRI's report in 2005, Under assumptions that DME production is 5,000MTPD (1,642,500tons/y) and feed gas is supplied at the price of 0.5 US$/MMBtu, total capital cost of a DME plant is about 590~840 Million US$ and the DME production cost is 4.45~5.03 US$/MMBtu, respectively

Table 2. DME production cost

Process	Total Capital Cost (Million US$)	Production Cost	
		US$/ton	US$/MMBtu
JFE	842.2	135.58	5.03
Haldor Topsoe	616.2	100.00	3.71
Toyo	590.5	119.93	4.45

[source: SRI Report (Sep, 2005)]

Major companies have reported that DME is economically more feasible than LPG. Toyo has reported in 2005 that DME CIF price in Japan is estimated 5.5~6.5 US$/MMBtu under the assumption of a 2 million tons/y production in Qatar and 1 US$/MMBtu for feed gas price. Toyo's report also shows that about 122 US$/MT for 2.4 million tons/y production in the Middle East can be achieved at 0.7US$/MMBtu and IRR 15 % before tax for feed gas. 122 US$/MT is equivalent to about 4.1 US$/MMBtu and LPG average price CIF Japan in the past five year is about 7.0 US$/MMBtu. Lurgi has also estimated 5~7 US$/MMBtu as DME production cost under the assumption of a 1.7 million tons/y production and feed gas price at 1 US$/MMBtu.
Recently, an economic study for a 1 million ton/year DME plant constructed in Southeast Asia for the Korean market, taking into account natural gas prices, was carried out by Korea Gas Corporation. Assuming that total capital cost is 715 Million US$ and feed gas price is 2 US$/MMBtu, DME CIF price in Korea is about 13 US$/MMBtu, 73% of average LPG CIF price in Korea based on an oil price of 90 US$. The production cost of DME is heavily sensitive on the feed gas cost rather than the product price. Therefore, in-depth considerations of feedstock, such as volatility in price, should be analyzed.

4.3. Related Research Works

There have been several economic analyses for individual GTL processes using natural gas as raw material. M.J. Gradassi and N.W. Green (1995) showed that the payout time of alternative technologies for natural gas conversion (12~91yrs) will be much longer than that of a conventional plant (7yrs). However Choi et al (1997) demonstrated that once-through natural gas FT plants can be competitive with crude oil plants, with the crude oil price at around $18.8/bbl. Patel (2005) showed that GTL diesel is competitive with existing fuel because its production cost is lower than that of refinery processes and its revenue ($2.42-3.15/MMBtu) is comparable with the returns of LNG processes ($2.64-3.08/MMBtu). Rahmim (2005) suggested that GTL processes would be viable and competitive to LNG processes when a gas price of $0.5/MMBtu or lower and capital cost of $20,000-30,000/bbl are available.

Morita (2001) compared the marketabilities of three major GTL products: FT-diesel, DME, and Methanol. Through CIF price studies, he concluded that the most promising choice for the substitute for diesel and LPG is DME when the feed gas price ranges $0.5 to 1.0/MMBtu in Japan. He showed that while FT-diesel is good for its environment-friendliness, it requires some premium to be comparable to petroleum-based diesel, and methanol is considered unsuitable because of its low power. However, there are few studies on the economics of GTL products, especially considering price variations of feedstock and product price. Along these lines, Lee (2009) compared the economic evaluations of three GTL products (FT-diesel, DME, and Methanol) to determine the optimal GTL product. In this study, comparative economic analyses were conducted using process design, cost estimation, and profitability evaluation, in that order. When the natural gas is supplied at the price of $3.00/MMbtu, constructing a DME plant is the most profitable.

5. Summary and Concluding Remarks

The exploitation of sustainable energy resources is indispensable for the development and the prosperity of human beings. Although the fuel utilization of green energy such as solar, geothermal energies, and wind or tidal power might be the ultimate goal for that, the development of synthetic energy is a currently high priority task in the aspects of environment friendliness, efficiency, energy density and possibility of commercialization. Among those, DME is one of most promising energy resources because it has better environmental performance as well as properties similar to traditional fuels.

DME can be manufactured directly from synthesis gas produced from many sources, including renewable materials (biomass, waste and agricultural products) and fossil fuels (natural gas and coal). Thus DME can increase the energy security by displacing petroleum derived fuels. Also, It has remarkable market potential as an automotive fuel, for electric power generation, and for home energy source such as heating and cooking, and is considered price competitive with LPG and diesel fuel.

Currently, various production technologies are developed and many commercial projects are actively being progressed by major industries especially in Asia. However, the profitability of DME is heavily dependent of the raw material cost, so in-depth studies of process technologies and economics with various feedstock (e.g., coal, biomass and unconventional gas such as CBM, LFG) should be preceded. Then, DME will play a major role as an alternative fuel.

Global optimization of integer and mixed-integer bi-level programming problems via multi-parametric programming

Luis F. Domínguez and Efstatios N. Pistikopoulos

Centre for Process Systems Engineering, Department of Chemical Engineering, Imperial College London, SW7 2AZ, UK

Abstract

Bi-level programming problems (BLPPs) arise very often in areas of engineering, transportation control. A key feature of such problems from a mathematical viewpoint is that even for the simplest linear case, a global optimization approach is typically necessary. In this work, we present two multi-parametric programming based algorithms for the solution of integer and mixed-integer bi-level programming problems. The first algorithm addresses the mixed-integer case of the BLPP and employs a reformulation linearization technique (Sherali and Adams, 1990, 1994; Adams and Sherali, 2005) and continuous multi-parametric programming for the solution of the inner problem. The second algorithm addresses the integer case of the BLPP and approaches the inner problem using global multi-parametric mixed-integer programming (Dua et al. 2004). In both algorithms the solution of the inner problem is embedded in the outer problem to form a set of single-level optimization problems that can be solved to global optimality using a global optimization software.

Keywords: Bi-level Programming, Mixed-Integer Bi-level Programming, Reformulation Linearization Technique, Multi-parametric Programming.

1. Introduction

Originally introduced in the areas of game theory and multicriteria decision making, bi-level programming (BLP) has found important applications in areas of engineering, transportation and control. The main characteristic of bi-level programming problems (BLPP) is that the outer optimization problem is constrained by an inner optimization problem as follow:

$$\begin{aligned} &\min_{x,y} F(x,y) \\ &s.t.\ \ G(x,y) \\ &\quad \min\ f(x,y) \\ &\quad s.t.\ g(x,y) \le 0 \end{aligned} \tag{1}$$

where $x \in \Re^{n_1}$, $y \in \Re^{n_2}$ and functions $F(x,y)$, $f(x, y)$, $G(x, y)$ and $g(x, y)$ are assumed to be continuous and twice differentiable.

Considerable research effort has been made on devising algorithms for the mixed-integer non-linear case of Problem (1). Edmunds and Bard (1992) proposed a branch and bound (B&B) algorithm for the mixed-integer linear-quadratic BLPP and identified efficient branching rules to reduce computational burden along the difficulties associated with their B&B algorithm. Gümüs and Floudas (2005) introduced two approaches for the mixed-integer non-linear BLPP. The first approach addressed the case in which only continuous variables (linear or nonlinear) are present in the inner problem and mixed-integer variables (linear or nonlinear) are present in the outer problem. The second approach addressed the general case in which mixed-integer variables (linear or nonlinear) are present in both, the inner and outer problems. Whereas the first approach is an extension of their earlier work (Gümüs and Floudas, 2001), the second approach is based on using a reformulation linearization technique (Sherali and Adams, 1990, 1994; Adams and Sherali, 2005) to generate the continuous convex hull representation of the inner problem feasible space and transforming the reformulated inner problem using its KKT optimality conditions. The resulting single-level optimization problem is then solved to global optimality with the deterministic solver αBB. More recently, Faísca et al. (2007) proposed a parametric global optimization algorithm for various types of BLPPs. Among the classes that were covered in their work lie the linear-linear, linear-quadratic, mixed-integer linear and BLPPs with uncertainty. They used multi-parametric programming techniques developed at Imperial College (Pistikopoulos et al., 2007; Dua et al., 2002) to solve the inner problem parametrically. Rational reaction sets, obtained through the reformulation and solution via multi-parametric programming, were used to generate a set of single-linear, -quadratic or -mixed-integer programming problems which were subsequently solved to global optimality.

This work proposes two algorithms for the solution of integer and mixed-integer bi-level programming problems via multi-parametric programming. The first algorithm addresses the integer case of the BLPP and employs a reformulation linearization technique (RLT) to construct a parametric polyhedral convex hull representation of the inner problem. Because the RLT technique introduces nonlinearities during the inner problem reformulation a convexification procedure is employed in which nonlinear terms are -under and -over estimated and their convex envelopes constructed. Subsequently, continuous multi-parametric programming is employed to solve the reformulated convex inner problem. The second algorithm addresses the mixed-integer case of the BLPP and employs the same convexification procedure used in the first algorithm. In contrast to the first algorithm, which employs a continuous multi-parametric programming approach, the second algorithm makes use of multi-parametric mixed-integer programming to solve the inner problem. In both algorithms the solution obtained through multi-parametric programming is embedded in the outer problem to create a set of single-level optimization problems which are solved to global optimality using standard optimization techniques.

The paper is organized as follows. In Section 2 we provide an insight into the reformulation of the inner problem. In Section 3 & 4 we present two multi-parametric algorithms for the integer and mixed-integer cases of the BLP problem. Finally, concluding remarks are summarized in Section 5.

2. Inner Problem Reformulation

Using the property that any integer program can be substituted by its linear programming relaxation only if its constraint set can be represented by its vertex polyhedral convex hull (Wolsey, 1998), Gümüs and Floudas (2005) showed that, for integer and mixed-integer BLPPs, transformation of the inner problem using its KKT conditions produces an optimal integer solution only if a polyhedral convex hull representation of the inner constraint can be obtained. To obtain the explicit convex hull representation of the feasible solution space for the inner problem, Gümüs and Floudas (2005) employed a reformulation linearization technique (Sherali and Adams, 1990, 1994; Adams and Sherali, 2005). Due to the nonconvexities introduced by the RLT and the KKT transformation the resulting single-level optimization problem required of a global optimization algorithm for its solution.

Since the above property is also valid when the polyhedral convex hull is defined parametrically in the outer variables (Gümüs and Floudas, 2005), the idea of this work is to obtain the parametric polyhedral convex hull representation of the inner problem, reformulate the inner problem as a multi-parametric programming problem and then solve it using multi-parametric programming techniques.

Based upon the above insight, two algorithms for the solution of integer and mixed-integer BLPPs are presented next.

3. A Multi-parametric Programming Algorithm for Integer Bi-level Programming Problems

Consider the integer BLPP of the following form:

$$\begin{aligned} &\min_{x,y} F(x,y) \\ &s.t.\ G(x,y) \\ &\quad \min\ f(x,y) \\ &\quad s.t.\ g_l(x)y \le 0 \quad l = 1,...,L; \end{aligned} \tag{2}$$

where F and G are nonlinear nonconvex functions with $x \in X \subseteq [0,1]^{n_x}$ and $y \in Y \subseteq [0,1]^{n_y}$ and *f* and *g* are linear or polynomial functions.

Focusing on the inner problem, the convex hull representation of the inner constraint set is obtained by multiplying every constraint *l = 1, ...,L* in (2) by a polynomial factor $F_n(J_1, J_2)$ (Sherali and Adams, 1990, 1994; Adams and Sherali, 2005):

$$\begin{aligned} &\sum_{j=1}^{ny} g_l(x) y_j F_n(J_1, J_2) \le 0, \quad j = 1,..,L \\ &-F_n(J_1, J_2) \le 0, \quad \forall (J_1, J_2) \end{aligned} \tag{3}$$

After using the identity $y_j^2 = y_j$ and substituting $\omega_j = \prod_{j \in J_j} y_j$ and for all $j \in n_y$, a compact representation can be obtained as follows:

$$\begin{aligned} &\sum_{j=1}^{n_y} g_l(x) f_n(J_1, J_2) \le 0, \quad l = 1,..,L \\ &\text{-}f_n(J_1,\ J_2) \le 0,\ \forall (J_1,\ J_2) \end{aligned} \tag{4}$$

where $f_n(J_1, J_2)$ corresponds to the linearized version of $F_n(J_1, J_2)$.

From Equation (4) it is clear that multiplication of the inner constraint set by functional factors produces nonlinear terms $g_l(x) f_n(J_1, J_2)$ in the constraint set of the inner problem. This nonlinearity can be circumvented by constructing convex envelopes for the nonlinear terms generated by the RLT. By introducing convex estimators $\gamma_{i,j} = g_l(x) f_n(J_1, J_2)$ with corresponding envelopes $g_l^{conv}(x,y,\omega,\gamma)$, and grouping the optimization variables as:

$$y'(x) = [y(x),\ \omega(x),\ \gamma(x)]^T \tag{5}$$

the reformulated inner problem can be expressed as:

$$\begin{aligned} &\min_{y'} \ f(x, y') \\ &s.t. \sum_{j=1}^{n_y} \gamma_{l,j} \le 0, \quad l = 1, .., L \\ &\quad a'x + b'y' + c'\omega_{l,j} + d'\gamma_{l,j} \le 0,\ j = 1, ..., n_y \end{aligned} \tag{6}$$

where $a', ..., d'$ are coefficients derived from convex envelope g_l^{conv}.

Problem (6) corresponds to a multi-parametric programming problem, the solution of which can be obtained by using the algorithm of Dua et al. (2002). The solution of Equation (6) via multi-parametric programming allow us to obtain the inner variables as parametric functions of the outer variables and their regions of optimality:

$$y'(x) = \begin{cases} M^1 + N^1 x & \text{Valid in } \Pi^1 x \le \pi^1, \\ M^2 + N^2 x & \text{Valid in } \Pi^2 x \le \pi^2, \\ \quad \vdots & \quad \vdots \\ M^K + N^K x & \text{Valid in } \Pi^K x \le \pi^K, \end{cases} \tag{7}$$

where K is the number of computed parametric solutions, M^K, and π^K are constant vectors and N^K and Π^K are constant matrices obtained through the multi-parametric programming algorithm. The sets of affine functions thus obtained can be substituted into the outer problem to form K single-level I(NL)P optimization problems:

$$\begin{aligned} &\min_{x,y} F(x, y) \\ &s.t.\ G(x, y) \le 0 \\ &\quad \Pi^k x \le \pi^k, \quad k = 1, ...K \\ &\quad y'(x) = M^k + N^k x \end{aligned} \tag{8}$$

4. A Multi-parametric Programming Algorithm for Mixed-integer Bi-level Programming Problems

Consider the mixed-integer BLPP of the following form:

$$\begin{aligned} &\min_{x_1,x_2,y_1,y_2} F(x_1, x_2, y_1, y_2) \\ &s.t. \quad G(x_1, x_2, y_1, y_2) \le 0 \\ &\qquad \min_{y_1,y_2} f(x_1, x_2, y_1, y_2) \\ &\qquad s.t.\ g(x_1, x_2, y_1, y_2) \le 0 \end{aligned} \tag{9}$$

where F and G are nonlinear nonconvex functions with $x_1 \in X_1 \subseteq \Re^{n_{x_1}}$, $x_2 \in X_2 \subseteq [0,1]^{n_{x_2}}$, $y_1 \in Y_1 \subseteq \Re^{n_{y_1}}$, $y_2 \in Y_2 \subseteq [0,1]^{n_{y_2}}$ and f and g correspond to linear or polynomial functions.

Although a prametric convex hull representation of inner problem in (9) can also be obtained using a RLT, its construction is not necessary. The inner problem can be treated as the following multiparametric mixed-integer programing problem :

$$\begin{aligned} &\min_{y_1,y_2} f(y_1, y_2, \theta, \xi) \\ &s.t.\ g(y_1, y_2, \theta, \xi) \le 0 \\ &y_1 \in Y_1 \subseteq \Re^{n_{y_1}} \\ &y_2 \in Y_2[0,1]^{n_{y_2}} \\ &\theta \in \Theta \subseteq \Re^{p} \\ &\xi \in \Xi \subseteq [0,1]^{q} \end{aligned} \tag{10}$$

where the parameters θ and ξ are continuos and integer variables of the outer problem.

Problem (10) can be solved, for instance, with the algorithms of Dua and Pistikopoulos (2000), or Dua et al. (2004). By solving Problem (10) via multparametric mixed-integer programming a map of integer solutions with their continuous counterpart are obtained, each having regions of optimality of the form:

$$\{y_2, \xi\}^i \quad y_1^i(\theta) = \begin{cases} M_i^1 + N_i^1\theta & \text{Valid in } \Pi_i^1\theta \le \pi_i^1, \\ M_i^2 + N_i^2\theta & \text{Valid in } \Pi_i^2\theta \le \pi_i^2, \\ \quad \vdots & \qquad \vdots \\ M_i^K + N_i^K\theta & \text{Valid in } \Pi_i^K\theta \le \pi_i^K, \end{cases} \tag{11}$$

where $i = 1, .., I$ correspond to the number of integer feasible solutions.

Once the multi-parametric solutions for the inner problem have been found these can be embedded into the outer problem to form k single-level MI (N)LP problems as follows:

$$\begin{aligned} &\min_{x_1,x_2,y_1,y_2} F(x_1, x_2, y_1, y_2) \\ &s.t.\ G(x_1, x_2, y_1, y_2) \le 0 \\ &\quad \{y_2, x_2\}^i, y_2^i(x_1) = M_i^k + N_i^k x_1 \quad i = 1, ..., I \\ &\quad \Pi_i^k x_1 \le \pi_i^k, \quad k = 1, ..., K \end{aligned} \tag{12}$$

5. Concluding Remarks

Bilevel programming problems are inherently parametric and multi-parametric based algorithms take advantage of the parametric nature of such problems. For the solution of integer and mixed integer bi-level programming problems, we introduced two new algorithms based on continuous and mixed-integer multiparametric optimization. The proposed algorithms can provide not only the bi-level optimal solution but also any solution that is optimal for the inner and outer problems. This characteristic makes multi-parametric programming based algorithms suitable for problems involving optimistic (co-operative) formulations where there exist multiple optimal solutions and the leader can choose among them.

Abstract

A model-based experiment design techniques is used to design improved test protocols for the identification of the parameters of a detailed physiological models of diabetes specific to single subjects. This paper considers the problem of parameter identification focusing on the impact of some decision variables such as sampling frequency and test duration on both the design effectiveness and the ability to meet safety critical constraints on the subject response. The proposed methodology permits to establish the minimal experimental budget required to achieve a satisfactory parameter estimation from the planned test without upsetting the subject excessively.

Keywords: model-based experiment design, parameter estimation, model identification, biomedical applications, diabetes mellitus.

1. Introduction

Type 1 diabetes mellitus (T1DM) is a metabolic disease of the glucoregulatory system affecting millions of people worldwide and causing the expenditure of millions of euros every year for health care. T1DM usually begins before the age of 40 and is characterized by a progressive destruction of the pancreatic islets and by an absolute deficiency of secreted insulin in the body. As a consequence, people with T1DM are not capable of maintaining the blood glucose concentration within a narrow normoglycaemic range and must rely on hexogenous insulin for survival. One of the most promising therapies for the disease derives from the use of an artificial pancreas, an external piece of equipment based on a control system maintaining the subject's normoglycaemia. An accurate dynamic simulation model of the glucose-insulin system can be useful to assist diabetes care and test glucose sensors, insulin infusion algorithms and decision support systems for diabetes. Several physiological models have been developed in the last four decades [1]. A specific difficulty is posed by the need to tailor a generic model to individual subjects, given the high variability of the responses, Standard clinical tests [2] are used to help diagnosing diabetes and to identify the parameters of simple models of glucose homeostasis, but, as long recognised [3], the optimal input perturbation to identify the metabolic parameters precisely could be different from that of a standard test. An "ideal" clinical test should be i) as quick and easy as possible to perform; ii) as informative as possible for parameter estimation purpose; iii) not invasive or harmful for the subject (i.e. oral tests are preferred to infusion tests) and iv) as undemanding as possible in terms of analytical resources.

Model-based design of experiments (MBDoE) [4] can be used to design a set of optimally informative clinical tests, allowing to estimate the model parameters in a statistically sound way, while at the same time fulfilling the required constraints of safety for the patient and an ease of conduction [5]. An MBDoE procedure is presented in this paper which includes, together with the definition and the assessment of a suitable optimality criterion, the definition of a set of constraints on both the experiment design variables and (more importantly here) on the dynamics of the predicted patient response. In particular, the frequency of the measurements and the duration of the test are determined, which together with other test design variables (e.g. time and size of insulin bolo uptake), affect both the optimality criterion and the dynamics of the glycaemia response in the subject. The focus of this work is to evaluate i) the impact of these design variables on the final parameter estimation, ii) the ability to meet critical safety constraints on the patient response within a specified degree of confidence and iii) the minimal experiment budget required to get a satisfactory parameter estimation from the planned test without upsetting the patient excessively. The study is carried out using a detailed physiological model of glucose homeostasis on a simulated subject.

2. MBDoE under constraints for physiological models

Several models have been proposed in the literature that are able to represent the dynamics of subcutaneous insulin infusion and of the rate of glucose appearance following a meal. In this study we adopt the Hovorka model with the insulin infusion sub-model proposed by Wilinska et al. [6] denoted as the Hovorka-Wilinska model (HWM). HWM belongs to the class of nonlinear dynamic models described by the following set of differential and algebraic equations (DAEs):

$$\begin{cases} \mathbf{f}\left(\dot{\mathbf{x}}(t), \mathbf{x}(t), \mathbf{u}(t), \mathbf{w}, \theta, t\right) = 0 \\ \hat{\mathbf{y}}(t) = \mathbf{g}\left(\mathbf{x}(t)\right) \end{cases}, \tag{1}$$

where $\mathbf{x}(t)$ is the N_x-dimensional vector of time-dependent state variables, $\mathbf{u}(t)$ and $\mathbf{w}$ are the time-dependent and time-invariant control variables (of dimensions N_u and N_w) , respectively, $\boldsymbol{\theta}$ is the N_θ-dimensional set of unknown model parameters to be estimated, and t is the time. The symbol ^ is used to indicate the estimate of a variable (or of a set of variables): thus, $\mathbf{y}(t)$ is the vector of measured values of the outputs, while $\hat{\mathbf{y}}$ is the vector of the corresponding values estimated by the model. In our case, the time-dependent manipulated inputs $\mathbf{u}(t)$ comprise the insulin subcutaneous infusion and the insulin subcutaneous bolus, whereas the glucose intake is represented as a time-invariant control variable w. There is only one measurable output $y(t)$, the blood glucose concentration G.

Model-based experiment design procedures aim at decreasing the model parameter uncertainty region predicted by model (1) as the solution of the optimisation problem

$$\boldsymbol{\varphi} = \arg\min\left\{\psi\left[\mathbf{V}_\theta\left(\boldsymbol{\theta}, \boldsymbol{\varphi}\right)\right]\right\} = \arg\min\left\{\psi\left[\mathbf{H}_\theta^{-1}\left(\boldsymbol{\theta}, \boldsymbol{\varphi}\right)\right]\right\} \tag{2}$$

subject to a set of constraints

$$\widetilde{\mathbf{C}} = z\left(\dot{\mathbf{x}}(t), \mathbf{x}(t), \dot{\mathbf{u}}(t), \mathbf{u}(t), \mathbf{w}, \boldsymbol{\theta}\right) \leq 0 \tag{3}$$

by acting on the experiment design vector $\boldsymbol{\varphi}$:

$$\boldsymbol{\varphi} = \left[\mathbf{y}_0, \mathbf{u}(t), \mathbf{w}, \mathbf{t}^{sp}, \tau\right]^T \tag{4}$$

which includes the N_y-dimensional set of initial conditions $\mathbf{y}_0$ on the measured variables, the duration of the experiment (τ), the continuously manipulated inputs $\mathbf{u}(t)$, usually approximated through a discrete (piecewise constant or piecewise linear) function and the time-constant manipulated inputs, $\mathbf{w}$. The set of time instants at which the output variables are sampled (blood sampling schedule) is also a design variable, and is expressed through the n_{sp}-dimensional vector $\mathbf{t}^{sp}$ of sampling times. $\mathbf{V}_\theta$ and $\mathbf{H}_\theta$ are the variance-covariance matrix of model parameters and the dynamic information matrix, respectively. The experiment is chosen to minimise a measurement function ψ of $\mathbf{V}_\theta$ (the particular form of the function represents the chosen design criterion [7]) which maximises the predicted information content of the experiment. The latter is expressed as the $N_\theta \times N_\theta$ dynamic information matrix

$$\mathbf{H}_\theta(\boldsymbol{\theta},\boldsymbol{\varphi}) = \sum_{k=1}^{n_{sp}} \sum_{i=1}^{N_y} \sum_{j=1}^{N_y} s_{ij} \mathbf{Q}_i^T \mathbf{Q}_j + \mathbf{H}_\theta^0 = \sum_{k=1}^{n_{sp}} \mathbf{M}_k + \mathbf{H}_\theta^0 \tag{5}$$

where $\mathbf{Q}_i$ is the $n_{sp} \times N_\theta$ dynamic sensitivity matrix of the i-th measured response, s_{ij} is the ij-th element of the $N_y \times N_y$ inverse matrix of measurements error, and $\mathbf{H}_\theta^0$ is the prior dynamic information matrix, taking into account the statistical information about the parametric system before each trial is carried out. The optimisation solution must fulfil an n_c-dimensional set of equality and inequality constraints in the form of eq. (3), where z is a complex function linking state, control and information variables. For the system under investigation there are important physical/physiological constraints that are strictly related to the physiology of the glucoregulatory system and should not be violated as they determine the maintenance of normoglycaemic levels during the test and the return to basal conditions at the end of the test.

The $\mathbf{M}_k$ matrix represents the contribution of the k-th sample to the overall predicted information content $\mathbf{H}_\theta$. This is deeply affected by the frequency of sampling (in terms of n_{sp}/τ ratio) and by the excitation pattern of the manipulated inputs; thus, the choice of sampling protocol has an impact on the effectiveness of test in terms of information availability. Discrete sampling and off-line analysis (typically, at rather low frequency) allow for the most precise analytical laboratory techniques to be used, albeit with a time delay; however, recent sampling techniques such as CGM (continuous glucose monitoring) could enrich the information content of the glucose test, allowing for a continuous recording of glucose level over a 24-hour period (high sampling frequency) [8]. In view of the above, it is worth assessing the effect of the sampling frequency in the design of a clinical test for parameter identification.

3. Case study

As in a recent study [5], the MBDoE approach is applied to a diabetic patient modelled using HWM. The purpose is to modify the usual protocol of standard tests such as PGT (postprandial glucose test) and OGTT (oral glucose tolerance test) so as to increase the overall information content of the test after a preliminary reference test. Here, the goal is to estimate precisely, with only one properly designed experiment, the set of metabolic parameters $\boldsymbol{\Theta}$ describing the insulin sensitivity of a specific subject (Θ_1, Θ_2, Θ_3) and his/her endogenous glucose production (Θ_4). Safe conditions must be guaranteed at all times during the clinical test; besides, the test should be completed within a specified time interval. It must be also guaranteed that after the test the subject may return to and remain at the basal settings. A D-optimal design procedure is carried out with the following constraints: interior constraints on the glycaemic curve to ensure

normoglycaemia at all times (60-170 mg/dL); an end point constraint on the glucose concentration (80 mg/dL), a constraint on the final derivative of the glucose concentration to ensure steady glycaemia at the end of the test, and a constraint on the test duration. The test formally ends with the last sampling point (which defines the duration of the experiment). The (simulated) glucose measurements are available with a constant relative variance of 0.033 and the elapsed time between two consecutive measurements cannot be shorter than 5 minutes.

The following protocols are proposed and assessed:

1. MPGT-n_{sp}: modified postprandial glucose test with n_{sp} = 5, 10, 20 (τ = 600 min);
2. MOGTT-n_{sp}: modified OGTT with n_{sp} = 5, 10, 20 (τ = 840 min);
3. MPGT-opt: modified postprandial glucose test with n_{sp} = 20 and τ optimised;
4. MOGTT-opt: modified OGTT with n_{sp} = 20 and τ optimised.

A variable number of samples is chosen in protocols 1. and 2. to evaluate the impact of the sampling frequency on the quality of the final estimate, while in 3. and 4. the goal is to assess whether a test duration could be shortened by increasing the sampling frequency. To improve numerical robustness, parameters are normalised with respect to the true values describing the subject.

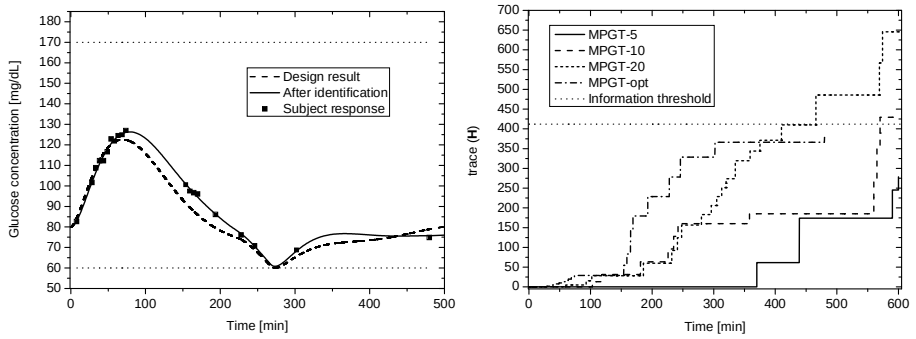
3.1. Modified Postprandial Glucose Test (MPGT)

The purpose is to identify the model set of parameters with a single experiment comprising two meals (breakfast and lunch, scheduled at 8:00 AM and 1:00 PM). The variables being optimised are: the CHO content of the meals, $D_{g,1}$ and $D_{g,2}$ (bounds on breakfast: 5 – 40 g CHO; bounds on lunch: 30 – 70 g CHO); the glucose-dependent insulin infusion rate $u_s(t)$ (parameterised as a piecewise constant function, with n_z = 9 levels and n_{sw} = 8 switching times to optimise), the amount of insulin of the boluses $u_{bol,1}$ and $u_{bol,2}$ and the sampling times. The last sampling point can be taken not later than 600 min (10 h) from the beginning of the experiment (6:00 PM). The time interval between consecutive meals is not optimised, and the insulin bolus amount is not constrained to an insulin/CHO ratio. The end point constraints on the glucose concentration and on the derivative of the glucose concentration must be reached within 600 min.

Table 1 Comparison of different MPGT protocols. Superscript * indicates *t*-values failing the *t*-test (t_{ref} is the reference *t*-value and $\boldsymbol{\Theta} = [1.000\ 1.000\ 1.000\ 1.000]^T$)

Design	Parameter Estimate $\hat{\Theta}$	Conf. Interval (95%)	*t*-values	t_{ref}
MPGT-5	[1.045 0.729 1.222 1.043]^T	[±0.3665 ±1.2940 ±1.1300 ±0.2341]	[2.85 0.56* 1.08* 4.45]	1.795
MPGT-10	[0.997 0.915 1.059 1.007]^T	[±0.2955 ±0.5136, ±0.3217 ±0.0514]	[3.37 1.78 3.29 19.58]	1.745
MPGT-20	[1.008 0.808 1.114 1.015]^T	[±0.1878 ±0.4276, ±0.2603 ±0.0430]	[5.37 1.89 4.28 23.6]	1.705
MPGT-opt	[0.944 0.826 1.147 1.020]^T	[±0.2235 ±0.7305, ±0.4295 ±0.0713]	[4.23 1.12* 2.67 14.3]	1.705

As can be seen from Table 1 at least 10 samples are necessary to perform a statistically sound parameter estimation. Figure 1 (b) shows the contribution of each sample to the overall information (5) given by the trace of $\mathbf{H}_0$. The information threshold refers to a mean standard deviation of 10% on the final estimate. When the test duration is also optimised (MPGT-opt), the samples are concentrated at the very beginning of the test, where the test is scarcely informative. The test is safe and short (τ = 480 min = 8 h) but the estimation is not statistically satisfactory (although just marginally).



(a) (b)

Figure 1 (*a*) Predicted glucose response for the optimal test, measurements from this designed (simulated) experiment and subject glucose response after identification with test data for protocol MPGT-opt and (*b*) contribution to eq. (5) for different MPGT protocols.

3.2. Modified Oral Glucose Tolerance Test (MOGTT)

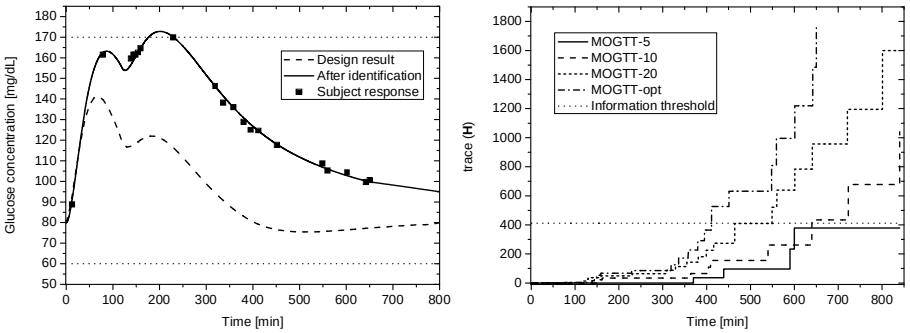
The identification test involves multiple glucose solution and insulin bolus intakes. The optimisation variables are: the glucose content of the four meals (glucose solution drink); the time interval between consecutive meals (acceptable range 15-840 min); the amount of each insulin bolus the sampling times, and duration not greater than 840 min (14 h). An additional constraint was imposed on the total amount of ingested glucose (acceptable range: 75-156 g CHO). The end point constraints on glucose concentration and its derivative must be fulfilled within 840 min from the last meal. The amount of bolus per meal was modelled as:

$$u(t) = u_{bas} + \alpha \sum_{i=1}^{N_{meals}} \delta_i(t) k_i D_{g,i} \tag{6}$$

where α = 52.63 mU/g CHO represents the optimal insulin/CHO ratio. The "relaxing factors" k_i are also optimised in the design. As underlined in [5], this test is more informative (compare the *y*-axis scale of Figure 1b and 2b), but a longer experiment duration has to be adopted since the four meals need to be spaced over a sufficiently long period of time. When τ = 840 h (14 h) the estimate is statistically satisfactory only with more than 5 samples (Table 2), but, interestingly, the MOGTT approach allows shortening the test duration from 14 to 10.8 h without much affecting the quality of the final estimate, while ensuring a safe and informative test (Figure 2).

Table 2 Comparison of different MOGTT protocols. Superscript * indicates *t*-values failing the *t*-test (t_{ref} is the reference *t*-value and $\boldsymbol{\Theta} = [1.000\ 1.000\ 1.000\ 1.000]^T$).

Design	Parameter Estimate $\hat{\Theta}$	Conf. Interval (95%)	*t*-values	t_{ref}
MOGTT-5	[1.096 0.800 1.231 1.024]^T	[±0.2437 ±0.4978 ±0.3028 ±0.1088]	[4.49 1.61* 4.06 9.41]	1.795
MOGTT-10	[0.902 1.007 1.089 1.022]^T	[±0.2139 ±0.1593, ±0.3054 ±0.1018]	[4.22 6.32 3.57 10.04]	1.745
MOGTT-20	[0.957 0.975 1.077 1.021]^T	[±0.1634 ±0.1176, ±0.2447 ±0.0817]	[5.86 8.29 4.40 12.49]	1.705
MOGTT-opt	[0.906 0.953 1.131 1.035]^T	[±0.1813 ±0.2277, ±0.3138 ±0.1014]	[5.00 4.19 3.61 10.22]	1.705



(a) (b)

Figure 2 (*a*) Glucose response modeled by design, after identification and subject response for protocol MOGTT-opt and (*b*) contribution to (5) for different MOGTT protocols.

4. Final remarks

A MBDOE has been applied to a complex model of glucose homeostasis with the purpose of evaluating the impact of sampling frequency and test duration on parameter estimation on modified Post Prandial and Oral Glucose Tolerance Tests. The results clearly show that an modified OGTT protocol is more effective with a higher number of samples and longer test duration. The results also demonstrate the flexibility of this protocol, which is simpler to be carried out and allows achieving a statistically sound parameter estimation in a short test without being invasive or harmful to the subject .

From a Generic Paradigm to a Generic Tool Set: Exploring Computer-Aided Multiscale Modeling

Aidong Yang, Yang Zhao

Division of Civil, Chemical and Environmental Engineering, Faculty of Engineering and Physical Sciences, University of Surrey, Guildford GU2 7XH, UK

Abstract

Multiscale modeling is now widely regarded as a promising and powerful tool in various disciplines, including the broad area of process engineering. However, a multiscale model is usually much more difficult to develop than a single-scale model due to a range of conceptual, numerical, and software challenges. Currently, there is little support developed to facilitate multiscale modeling. This paper discusses the key challenges faced by computer-aided multiscale modeling (CAMM) and presents a methodology considered in an ongoing initiative which explores the way to a computer-based, generic and open supporting framework for multiscale modeling. Details are particularly provided on the development of a conceptual modeling tool, an important element of the envisaged tool set for CAMM.

Keywords: multiscale modeling, computer aided modeling, conceptual modeling

1. Introduction

Multiscale modeling is an emerging modeling paradigm which combines the models of different resolution scales of a complex system to obtain a high-quality characterisation of the system. This modeling paradigm is now widely regarded as a promising and powerful tool in various disciplines. As reflected by several reviews (e.g. Charpentier, 2002; Braatz et al., 2004; Vlachos, 2005), typical applications for chemical process systems include the simulation of growth of materials (such as thin films) and reaction systems involving a bulk phase and a catalytic surface, frequently characterized by combining kinetic Monte Carlo simulation with PDE/ODE-based continuum modeling. There are also process engineering applications which reply on the integration of different continuum scales for the purpose of improving computational efficiency (as opposed to handling physical heterogeneity across different scales), e.g. the coupling of a process simulator with a CFD package for modeling crystallisation and biochemical processes (e.g. Bezzo et al., 2004; Kulikov et al., 2005). Similar applications have also been developed in areas other than process engineering, including particularly material science, computational mechanics, and systems biology.

Developing a multiscale model is generally much more challenging than building a single scale model, because one has to determine what scales to be involved and how the involved scales should be connected. To tackle the difficulties, several efforts in formulating modeling methodologies have aimed to provide some kind of generic guidance to the development of new applications. The most notable activities are devoted to the classification of multiscale modeling approaches, schemes or frameworks which define the generic ways how submodels of different scales of a system can be introduced and coupled to form an integral model. Pantelides (2001) classifies scale integration strategies into serial, parallel, hierarchical, and simultaneous approaches.

This classification was expanded and adapted by Ingram et al (2004) which identifies a number of integration frameworks and discusses the compatibility issue. Li et al. (2005) articulate the difference between what is called descriptive, correlative, and variational methods. Vlachos (2006) makes the distinction between sequential or serial approaches and those referred to as hybrid, parallel, dynamic, and concurrent approaches.

While the conceptual guidance offered by the generalised modeling methodologies may help the "novice" modellers to some extent, what can provide much stronger support is computer-based tools (Marquardt et al, 2000; Ingram et al, 2004). Unfortunately, very little development exists in this direction. Consequently, the application of multiscale modeling still remains a special privilege of highly skilled modeling experts and its success is established very much on a case-specific basis (Fraga et al, 2006); the majority of scientists and engineers has yet to struggle with conceptual and practical difficulties, despite their high expectations on benefiting from this modeling paradigm.

To address the above problem, a research initiative has recently been started to explore the way to a computer-based, generic and open supporting framework for multiscale modeling. This paper discusses the starting point of this initiative, the key challenges to be addressed by computer-aided multiscale modeling (CAMM), as well as the concepts and methodology being developed. Particularly, it reports the development of a prototypical tool which supports the conceptual modeling step, as a key element in the envisaged tool set for CAMM.

2. Computer-Aided Multiscale Modeling: Starting Point and Key Challenges

In process engineering, the current lack of computer-based support to multiscale modeling is in sharp contrast with the advances in computer-aided process modeling (CAPM) prior to the era of multiscale modeling. This includes a number of commercially highly successful software packages for process modeling, simulation, and optimization. In academic research, an important methodological development in CAPM has been phenomena-based modeling, which is aimed at reducing the effort of human modellers by allowing them to work with process engineering concepts instead of mathematical details, as advocated by e.g. Stephanopoulos et al. (1990), Marquardt (1995), Perkins et al. (1996), Jensen & Gani (1996), Bieszczad (2000), and Bogusch et al. (2001). More recently, Yang et al. (2004) propose an ontology-based modeling approach to improve the generality and extensibility of phenomena-based modeling tools, which utilises ontologies (Gruber, 1993), i.e. explicit specifications of conceptualisation of domains of interest in terms of definitions of concepts and their relations, to establish conceptual models of the process systems being modeled.

Starting with the existing development of CAPM, two different sets of challenging issues must be addressed in the process of marching towards CAMM. Within the first set, there are conceptual, numerical, and software implementation related issues which will be faced by any modeller in a specific multiscale modeling application; the strategy and software framework to be developed in this work must provide corresponding solutions to these issues:

- *Conceptually*, and usually at the early stage of developing a multiscale model for a specific system/problem, the modeller has to decide what scales of the system or the subsystems should be considered, what characteristics of each of these scales should be modelled, and what connections should be established between these scales and between subsystems. Essentially "designing" the multiscale model, it often proves to be a nontrivial task especially for an inexperienced modeller.

- *Numerically*, one may expect that coupled simulation codes for different scales will run stably if each of these codes is numerically stable when being executed individually. This is however not necessarily the case (Pantelides, 2001, Rusli et al., 2004, Bezzo et al., 2005; Braatz et al., 2006). Numerical instability may arise in multiscale modeling due to e.g. temporal/spatial mismatch between the solutions at different scales or noises in the data passed between scales. Furthermore, modeling errors may occur as the consequence of handling numerical instability by means of filtering, or due to the aggregation and disaggregation of the information between different scales. To render successful coupling, one should be aware of the numerical consequences of implementing a particular coupling scheme, and apply appropriate methods to suppress numerical instability and to reduce modeling errors whenever possible.
- *With respect to software implementation*, a common issue in multiscale modeling is that different specialty modeling tools may be used for different scales of a system; these tools will have to be integrated to allow a multiscale model to be solved or executed as a whole. As these tools have usually been developed separately by different parties, significant heterogeneity often exists in their data structures, interfaces, and even supported operating systems, making the integration of these tools a very challenging task. A main research question in this aspect is how to leverage the enabling technologies provided by the CAPE-OPEN initiative (Braunschweig et al., 2000).

Additionally, there is a second set of challenging issues which are concerned with the generality and "powerfulness" of a *computer-aided* multiscale modeling solution. Briefly, the challenges there are about providing answers to the following two questions:

- *How to maximise the support to modellers at each step of model development*, given the very different nature of the conceptual, numerical, and software related problems to be tackled and given the varying levels of expertise possessed by different modellers?
- *How to make a computer-aided modeling system as generic as possible*, in light of the highly diverse nature of various multiscale modeling applications?

3. Towards a Methodology for CAMM

To effectively address the aforementioned challenges, a methodology with the following two aspects is proposed (cf. Fig. 1).

1. Establishing a theoretical framework of multiscale systems as the basis for computer-aided multiscale modeling

A unified theoretical framework may be established to cope with the diversity of applications that a generic solution for computer-aided multiscale modeling should support. This essentially follows the method proposed by Yang et al. (2004) for general systems modelling with extensions to handle multiple scales. More specifically, this framework may possess a hierarchical structure comprising a *fundamental level* and a *domain-specific level*. The former aims to provide *a unified theory for general multiscale systems*. As demonstrated in a recent publication (Yang & Marquardt, 2009), this may be achieved by a *deductive* approach on the basis of general systems theory and its formal formulations, allowing the formulation of explicit and rigorous definitions of fundamental concepts in multiscale modelling. These concepts may include (i) *system, subsystem, environment, inter-subsystem relation, system-environment relation*; (ii) *scale, inter-scale relation*, and (iii) *property and law (set) of*

all the above items. From these concepts and particularly the inter-subsystem and inter-scale relations, a variety of *generic multiscale modeling schemes* may be derived naturally and rigorously.

On top of this *fundamental level*, multiscale concepts for specific domains will be introduced. For the domain of process engineering, this level aims to provide generic definitions of scales typically involved in the multiscale modeling of process systems, such as *molecules*, *molecule clusters*, *particles*, *surfaces* and *phases*, *process units*, *plants*, *sites*, etc. Existing conceptualization of chemical process systems such as OntoCAPE (Morbach et al., 2007) may be adaptively reused for this purpose.

It is expected that, by building upon this unified, hierarchical theoretical framework, the generality of the CAMM solutions can be maximised: When a method for a particular problem (be it a conceptual, numerical, or software-related one) is developed, one can always try to base it, in the first place, only on the theory of general multiscale systems (i.e. the fundamental level). If it is successful, the resulting method will be applicable to all kinds of applications as long as the targets of modeling conform to this theory. If the method has to exploit domain-specific (process engineering for instance) concepts, the generic theory for multiscale process systems at the *domain-specific level* will come to play. This will ensure that this method be applicable to various process systems modeling applications.

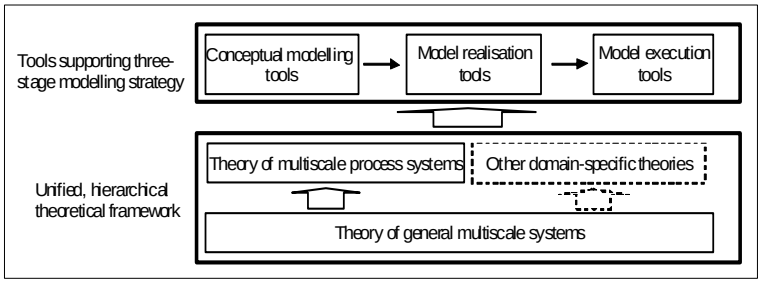

Figure 1. A methodology for computer-aided multiscale modeling.

2. Applying a three-stage strategy to maximise computer-based support

Motivated by the need of addressing different types of modeling issues while maximising computer-based support to human modellers, it would be instrumental to separate the most creative modeling tasks which inevitably require the input/intervention from the human modellers (referred to as Group 1), from other tasks which can be handled more "automatically" by software tools (referred to as Group 2). For this purpose and as an extension of the method previously proposed by Yang et al. (2004), activities in a multiscale modeling application may be organized into three successive stages: *conceptual modeling*, *model realisation*, and *model execution*. For a given modeling problem, the first stage results in a *conceptual model* which dictates ("by words") what scales to be included in the model and what kind of linkages should be established between these scales. This is a stage which mainly addresses the aforementioned *conceptual* challenges. Largely belonging to Group 1, the tasks in conceptual modeling can hardly be fully *automated*; they will rather be *supported* through the interactions between a computer-based conceptual modeling system and its users. Following this stage, the model realisation and execution stages deal with *(i)* the realisation of the conceptual model (to a form which is ready to execute) and *(ii)* the actual execution of model, respectively. The modeling tasks to be tackled in these two stages largely belong to Group 2, because they involve predominantly numerical and

software implementation related work as opposed to conceptual work. This type of work may be completed mainly by using designated software tools that implement numerical procedures for handling issues commonly encountered in multiscale modeling, hence requiring minimum effort from the human modeller.

4. A Prototypical Tool for Conceptual Modeling

Following the methodology proposed above, a prototypical tool to support conceptual modeling has been developed. It is based on the theory or conceptualization of general multiscale systems reported in Yang and Marquardt (2009) with minor extensions. This conceptualization is expressed using ontology modeling language OWL (cf. www.w3.org) and is referred to as the meta ontology. Any domain specific conceptualization or theory of multiscale systems should be derived from this meta ontology and expressed using the same modeling language. By doing so, a domain specific theory is manifested as a domain ontology which concretizes the general concepts defined in the meta ontology. For a specific modeling task, a domain ontology should offer the "top" concept, i.e. the one that represents the system to be modeled at the top level, as well as all the other concepts required for characterizing the decomposition of the system at lower levels. When applied to a specific task, this tool loads an appropriate domain ontology and establishes the possible scale structure according to the "top" concept of this task. When doing so, this tool relies purely on what is defined in the meta ontology, without needing to refer to the semantics of the domain specific terms. This feature is maintained in supporting the rest of the conceptual modeling process as schematically illustrated in Figure 2 for modeling a N-scale system.

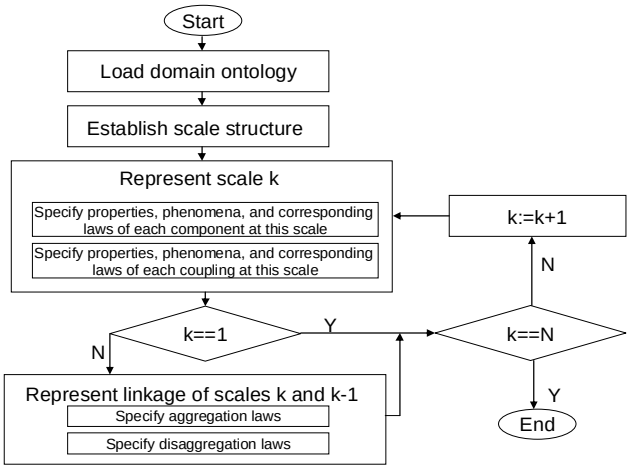

Figure 2. A simplified representation of the workflow for conceptual modeling.

The main function of the tool is to guide a human modeler by means of a series of modeling steps leading to a complete conceptual model of a specific (type of) system. The laws specified for the individual components at various scales may materialize in the form of either symbolic model building blocks or some kind of existing software code, a difference that will impact and be handled by the subsequent stages of model realization and model execution. The laws that govern the inter-scale relations will materialize as "glue" blocks to be offered as part of the tool set for the model realization

stage. These blocks will be joined by some others in this tool set which are to address common numerical issues as outlined earlier in Section 2. The development of the tools for modeling realization and execution is the subject of on-going work.

5. Concluding Remarks

As a generic and promising modeling paradigm, multiscale modeling is yet to gain computer-based support in order to help human modelers overcome difficulties in conceptual, numerical, and software implementation aspects. The development of such support may be guided by a methodology which is grounded on a unified, hierarchical framework of multiscale systems theories to achieve a high degree of generality, and which suggests building a set of tools around three successive modeling stages in order to maximum the facilitation the tools can offer to human modelers. This methodology has been partly implemented by the development of a prototypical tool for conceptual modeling, while work on the evaluation of the other parts of the methodology is ongoing. Given the fact that computer-aided multiscale modeling is still in its infant stage, the initiative reported in this paper is undoubtedly of an explorative nature; long term efforts with multidisciplinary collaborations are naturally expected in order to make substantial progresses in this area.

Abstract

The physical deacidification step must be designed in order to take the high difference in the volatility of undesirable compounds and the neutral oil under high temperatures and vacuum, without causing damage to nutraceutical compounds, excessive production of *trans* fatty acids and neutral oil loss. Improving the process conditions of this important stage of vegetable oil refining is a relevant topic nowadays. The present study aimed to investigate experimentally the batch steam deacidification of fatty systems with known compositions (two models systems and one vegetable oil), while keeping an accurate measurement and control of the main process variables (temperatures, pressure and mass percentage of injected steam). With this precise information, a validation of a simulation tool developed in the research group was achieved by comparing experimental results with computational ones.

Keywords: steam deacidification, computational simulation, buriti oil, palm stearin, palm olein.

1. Introduction

Steam deacidification and deodorization processes in the oil industry aim to vaporize odoriferous compounds and fat acids from the oil, and are based on the high differences in volatility between the oil and the majority of its unwanted substances. The separation is successfully accomplished by applying high temperatures and low pressures. However, these processing conditions also ease the occurrence of loss of neutral oil, the retention/recovery of nutraceutical compounds, and chemical reactions.

Steam deacidification of edible oils involves necessarily triacylglycerols plus fatty acids and, eventually, some minor compounds, as partial acylglycerols, tocopherols and carotenes. The batch process, although rarely used in industrial scale, gathers the main features of the continuous equipment and is suitable for research purposes. In fact, it has been extensively studied in the literature, but none of the previous works provide information in a way to allow a precise modeling of the entire system, and consecutively, the simulation of the process. In fact, this problem has been highlighted in recent articles published in the literature dealing with simulation of steam deacidification and deodorization of edible oils (Ceriani and Meirelles, 2007). In this context, our goal was to investigate the steam deacidification of model systems and of a real system (vegetable oil) with a reliable controlling and monitoring of processing

variables, such as temperature, pressure and amount of stripping steam injected, and with pertinent chemical analysis of the load (feed) and products (distillate and deacidified oil). Considering the goal was to obtain accurate data for validation of modeling/simulation, the independent variables (temperature and % of sparge steam) were monitored during each experiment in a five minute interval by means of two thermocouples installed at different points of the reactor and a microperistaltic pump.

2. Experimental Procedures

2.1. Materials

Pure tricaprylin (99%), commercial triolein (65-88%) and oleic acid (72%) (model system M_1). Stearin and olein from palm oil and oleic acid (model system M_2). Crude buriti (*Mauritia flexuosa*) oil (real system R_1).

2.2. Experiments

The experiments were conducted in a batch deodorizer developed by the research group, as an improved version of the equipment described by Decap et. al.(2004). In all experiments, steam was injected for 60 minutes after the desired temperature of the experiment has been reached, as usually occurs in such procedures (Petrauskaitè, et. al., 2000). The temperatures of the liquid in the reactor and of the volatile phase were measured in a five minute interval throughout the experiment. Pressure was also monitored using both a digital signal for vacuum and a mercury column for absolute pressure. Samples were collected after 60 minutes of stripping and immediately cooled, to avoid formation of acidity. These samples were analyzed in accordance with the procedures described in Section 2.3. Mass balances attested the reliability of the experiments. Each system (M_1, M_2 and R_1) was submitted to experimental trials as detailed below.

2.2.1. System M_1

The system M_1 was composed by 31:69 (m/m) of tricaprylin/triolein with an addition of 3.5 % of a free fatty acid (oleic acid). Experiments with 900g of this model system were done following a simple factorial design with 2 independent variables, temperature (ranging from 190°C up to 260°C) and steam flow rate (from 0.5 % up to 3.5 % of the load). Samples were collected and analyzed to obtain the responses of interest (acidity and neutral oil loss) and to evaluate the effects of process variables on these responses.

2.2.2. System M_2

The system M_2 was composed by different proportions of stearin and olein and also oleic acid, so the initial acidity was set as 3.0 %. Experiments with 1000g of this model system were done following a full factorial design with 3 independent variables, temperature (from 200°C up to 260°C), steam flow rate (from 0.5 % to 6.5 % of the load) and the proportion (m/m) between stearin and olein (from 0.1 up to 0.9). Samples were collected and analyzed to obtain the responses of interest (acidity and neutral oil loss).

2.2.3. Real System (R_1)

Crude buriti oil, extracted from a palm tree native of Brazil, has a high concentration of monounsaturated fatty acids (MUFA) and nutraceutical compounds, as tocopherols (antioxidant) and carotene (vitamin A activity). The selection of this oil as the real system, allowed studying also tocopherol loss and carotene degradation during deacidification process. Initial acidity of crude buriti oil was 3.11%, expressed as oleic acid. Experiments with 700 g of crude buriti oil were conducted following a full factorial design with 2 independent variables, temperature (ranging from 150°C to up to

260ºC) and steam flow rate (from 0.5 up to 8.5% of the load). In this case, samples were collected after 30 and 60 minutes of stripping.

2.3. Factorial design

For multivariable processes, such as food systems, a large number of factors (processing conditions) can influence the outcomes (responses) of the process. Correlating observed changes in individual factors (process variables) to changes in a response of interest is, usually, not an easy task. In this work, factorial design was applied to sketch the process conditions of experiments and simulation, according to Box et al. (1978).

2.4. Analytical Procedures

The free fatty acid content (acidity) was determined by titration with sodium hydroxide according to the IUPAC method 2201 (IUPAC, 1976). Tocopherol content was determined by HPLC combined with diode array detector following methodology proposed by SILVA et al. (2009). Total tocopherol content was obtained by fractions (α-, β-, γ- and δ-) sum. The moisture in the oily phases was determined by Karl Fischer titration according to the AOCS official method Ca 2e 55 (AOCS, 1998) and in the aqueous phase was determined according to the AOCS official method Ca 2c-5 (AOCS, 1998). These results were used in mass balances to assure the quality of the experiments. The neutral oil loss was calculated by difference.

2.5. Simulation

Oil composition and process parameters (temperatures and pressures measured during the experiments) are inputs of the simulation program. For each fatty system (M_1, M_2 and R_1), the fatty acid composition was determined by Gas Chromatography following official method Ce 1-62 (AOCS, 1998). The acylglycerol profile of crude buriti oil was determined following the method Cd 11c-93 (AOCS, 1998). The probable triacylglycerol (TAG) composition was determined using the method of Antoniossi Filho et al. (1995), cited by Ceriani & Meirelles (2007). Di- and monoacylglycerols of buriti oil were obtained from the stoichiometry of the hydrolysis reaction of TAG.

Ceriani and Meirelles (2007) modeled a laboratory-scale batch deodorization as a multicomponent differential distillation. In this process, a still (batch deodorizer) is fed and then heated until the deodorization temperature is reached. The injection of sparge steam begins and the process is performed until the required oil acidity is obtained. The volatile compounds flow overhead, are condensed and collected in a receiver. Thus, the whole deodorization process can be divided in two parts: heating (in absence of water) and stripping with sparge steam at constant temperature, which was allowed by the presence of water in the liquid-phase. The computational simulation program consisted of a differential distillation model with molar balances and equilibrium relationships. The energy balance was suppressed, and the molar vaporization rate was set as the experimental value found in each experiment. More detailed information about the computational tool/methods can be found referring to Ceriani and Meirelles (2007).

3. Results and Discussion

For sake of simplicity, this work presents only the experimental results and the comparison of them with the simulations. The results obtained by statistical models (for M2 and R1 systems) are not shown. The experimental results of the simple factorial design for model system M_1 and its comparison with the simulation results are shown in the Table 1.

The experimental results for model system M_1 indicated that: (1) while higher T (°C) and % steam improve the removal of free fatty acids, they also increase neutral oil loss

to unacceptable levels (trials 2 and 4), and (2) there is a synergetic effect between these two variables.

Table 1 – Experimental and simulation data from system M_1.

Trial	Variables		Acidity[a] (%)		NOL[b] (%)	
	T (°C)	% steam (mL/min)	Exp.	Simul.	Exp.	Simul.

RES[c]			0.25		0.14	

[a] values expressed as oleic acid; [b] Neutral Oil Loss, [c] Residue (Eq.1 - mean value).

Trials 5, 6 and 7 (central point of the factorial design) indicate a good replication of the experiments. In relation to the simulation of the process, a satisfactory correlation between its results and the experimental ones was generally achieved. Note that, in some cases, the simulation results coincided with the experimental values found. The residues shown in Table 1 were calculated using the absolute difference between the experimental and simulation results:

$$RES = ABS\ (experimental - simulation) \qquad (eq.1)$$

Table 2 shows the results for the complete factorial design of model system M_2.

[a] values expressed as oleic acid; [b] Neutral Oil Loss, [c] Residue (Eq.1 - mean value).

Besides the effects of temperature and of % steam, already discussed, one can see the

effect of increasing the ratio stearin/olein (exemplified by the pair 13-14). Increasing the proportion of stearin in the system increases its volatility, which eases the removal of acidity and also the occurrence of NOL. Once more, the comparison between simulation results and the experimental ones gave low residues for acidity and neutral oil loss.

Experimental data for the deacidification of buriti oil (Table 3) shows that 30 minutes of stripping was not sufficient to get acidity below 0.3%, as recommended by Codex Alimentarius (1999). Sixty minutes of stripping, however, were enough to get more satisfactory values (0.31 and 0.29 for trials 4 and 6, respectively). It is interesting to note the evidence of hydrolysis reaction of triacylglycerols during trial 5: acidity values after 30 and 60 minutes of stripping (3.32% and 3.37%, respectively) were greater than the initial value.

Trial 6 presented the highest neutral oil loss, followed by trials 2 and 4, as an effect of higher temperatures. This was an expected value, because neutral oil losses are related with high temperatures. In general, the neutral oil loss values were very low in other trials.

Table 3 – Experimental data for buriti oil after stripping

[a] values expressed as oleic acid; [b] Neutral Oil Loss, [c] Sample not collected

Buriti oil used in this work had all fractions of tocopherols. The most important ones were α- and β- fractions (61.4 mg/100g and 68.7 mg/100g, respectively), followed by δ-tocopherol (13.6 mg/100g) and γ-tocopherol (5.0 mg/100g). Buriti oil also had, in lower concentrations, γ- and δ-tocotrienol (1.2 and 1.8 mg/100g, respectively).

Table 3 brings the results in terms of total tocopherols (α- and β- fractions) for each trial, after 30 and 60 minutes of stripping. As one can see, the main effect on the loss of tocopherols is the applied temperature. Besides this effect, which increases the volatility of tocopherols, there is also a consumption of tocopherols during the deacidification process caused by their antioxidant activity. This observation, in fact, explains the value found for trial 5 in which the lowest temperature was applied.

Table 4 shows the results of total tocopherols obtained by the simulation tool for the processing conditions of trials 1 to 11. As one can see, a very good representation of the experimental results was obtained for samples after 30 and 60 minutes of stripping. The average relative deviations between the experimental and simulation results were 5.52% and 7.96%, respectively.

Table 4 – Simulation results for total tocopherol (mg/100g) for buriti oil after stripping

Trials	T (ºC)	% steam (mL/min)	30 minutes	60 minutes
1	166	1.66 (0.194)	135.26	135.29
2	244	1.66 (0.194)	134.93	134.14
3	166	7.33 (0.855)	135.33	135.42
4	244	7.33 (0.855)	134.43	129.96
5	150	4.5 (0.525)	135.26	135.29

9	205	4.5 (0.525)	135.32	135.33
10	205	4.5 (0.525)	135.31	135.34
11	205	4.5 (0.525)	135.26	135.36
RES [a]			6.87	9.14

[a] Residue (Eq.1 - mean value).

Controlling and monitoring of the experiments allowed a better understanding of the process studied, enabling a better mathematical modeling of the process. The simulation tool was, then, efficient in predicting the losses of neutral oil, the acidity and tocopherols in the final oil, and gave a good perspective to help the quality of the final oil improving, by defining the process parameters according to raw material and final product specification.

Interfacing IPOPT with Aspen Open Solvers and CAPE-OPEN

Weifeng Chen, Zhijiang Shao* and Jixin Qian

State Key Laboratory of Industrial Control Technology, Institute of Industrial control,Zhejiang University, Hang Zhou 310027, China

Abstract

CAPE-OPEN (CO) is brought forward as the standard for the next generation of process system simulation platform. In this work, the IPOPT algorithm and interface developed by (Lang and Biegler, 2005) is extended. IPOPT is encapsulated and is embedded into Aspen Plus through Aspen Open Solvers (AOS) Interface. A scaling module based on starting point is developed for scaling the models from Aspen Plus before optimization. The validity of AOS compliant IPOPT is tested by solving the economic optimization problem of depropanizer and debutanizer multi-column system and the reconciliation problem of large-scale air separation system. Compatibility of Aspen Plus for CO solvers is extended based on AOS interface through COM technology. In order to demonstrate validity of the extended compatibility, CO compliant IPOPT is integrated with Aspen Plus. It is tested by the same examples as AOS compliant IPOPT. Further analysis is made on effect of model scale on efficiency loss since the introduction of CO.

Keywords: Aspen Open Solvers, CAPE-OPEN, Scaling, Optimization

1. Introduction

Process system simulation and optimization have long been used as means to estimate the economic benefit and impact for environment of different design options. There have been many process simulation tools with excellent solvers, abundant unit models, or precise thermodynamic and physical properties. However, there are still critical demands for effective interactions among different modules.

CAPE-OPEN (CO) is brought forward as the standard for the next generation of process system simulation platform. It is conceived to achieve the goals of facilitating process modeling and design and increasing interoperability among various process simulation tools. The CO interoperability standard allows interoperation among heterogeneous Process Modeling Components (PMCs) and Process Modeling Environments (PMEs) from different software providers, independent of their algorithmic details, programming languages and operating system (Yang et al, 2007).

Many highly competitive software suppliers and famous research groups are involved in developing and utilizing CO compliant software, however, most of them focus on the development of CO compliant unit operations and CO compliant thermodynamic and physical properties (Ricardo et al, 2008; Testard et al, 2005). CO compliant numeric solvers, especially optimization solvers, are seldom concerned.

In this paper, the IPOPT algorithm and interface developed by (Lang and Biegler, 2005) is extended. Section 2 discusses IPOPT for Aspen Plus through Aspen Open Solvers (AOS) Interface. Section 3 presents compatibility of Aspen Plus for CO solvers based

*Corresponding author. E-mail address: zjshao@iipc.zju.edu.cn

on AOS Interface through COM technology. Section 4 then presents a number of case studies that test the validity of AOS compliant IPOPT and the compatibility of Aspen Plus for CO solvers. A further analysis is made on the effect of model scale on efficiency loss. Finally, some concluding remarks are given.

2. AOS Compliant IPOPT

This section deals with two issues for embedding IPOPT into Aspen Plus using Aspen Open Solvers (AOS) (Aspen Technology, 2003). First, a scaling module based on starting point is developed for scaling the models. And then, IPOPT is encapsulated into Dynamic Link Library (DLL) and an AOS wrapper for IPOPT is developed.

2.1. Scaling Module

Since the scaled models from Aspen Plus sometimes are not suitable for IPOPT to solve because of the ill-conditioned matrix. A scaling module based on starting point is developed for scaling the models again before optimization.

The scaling method is different from (Lid et al, 2008) which scales all the nonzero values of the Jacobian matrix of constraints. Original and scaled NLP formulations are

$$\begin{cases} \min\limits_{x} \quad f(x) \\ \text{s.t.} \quad c(x) = 0 \\ \qquad x \ \geq \ 0 \end{cases} \quad \Rightarrow \quad \begin{cases} \min\limits_{\tilde{x}} \quad \tilde{f}(\tilde{x}) \\ \text{s.t.} \quad \tilde{c}(\tilde{x}) = 0 \\ \qquad S_x \tilde{x} \ \geq \ 0 \end{cases} \tag{1}$$

where the scaled variable $\tilde{x} = S_x^{-1} x$, the scaled objective $\tilde{f}(\tilde{x}) = f(S_x \tilde{x})$, the scaled constraints $\tilde{c}(\tilde{x}) = S_c^{-1} c(S_x \tilde{x})$. S_x and S_c are fixed diagonal scaling matrices. The proposed scaling procedure is as follows,

1. Scale variables based on the starting point. If the absolute initial value of some variable is larger than one, it will be scaled. The variable scaling matrix is as follows, where x_0 is the starting point

$$S_x(i,i) = \begin{cases} |x_0(i)|, if \ |x_0(i)| > 1 \\ 1, else \end{cases} \tag{2}$$

2. Scale constraints based on the initial Jacobian matrix, $\partial c_j / \partial x_i$ is a column vector.

$$S_c(j,j) = \begin{cases} \left\| S_x(\partial c_j / \partial x_i) \right\|_\infty, if \left\| S_x(\partial c_j / \partial x_i) \right\|_\infty > 1 \\ 1, else \end{cases} \tag{3}$$

The scaling module exposes an interface (IScalingModelInfo) to supply IPOPT with all the required information.

2.2. Embedding IPOPT into Aspen Plus

We encapsulate IPOPT into DLL which exposes a class NLPStruct and a function AOS_IPOPT (NLPStruct* mynlp). NLPStruct is derived and the member methods of NLPStruct are overridden utilizing IScalingModelInfo interface. AOS_IPOPT is the entrance of the whole algorithm. PseudoSolver implementing AOSNumericNLPSystem and AOSNumericNLPSystemFactory interfaces exposes GetFactoryNLPSystem

method. When loading PseudoSolver, Aspen Plus looks for GetFactoryNLPSystem method and invokes it to create an instance of CNumericNLPSystemFactory class. For an AOSNumericNLPESO object in a being solved model, there is a corresponding CNumericNLPSystem instance allocated by the CNumericNLPSystemFactory instance in the PseudoSolver. Finally, AOSNumericNLPSystem is invoked and AOS_IPOPT function is called. IPOPT gets the required information of the model being solved by calling NLPStruct interface and CNLPStruct gets corresponding information by calling IScalingModelInfo interface. Interactions between IPOPT and Aspen Plus though AOS are shown as figure 1.

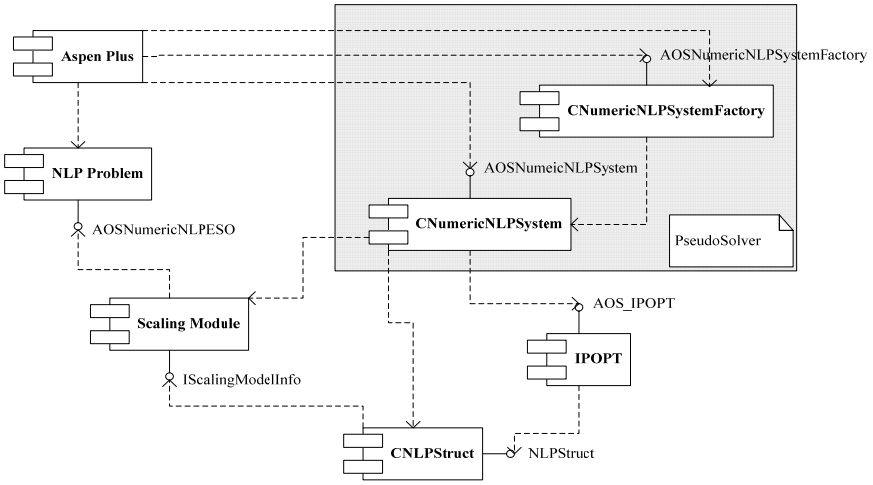

Fig 1 Component Diagram of Interaction between AOS Compliant IPOPT and Aspen Plus

3. Compatibility of Aspen Plus for CO Solver

Aspen Plus supports the CO Unit Operation and CO Thermodynamics standards. Unfortunately, so far there is no report that Aspen Plus is compatible with CO solvers. The compatibility of Aspen Plus for CO solvers is extended based on AOS Interface through COM technology.

The CO Optimization Interface issued by CO-LaN for MINLPs (CO-LaN, 2003a) is comprised of ICapeMINLP, ICapeMINLPSolverManager and ICapeMINLPSystem. One of the first steps for achieving the compatibility of Aspen Plus for CO compliant NLP solver is to implement the common CAPE-OPEN interfaces, such as Identification Common Interface (CO-LaN, 2003b), Parameter Common Interface (CO-LaN, 2003c) and Collection Common Interface (CO-LaN, 2003d). All the CAPE-OPEN components implement Identification Common Interface to provide their names and descriptions. Parameter Common Interface includes ICapeParameter, ICapeParameterSpec, ICapeOptionParameterSpec, ICapeRealParameterSpec, ICapeIntegerParameterSpec and ICapeBooleanParameterSpec. A CCapeParameterSpec class is created by implementing all the above referred parameter interfaces except ICapeParameter and it is contained in CCapeParameter class. The CCapeParameter class inherited from ICapeParameter represents all the parameters of the NLP solver. In order to facilitate handling parameters of the NLP solver, a CParameterCollection class is created by implementing ICapeCollection interface with map template class as a container.

NLP is a special case of MINLP, so it can be completely described by ICapeMINLP. CCapeNLP exposing ICapeMINLP is created by using IScalingModelInfo to represent the scaled model. CCapeMINLPSystem inherited from ICapeMINLPSystem connects a

selected NLP solver with a special CCapeNLP instance. CCapeMINLPSolverManager creates a CCapeMINLPSystem instance corresponding to a special CCapeNLP instance. It also handles the selection and configuration of the parameters of the selected solver.
In order to illustrate the progress of embedding CO solver (in this paper, we utilize CO IPOPT (Lang and Biegler, 2005) and it can be replaced by other CO solver immediately) into CO compliant Aspen Plus clearly, the component diagram of interaction between CO compliant IPOPT and Aspen Plus is given as figure 2. We can compare it with figure 1 to find out what makes Aspen Plus compatible with CO solver.

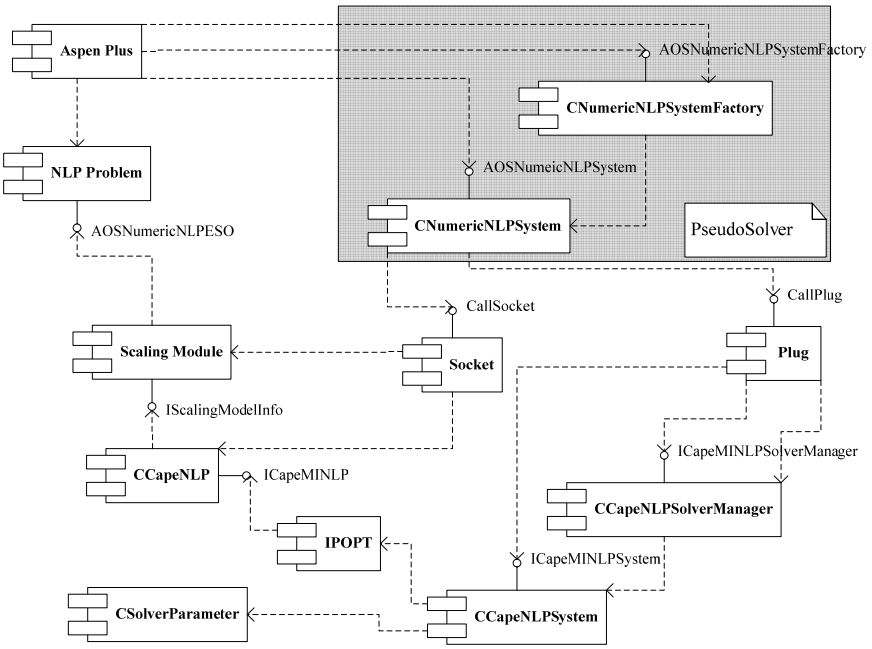

Fig 2 Component Diagram of Interaction between CO Compliant IPOPT and Aspen Plus

4. Numerical Experiments

This section deals with two issues. First, we test the validity of AOS compliant IPOPT by solving the economic optimization problem of depropanizer and debutanizer multi-column system and the reconciliation problem of large-scale air separation system. Simultaneously, we demonstrate the validity of the compatibility of Aspen Plus for CO solver by solving the same examples as AOS compliant IPOPT. Second, the effect of model scale on efficiency loss of CO compliant IPOPT is evaluated by solving two variable scale models.
All the numerical experiments are performed on the machine Dell Latitude D520 running Windows XP and with Intel(R) CPU T2300, 1.66GHz and 1.5G RAM memory.

4.1. Validity Test

Case 1 The depropanizer and debutanizer multi-column system is an important part in the ethylene production. We can refer to (Jiang et al, 2006) for the illustration of the flow sheet and the formulation of the optimization problem. For this NLP problem, number of variables is 3889, number of equality constraints is 3887, the degree of freedom is 2, and the number of nonzero elements of Jacobian in constraints is 76197. The results for solving this problem with AOS compliant IPOPT and CO compliant IPOPT respectively are presented in table 1. AOS represents the CPU time for solving

the problem with AOS compliant IPOPT. CO-InProcess represents the CPU time for solving the problem with CO compliant IPOPT run in "in process" (in the same process as Aspen Plus) mode while CO-Local is CO compliant IPOPT run in "out of process" (a separate process on the same computer as Aspen Plus) mode.

Tab.1 Numeric result of depropanizer and debutanizer multi-column system

objective	iteration	feasibility	AOS (s)	CO-InProcess (s)	CO-Local (s)
1.961e+1	11	1.95e-7	9.42	16.37	17.97

The problem is solved successfully and all the three runs have the same objective value, number of iterations and feasibility, we verify the validity of AOS IPOPT and the compatibility of Aspen Plus for CO IPOPT. Moreover, from table 1, we note that there is little difference in CPU time for solving this model in "in process" mode and in "out of process" mode.

Case 2 A large-scale air separation system was constructed which contains 36 units and 68 feed streams. Each stream has 3 components which are oxygen, nitrogen and argon. The measurement data of the process system reflects the run status of equipments and is the basis for process simulation and optimization. As the measurement error of data is inevitable, we need to revise the data before they are used as experiment data.

For this reconciliation model, the number of variable is 7184, the number of equality constraints is 7168, the degree of freedom is 16, and the number of nonzero elements of Jacobian of constraints is 40034. The results for solving this model using AOS compliant IPOPT and CO compliant IPOPT are shown in table 2.

Tab.2 Numeric result of large-scale air separation

objective	iteration	feasibility	AOS (s)	CO-InProcess (s)	CO-Local (s)
4.005e-2	173	9.44e-7	75.02	188.30	204.64

This model is also solved successfully and all the three runs have the same objective value, number of iterations and feasibility.

4.2. Efficiency Test

From section 4.1, we see that CPU time of CO wrapping increases much compared with AOS compliant IPOPT. Interoperability of Aspen Plus is gained at the expense of efficiency loss. A further test is made on the effect of model scale on efficiency loss. Two variable scale examples from (Biegler et al, 2000; Schmid, 1994) are tested.

Example 1

$$\min\ 0.5\sum_{i=1}^{n} x_i^2$$

$$x_1(x_{j+1}-1)-10x_{j+1}=0,\ j=1,\ldots,n-1$$

$$x_j^0=0.1$$

Example 2

$$\min\ \sum_{i=1}^{n-1}(x_i+x_{i+1})^2$$

$$x_j+2x_{j+1}+3x_{j+2}-1=0,\ j=1,\ldots,n-2$$

$$x_1^0=-4,\ x_i^0=1,\ i>1$$

The scale of the both examples varies from 5,000 to 200,000 with step 5,000. The relationship between the model scale and the CPU time cost is illustrated by figure 3. 'no CO' represents that the model is solved by AOS compliant IPOPT while 'CO' represents CO compliant IPOPT. 'Extra' represents the extra overhead because of the introduction of CO (namely 'CO' minus 'no CO'). Figure 3 indicates that a nearly linear relationship holds between extra overhead and model scale. The reason for this phenomenon is the implementation of the CO interface involving extra memory allocation and data copy.

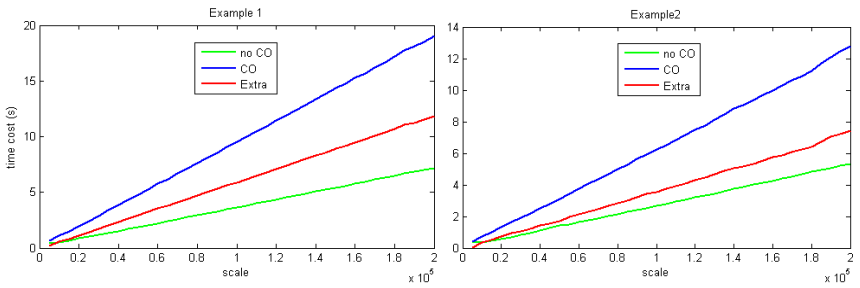

Fig 3 Relationship between the model scale and the CPU time cost

5. Conclusion

In this paper, we descirbe the development of AOS compliant IPOPT. The compatibility of Aspen Plus for CO solvers is extended based on AOS Interface through COM technology. The validity of AOS compliant IPOPT is tested by solving the economic optimization problem of depropanizer and debutanizer multi-column system and the reconciliation problem of large-scale air separation system. Moreover, validity of the extended CO compatibility of Aspen Plus is tested with the same examples as AOS compliant IPOPT.

IPOPT is embedded into Aspen Plus successfully as a new tool for solving process optimization problems. Compatibility of Aspen Plus is extended for CO compliant solver. A nearly linear relationship holds between the efficiency loss and model scale.

Abstract

The maintenance of CAPE-OPEN compliant process modelling components is a complex task. It requires accurate knowledge about three interconnected domains: the process itself, the CAPE-OPEN interfaces specification, and the middleware (COM, CORBA, and .NET). Consequently, maintenance tasks require the collaboration of several experts throughout the entire component lifecycle. Tools that assist experts in performing these tasks are thus required. This paper presents a tool that embeds enough knowledge about these three aspects, to automatically generate compliant code. Our approach is a software factory that takes as inputs three separated models describing: the process modelling component, the standard specification, and the middleware. These models are combined and refined using successive model transformations, until code is generated. In order to anticipate the evolution of the three domains, transformations are expressed on stable abstractions with respect to expected changes.

Keywords: CAPE-OPEN, Model Driven Engineering (MDE), Software Evolution

1. Introduction

The increasingly growing complexity of Computer-Aided Process Engineering (CAPE) tools, and the diversity of suppliers and technologies, has resulted in the emergence of interoperability needs, and led to the CAPE-OPEN standard [2]. This standard defines the interfaces that off-the-shelf Process Modelling Components (PMCs) [1] must implement to communicate with each other, in any compliant process modelling environment (e.g. PRO-II, Hysys). Since the adoption of the standard by the CAPE community, several tools that assist the developers of process modelling components have been made available by the CO-LaN [6]. These tools are used to guide the developer with producing CAPE-OPEN compliant components.

Most of these tools follow the same principle: the source code which does not support the calculation logic is automatically generated, while the implementation of the calculation code is left to the developers. However, in almost all of these tools, the generated code becomes hard to maintain when the component configuration changes, the standard evolves, or the middleware changes.

Indeed, the generated code includes concepts from three domains: the component model (e.g. ports, parameters), the standard specification (e.g. packages, interfaces, types) and the middleware specification (e.g. object structures, persistence, registration). Since in most existing wizards, these specifications are hard-coded, the developers need to collaborate with the wizard suppliers in order to understand how a given change affects the calculation routines. Moreover, they have to do the task manually because most existing wizards override the calculation code.

In this paper, we propose an approach that allows expressing changes through three separated views, and automatically propagating the effects of these changes to the already generated code, without losing any manually-added code. This way, the separation of views and the automation of code updates allow reducing considerably the maintenance effort of the generated code. This paper is organized as follows. Section 2 gives examples of changes impacting the three considered views. Section 3 presents our approach. Section 4 describes the validation process, and demonstrates the tolerance of the approach regarding changes impacting the three view. Section 5 summarises some related work, while a short conclusion is made in section 6.

2. Taking changes into account

Changes are considered along three axes: the process modelling component, the CAPE-OPEN specification, and the middleware. For example, a change in CAPE-OPEN can be moving operations from one interface to another (part of the transition from version 0.93 to 1.0). A change in the middleware can be the migration from COM to .NET or vice versa. A change in the process modelling component can be a modification in a unit operation's configuration, for example changing its ports and/or parameters.

As an illustrating example, suppose given a unit operation used to mix adiabatically two inlet streams to obtain a single outlet stream. A first step towards the development of such a unit is to use an existing wizard, generally specific to a standard version (e.g. CAPE-OPEN 1.0), and dedicated to COM middleware. One can start by configuring the unit ports, for example by specifying each port's name, type, and direction. Once the source code is generated, the calculation code is to add manually in the body of the Calculate method, which is localized in the ICapeUnit interface [2].

A common change impacting the unit operation is to add a supplementary inlet port, such that the unit mixes now three inlet streams instead of two inlet streams. In practice, there are two ways to take this change into account. The first way is to modify both the generated code and the calculation code manually. This requires from the developer additional effort such as declaring and initializing the new inlet port outside the calculation algorithm (namely in the constructor of the unit). The second way is to re-configure the unit using the same wizard and regenerate the code, and then modify the calculation code manually. This solution is less effort consuming for the developer, however, it requires from the wizard additional mechanisms that allow to preserve the calculation code during change propagation.

3. The Approach

Changes are expressed as editing operations on graphical models. In Model-Driven Engineering (MDE) terminology, a model is a graph of objects typed over -and constrained by- a meta model, which is a graph of classes (for example, a class diagram). A meta model is, in turn, typed over -and constrained by- a standard language, for example the Eclipse Modeling Framework (EMF)'s Ecore [11]. Model transformations are automatic operations performed on models in order to produce other models, or textual data. We call a view an association between a model and its typing meta model. The approach is illustrated in Fig. 1. Three separated views of the unit operation (1), the standard specification (2) and the middleware (3) are first introduced. The code generation process is a sequence of model transformations performed in two steps: first, an intermediate model (4) is produced, next code is generated.

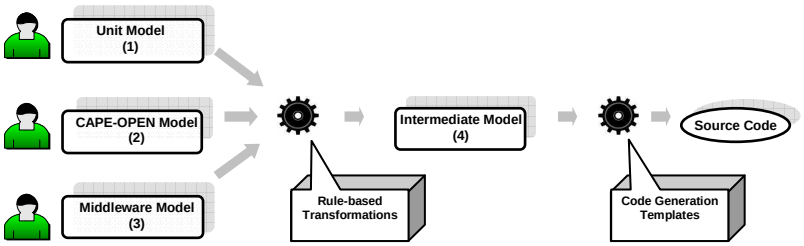

Fig.1. Overview on the approach

3.1. The unit operation view

A simplified unit meta model is presented in Fig.2. The developer configures the unit operation ports and parameters, typically using a graphical editor, which is automatically generated, by EMF, from the meta model.

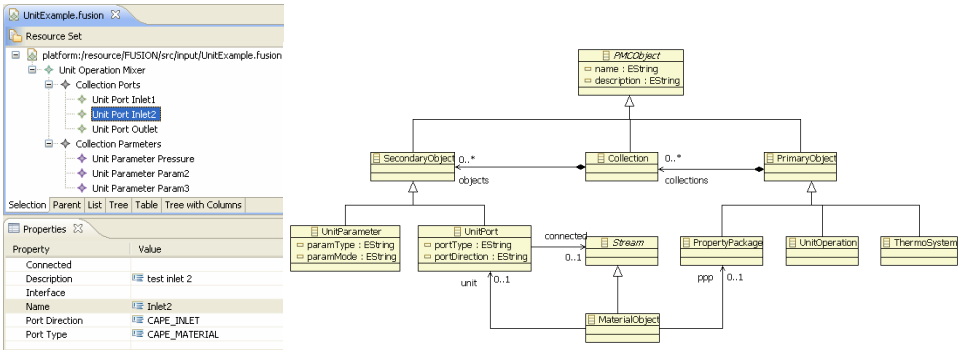

Fig.2. A unit model (on the left), the unit meta model (on the right)

3.2. The CAPE-OPEN view

The CAPE-OPEN meta model has been elaborated in order to give the user a dedicated language to express the standard types definitions. This allows specifying the standard using abstractions that are middleware-independent.

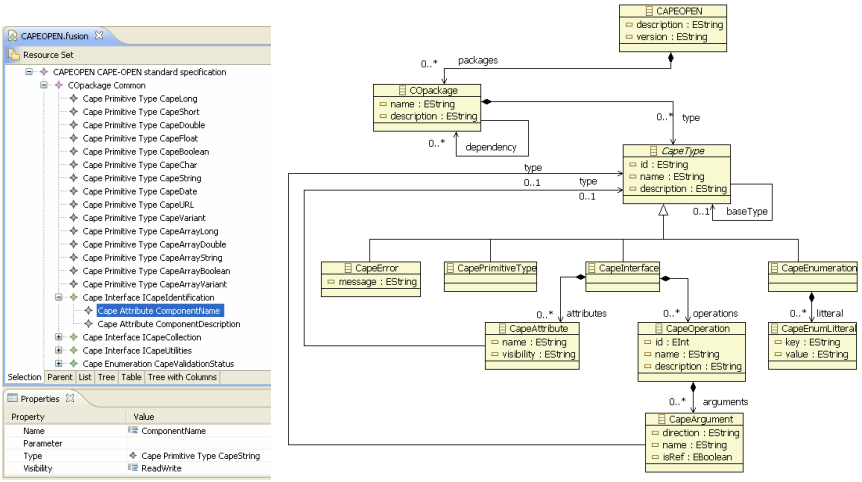

Fig.3. A CAPE-OPEN model (on the left), the CAPE-OPEN meta model (on the right)

3.3. The middleware view

The .NET meta model (Fig. 4) is inspired from [10]. Concepts relevant to COM Interop technology have been added to make the generated unit available to COM simulators. Externally, the generated unit is seen by any COM simulator as a COM based unit, assuming the .NET framework is installed in the hosting machine.

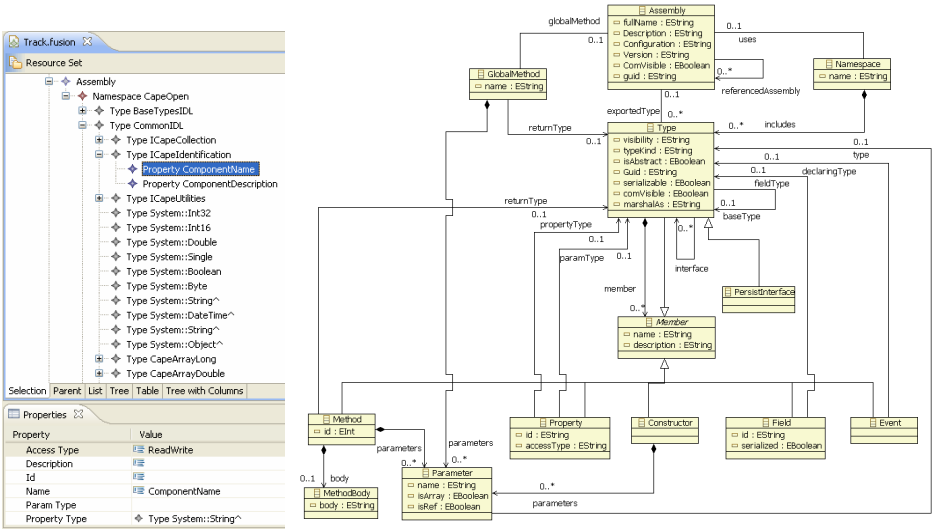

Fig.4. A .NET model (on the left), the .NET meta model (on the right)

3.4. The code generation process

The first transformation (see Fig. 1), designed using Tiger EMF [8], is based on the algebraic graph transformation theory [5]. It takes as inputs a unit operation model (1), a CAPE-OPEN model (2), and generates an intermediate model (4). The intermediate meta model is the union of the three meta models, plus traceability links used to guide the transformation strategy. The second transformation, written in Xpand language [9], is a combination of templates that take as input the model (4), and generate code.

4. Validation

In this section we give some elements towards the validation of the approach. Then, we discuss the tolerance of the approach regarding some elementary changes impacting the three views. Finally, we validate the current implementation on the example of section 2, and show how the generated code is updated while the calculation code is preserved

4.1. Validation of the approach

A first level of validation consists in validating each artefact involved in the proposed code generation process, which means meta models and transformations.

- Meta models

To validate the meta models, we adopted an iterative domain modelling approach based on code abstraction. First, an existing unit operation code has been refactored such that loosely coupled code blocks are clearly identified. Next, at each step, an abstraction is validated, and thus added to the meta model, if a change in its instances produces a code that can be compiled and tested in a compliant simulation environment. Such continuous meta model updates impact the development of the code generation process. However, the impact is quite limited in the first transformation because rules are

designed using the graphical editor of Tiger EMF, and their associated API is automatically generated by the tool.

- Rule-based transformations

Formal validation of the syntactical correctness of the first transformation has been made on general EMF models in [4]. Hence, the produced model fulfils both requirements: (i) it is typed over the output meta model, and (ii) it fulfils all the associated constraints.

- Code generation templates

The templates are validated with respect to two criteria: (i) the syntactical correctness of the generated code, and (ii) the ability of the templates to avoid writing over existing manually-added code.

4.2. Validation on case studies

Assuming meta models and transformations are validated, a second level of validation consists in quantifying the effort of taking into account some preliminary changes that impact the three considered views.

From the CAPE-OPEN view, elementary changes (e.g. changing operations signatures, moving operations) are performed manually using the associated graphical editor, and are automatically propagated by the code generation process. However, these changes have to be propagated also to the simulation environment, so that it can implement the same (changed) version of the standard.

From the middleware view, the use of .NET is due to the fact that the evolution from COM to .NET has been already anticipated by Microsoft. Indeed, mechanisms that allow making .NET components available to COM (e.g. COM Interop) have been integrated to the .NET framework as additional APIs. Hence, we expect to use the actual middleware view to generate both COM and .NET unit operations.

As to the unit operation view, some elementary changes have been tested (e.g. adding/removing ports, adding/removing parameters). In the example of section 2, we wanted to check if changes to the unit operation view were easily taken into account (e.g. adding a unit port). The following template code is responsible of instantiating all the ports configured in the unit operation model.

```
CapeOpen::Mixer::Mixer(void)
{
          «EXPAND TUnitPort::AddPorts»
}
«DEFINE AddPorts FOR TrakingModel»
«LET unitoperation.collections.get(0) AS ports»
«FOREACH ports.objects.typeSelect(UnitPort) AS aPort»
          this->PortCollection->Add(gcnew CUnitPort("«aPort.name»", "«aPort.description»",
          CapePortDirection::«aPort.portDirection», CapePortType::«aPort.portType»));
«ENDFOREACH»
«ENDLET»
«ENDDEINE»
```

The generated C++ code (below) is localized in the unit constructor, and called by the simulator when the unit is added to the flowsheet. This code is out of the scope of the calculation routines. A run is required to update it, unless the developer does the task.

```
CapeOpen::Mixer::Mixer(void)
{
          this->PortCollection->Add(gcnew CUnitPort("Inlet1", "test inlet 1",
          CapePortDirection::CAPE_INLET, CapePortType::CAPE_MATERIAL));
          this->PortCollection->Add(gcnew CUnitPort("Inlet2", "test inlet 2",
          CapePortDirection::CAPE_INLET, CapePortType::CAPE_MATERIAL));
          this->PortCollection->Add(gcnew CUnitPort("Outlet", "test outlet",
          CapePortDirection::CAPE_OUTLET, CapePortType::CAPE_MATERIAL));
}
```

In order to avoid losing the calculation code, the body of the Calculate method has been put into a protected region, so that its corresponding part in the generated code is not overridden by the next run. This preliminary solution allows updating the constructor of the unit operation, without writing over the calculation code.

```
«PROTECT CSTART "/*" CEND "*/" ID this.name+"::calculate"»
/**********************************/
/*    ADD CALCULATION CODE HERE    */
/**********************************/
/**********************************/
«ENDPROTECT»
```

5. Related Work

Several software tools are used to guide the developer on the steps to be taken towards producing CAPE-OPEN compliant components. Currently, two COM specific wizards are available on the CO-LaN website: the first one is compliant with version 0.93, and the second is compliant with version 1.0. Other unit operation wizards are also available: one written in C++ (donated by IFP) and one written in FORTRAN 90 (donated by TOTAL). Each of these tools is specific to a version of the standard, and a middleware. More recently, the development and integration of CAPE-OPEN compliant PMCs using the .NET framework has been discussed in [3]. A detailed COM/.NET interoperability guideline is also available on the website.

6. Conclusions and Perspectives

In this paper, we proposed an iterative model-driven approach for the generation of CAPE-OPEN compliant process modelling components. The approach takes three separated models as inputs, representing three expert views on the development of process modelling components. The combination of these models and code generation are delegated to the tool, using a sequence of model transformations. Future work will include a decomposition of changes into sequences of atomic editing operations that leads to tracking the history of changes within each expert view, and the elaboration of a more expressive unit meta model that allows generating parts of the calculation logic.

Abstract

A multiscale modelling approach for designing polymers is presented in this work. Here, the desired properties of a polymer is given as input in the polymer design problem, computer aided molecular design (CAMD) algorithm using group contribution plus models (macro-meso scale) gives out the polymer repeat unit structures satisfying the desired properties as output. The arrangement of polymer repeat unit structures to form a polymer chain and the properties corresponding to the generated polymer are studied in micro-scale approach. A case study using this multiscale approach is presented in this paper.
Keywords: CAMD, Polymer design, Multiscale modelling, Polyisobutylene.

1. Introduction

The search for new polymeric compounds with desired end-user properties is an important problem in chemical, pharmaceutical and food industries. There are a number of methods that can be used for designing new polymers with desired properties. But each method has its own set of advantages and limitations. For example some are too time consuming (like quantum mechanics based methods) while some are capital intensive (like laboratory scale preparation of too many polymers). The ability to predict the physical and chemical properties of macromolecular materials from their molecular structure prior to synthesis is of great value to the design of products with higher knowledge content, new functionalities and improved performance. Computer-aided approach can expedite the design process by establishing input-output relations between the type and number of molecular groups in a polymer repeat unit and the desired macroscopic properties. Integration of such computer-aided approaches on the basis of the molecular descriptor used to describe the polymer structures (*i.e.* based on the time and length scale shown in figure 1) is considered in this work which is called a *multi scale approach* for computer aided polymer design.

Identification of a basic polymer repeat unit at macro scale level requires an appropriate computer aided molecular design (CAMD) algorithm (where fragments are used to design the homopolymer repeat unit structures) and a set of property prediction models. Group contribution based property prediction models[1-3] are sufficiently simple and reliable for use in CAMD, but due to the limited availability of experimental data for polymer properties, one cannot expect to fill out the entire group parameter table. At times there can also be a polymer repeat unit structure that cannot be totally represented

by groups for a specific group contribution method. This is overcome by a meso-scale approach, where an atom-connectivity index method is applied to determine the missing groups and their contributions automatically without the need for additional experimental data. This integration of group and atom-connectivity index based models is called group contribution plus (GC^+) model. Integration of Marrero/Gani (MG) group contribution methods and atom-connectivity index methods that has been proposed as MG-GC^+ models for polymers in Satyanarayana et al[3] is used in this work. The next step is to decide on the type of CAMD algorithm. Different types of CAMD algorithms have been proposed for homopolymer repeat unit structure identification for a specified set of property criteria[5-8]. A multi-step, multi-level hybrid CAMD algorithm by Harper and Gani[8] suppresses the combinatorial explosion problem; it is also capable of generating a large number of structures. This method has been modified for using the GC^+ models of Satyanarayana et al[7] and it is the one employed in this work.

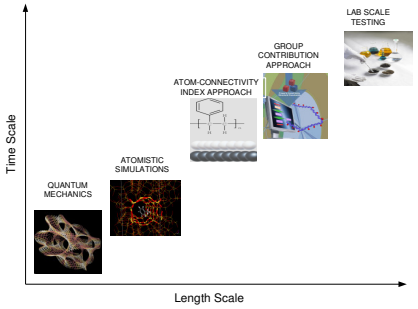

Fig 1. Multi scales for developing new polymer product

The identified basic repeat unit(s) are then used as input in molecular simulation algorithms (micro-scale) to generate a polymer chain with the desired number of repeat units and then to either predict or validate the required set of properties (some properties can vary with the varying chain length or varying number of repeat units). The accuracy of the results (e.g., thermodynamic, structural, conformational, etc.) obtained from molecular simulations depend on the efficiency of the simulation method used and the reliability of the force-field employed for describing the intra- and inter-atomic interactions. At low temperatures or for highly complicated polymer structures, these simulations are computationally intensive and time consuming. To overcome this, hierarchical simulation methodologies[9] are followed or multi-scale modeling algorithms are developed based on the definition of super-atoms. The latter approach is a method followed to reduce chemical complexity in a polymer chain without losing the chemical identity of the molecule. It is based on grouping a certain number of atoms or repeat units along the chain together into "super atoms" (or United Atoms) connected by effective bonds and governed by softer or smoother effective non-bonded interactions (shown in Stage 1 of figure 2). The resulting chain sequence is simpler and amenable to fast thermal equilibration and simulation through a brute-force application of the molecular dynamics (MD) method or by a Monte Carlo algorithm properly modified to account for the presence of the few different species along the chain.

By integrating the different scales, from macro- to micro-scale, the uniqueness of each method is retained while their limitations are avoided to some extent. Thus, this offers a promising avenue to the materials design problem, where one should propose structures satisfying a set of performance criteria. This methodology is illustrated for a case where materials performance is judged based on permeability (solubility and diffusivity) properties to small gaseous molecules.

2. Case Study

A case study using the detailed methodology (shown in figure 2) is performed. We consider here a problem referring to the design of a hermetic stopper for medical containers, which intend to secure against the entry of air or microorganisms and

maintains the safety and quality of the contents stored in their containers. Natural rubber (can cause latex allergies) and cork (has varying pore size) can also be used as sealants. It would be interesting to design a polymeric material for use as a hermetic stopper which can retain the advantages of existing stopper materials and overcome their disadvantages.

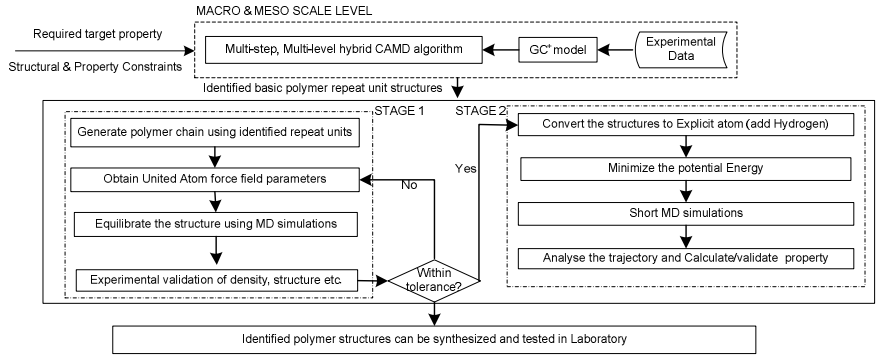

Fig 2. Schematic work-flow of the multiscale modeling.

2.1. Application of the macro-meso scale approach

*T*he basic homo-polymer repeat unit structures are identified in this approach. This requires specifying initially, a set of structural and property constraints.

2.1.1 Property Constraints (a) Glass transition temperature (T_g) – the polymeric stopper is required to be elastic over a wide range of temperature, and it is preferred to be made of a rubbery amorphous polymer so that its T_g is less than or equal to the room temperature (300 K)[1]. The upper limit for T_g can be relaxed to 350 K. By doing this, the effect of missing some candidates that have the required property (but are not identified due to inconsistency of the experimental data reported and also considered while developing the property prediction models) is minimized to some extent. (b) Dielectric constant (ε) – some contents stored in the medical containers need to be constantly agitated with electrical agitators before use. It is therefore required that the polymeric stopper should not conduct electricity and electrolyze the stored contents in the medical containers; this implies a low ε. Here, we impose a maximum constraint of 2.6 on the value of the ε. (c) Low permeation to moisture and air – the stopper should protect the stored contents from moisture and air, and to exhibit very low water (or moisture) absorption[1]. As the GC^+ model for predicting water absorptivity has not yet been developed, Van Krevelen's[1] group contribution model is used to predict this property (to verify if the identified repeat units have low water absorptivity) for the identified repeat units that satisfy both T_g and ε constraints. Moreover, low permeation to air implies low permeation to nitrogen (N_2) and oxygen (O_2). Since there is no direct group contribution method to study the solubility and diffusivity in the polymer, the micro-scale approach is also used for determining these properties (along with the arrangement of repeat units to form polymer chains).

2.1.2 Structural Constraints The focus here is to design a polymer with low permeability to moisture, therefore the polar and hydrogen bond forming functional groups should not be included in the basis set. Reason being, they often enhance chain-chain attractions, which tends to enhance crystallinity and tensile strength. Therefore, only the groups forming olefinic polymers are allowed. It is also known that the double bonds in polymers render them poor for weather resistance, thermal resistance, oxygen

resistance and ozone resistance. This applies also to olefinic groups with triple bonds. Taking this into account, olefinic groups with double and triple bonds are excluded from the basis set, which therefore included CH_3, CH_2, CH and C groups only. As the side chain forming groups (CH and C) are included in the basis set, in order to avoid too many side chains in the basic polymer repeat unit, the number of times each group can occur in the repeat unit is limited to 2 implying that the maximum number of groups that can occur with the combination of all the groups included in the basis set is 6. This is shown in eq. 1, where, n_j is the number of groups of type j.

$$2 \le \sum_j n_j \le 6 \qquad \text{(Eq. 1)}$$

As this case study aims at generating a basic homo-polymer repeat unit that has two free ends, the criterion of having two free ends in each generated structure is also specified (based on valency and octet rule) as shown in eq. 2, where n_j, v_j are the number and valency, respectively, of groups of type j and m =1, 0 or -1 for acyclic, monocyclic and bicyclic groups, respectively. As only olefinic groups are considered, the value of m=1.

$$\sum_j (2 - v_j) n_j = 2(m-1) \qquad \text{(Eq. 2)}$$

Table 1: Identified polymer repeat unit structures using CAMD algorithm

Property & Structural Constraints	Min	Max	
Glass Transition temperature (K)		350 K

Structural and property constraints were ser as input to the CAMD algorithm. 112 candidates of basic repeat unit structures with isomers were designed and 106 candidates among them were selected based on the given constraints. Removing the isomers, 12 basic polymer repeat units that satisfy all constraints are listed in table 1. The repeat unit structure of polyisobutylene (PIB) is one of the identified repeat units from the CAMD algorithm. PIB is important elastomers with low T_g and high friction coefficient. From different literature sources[10-12] it is also reported that this polymer exhibits low permeability properties to small gas molecules in comparison to other elastomers due to the presence of the two bulky pendant methyl groups on each basic repeat unit structure. Permeability is described as the product of solubility and diffusivity. Lower solubility and diffusivity values always correspond to low permeability. As it is highly time consuming to study the entire identified basic polymer repeat unit structures at the micro-scale level (at this point of time), only PIB was addressed in the present case study

2.2. Application of the micro scale approach

Recently, Tsolou et al[9] undertook a systematic study of PIB system models ranging from 8 up to 80 repeat (monomer) units per chain at different temperatures (from 600 K to 300 K). The development and implementation in the molecular simulations of a new UA force field for PIB, which reproduces faithfully the conformational, structural and thermodynamic properties of the polymer is the key feature of this work. Guided by Tsolou et al[9], the first stage of the micro-scale approach of the present case study involved the execution of atomistic MD simulations with a C_{320} PIB system at several temperatures. The outcome of these simulations was an ensemble of well-relaxed configurations, which were used next as input to all-atom (AA) simulations (simulations

in which the atomistic detail is restored with the insertion of the missing hydrogen atoms along each PIB chain) for the accurate prediction of the solubility and diffusivity properties of PIB to small molecules such as O_2 and N_2 of interest here. Through such an approach, Tsolou et al[9], for example, obtained excellent predictions of O_2, N_2, He and Ar solubility in PIB as a function of temperature. In the present study, the approach was extended in order to calculate the diffusivity of O_2 and N_2 in PIB. Overall, the steps undertaken in the micro-sale approach are: (a) 3-chain PIB system with 80 monomers per chain was subjected to long atomistic MD simulations in the NPT ensemble using the parallel LAMMPS code and the new UA model introduced by Tsolou et al[9]. (b) Well-relaxed configurations from these UA simulations at four different temperatures (350, 450, 500 and 550 K) were selected and converted to AA representations by re-inserting the hydrogen atoms that had been neglected in the UA simulations. (c) After a short energy minimization of the chosen PIB system, five O_2 molecules were randomly inserted at different positions inside the matrix at the temperature of interest, and the energy of the system was minimized again. (d) Long MD runs (up to 3 ns depending on the temperature) in the NPT statistical ensemble were carried out, which allowed us to monitor the time evolution of the 5 oxygen molecules. In all simulations with the all-atom model, the very detailed and accurate COMPASS force field was used.

The diffusivity of oxygen molecules in the PIB matrix was studied in terms of the time evolution of their mean square displacement (MSD) in the course of the MD simulation. The diffusion coefficient, D, can then be readily computed from the linear part of the curve through the Einstein relation[13], where $\mathbf{r}_i$ denotes the position vector of the center of mass of the diffusant and angular brackets denote ensemble average over five (*i.e.*, N_a=5) O_2 molecules and over all possible time origins in the course of the trajectory.

$$D = \frac{1}{6N_a}\lim_{t\to\infty}\frac{d}{dt}\sum_{i=1}^{N_a}\left\langle\left[\mathbf{r}_i(t)-\mathbf{r}_i(0)\right]^2\right\rangle \qquad \text{(Eq. 3)}$$

Clearly, as the temperature decreases, the diffusivity of O_2 in PIB slows down considerably. By plotting log(D) versus 1/T (Fig. 3), a linear plot is obtained whose slope provides an estimate for the activation energy of the diffusive process defined as:

$$E_a^{app} = -\frac{R}{0.434}\frac{\partial(\log D)}{\partial\left(1/T\right)} \qquad \text{(Eq. 4)}$$

The value obtained from the data of Fig. 3 is 5.7kcal/mol. (the experimental value of 11.9 kcal/mol reported by Amerongen[14] from diffusivity data measured over a range of lower temperature values). In fact, Amerongen reports that the activation energy is not constant but increases with decreasing temperature. This indicates that the relatively higher value of E_a^{app} predicted from our micro-scale approach is quite reasonable.

2.3. Case study results and discussion

This case study has justified the success of the potential application of a multilevel approach to the design of a polymer with a set of pre-specified properties. Using the macro-meso-scale approach, a set of basic polymer repeat units promising to have the required target properties is obtained. Water absorptivity values for the identified basic polymer repeat units were comparatively lower as shown in table 1. On the other hand, the macro-meso-scale approach alone cannot decide about the optimal arrangement of the repeat units or the chain length; in the context of the proposed multi-level approach, this is the task of the micro-scale component. In the present case, for example, we chose to simulate PIB with C_{320} and compute its permeability properties to small molecules like O_2 and N_2. The simulation results from micro-scale work seem to verify the low permeability of O_2 in the designed polymer. Given that the molecular size of O_2 is smaller than N_2, we can safely conclude that PIB will also be characterized by low

permeability to N_2. Therefore, this polymer will have a low permeability to air. Other PIB systems with varying carbon number (C_{80}, C_{120} and C_{240}) will also be studied in the future to verify which system has lowest permeability to air. But the next step is to recommend the polyisobutylene with a chain length of 80 monomer repeat units for laboratory scale synthesis, to experimentally validate the properties claimed here.

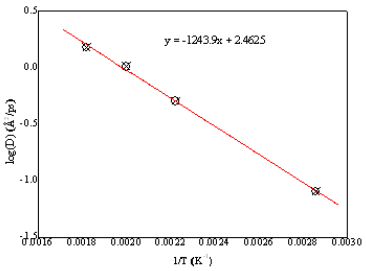

Fig 3. Log(D) versus 1/T for O_2 in PIB-C_{320} matrix

3. Conclusions

A multi-level approach for the design of polymers with a set of required properties, which can substantially help decrease the time for the development of new products have been presented in this paper. This approach relies first on the application of GC^+ property models in the CAMD algorithm for the identification of the polymer repeat unit structure properties; this greatly enhances the application range of problems that can be handled. Since the CAMD algorithm does give complete information on how the basic polymer repeat units should be arranged for the resulting polymeric structure to have the desired properties, a micro-level approach is also proposed to be employed. By providing the link to microstructure, it is capable of deriving reliable estimates of the desired properties based on the principles of quantum and statistical mechanics, and statistical thermodynamics. We have applied such a multilevel approach to a case study aimed at designing a polymer that can be used as a hermetic stopper. One of the basic polymers identified from the macro-meso-scale approach for such an application was polyisobutylene. In comparison to other elastomers and based on literature data, this polymer is characterized by a low glass transition temperature and markedly low permeability to O_2, N_2 and air. We concluded that PIB would be a candidate for constructing hermetic stoppers for use in medical applications.

Predicting refinery energy losses due to fouling in heat exchangers

Francesco Coletti and Sandro Macchietto

Department of Chemical Engineering - Imperial College London
South Kensington Campus
London SW2 2AZ (UK)

Abstract

Energy efficiency is paramount in an oil refinery and heat integration is critical, especially in the energy-intensive atmospheric distillation unit. Thermal and hydraulic performance of each exchanger in the network used to pre-heat the crude is greatly reduced by the progressive deposition of unwanted material on the thermal exchange surfaces. Here, a detailed mathematical model for a shell and tube heat exchanger undergoing crude oil fouling is used to predict local and average fouling rates and identify critical performance areas in the exchanger. The ease of configuring the model for industrial applications is detailed. With reference to an industrial unit, it is shown that unit averages mask very different local behavior, and that it is possible to achieve precise calculation of heat duty loss caused by fouling over time.

Keywords: Fouling, crude oil, modeling, refinery, energy, heat exchanger.

1. Introduction

Fouling is a major cause of energy losses in oil refineries. In particular, fouling in the crude pre-heat train of the atmospheric distillation unit is source of extra costs and greenhouse gas emissions, disruptions of operation and hazards. Losses due to fouling in the US alone were estimated to be in the order of $1.2 billion per annum in 1992 (ESDU 2000), or $1.8 billion in 2008 simply adjusting for inflation. The pre-heat train (PHT) is a network of shell and tube heat exchangers (of the type in Figure 1) that is used to recover heat from the hot products of the distillation column. This allows the refinery to decrease energy requirements at the furnace which brings the oil to the final temperature required for the fractionation. Although all the units in the PHT experience fouling, it is particularly severe in the hot-end, where the temperature is high enough to activate chemical reactions between crude components. Over months, a deposit layer builds up on exchange surfaces with the two-pronged effect of increasing the pressure drops across the unit and decreasing the overall heat transfer coefficient. As a result, more pumping power and more energy at the furnace are required, adding extra costs to operations. Moreover, large production losses arise when the furnace firing limit is reached as it is necessary to reduce throughput to maintain a constant inlet temperature at the column. Further large losses arise from periodic cleaning shut-downs.

The oil industry has faced this problem for decades and the efficiency of the pre-heat train is a primary concern for refinery operators. Operations are scheduled so as to minimize the energy lost due to fouling. The heat duty is constantly calculated (and fouling monitored) from plant data. However, tools to help refiners to analyze plant data

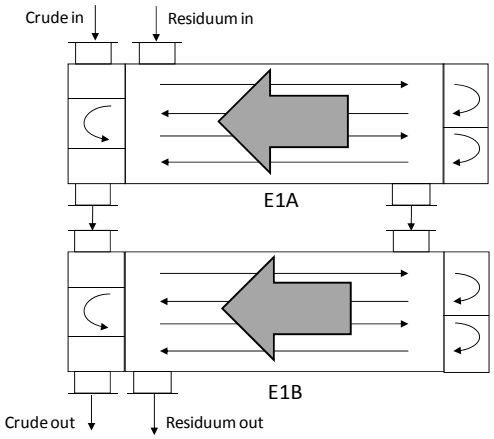

Figure 1 Heat exchanger geometry considered in the case study. The unit comprises two shells with four pass each. Crude is flowing on the tube side, residuum on the shell side.

and predict fouling behavior with accuracy are still lacking. Models based on the threshold concept (Ebert and Panchal 1995) have been used to include crude oil fouling when designing or retrofitting single units (Polley *et al.* 2002), whole PHTs (Nasr and Givi 2006; Yeap *et al.* 2004) and to assist in cleaning scheduling to improve the network operability and mitigate maintenance-related costs (Ishiyama *et al.* 2007; Smaili *et al.* 2001; Wilson and Vassiliadis 1997). All above use lumped models based on a macroscopic thermal balance and quasi-steady state approximations. They do not take into account local variation in conditions along the units (known to be significant) and dynamics. In this paper a distributed, dynamic first principle model (Coletti and Macchietto 2009) is used to predict fouling rates and identify critical performance areas in the heat exchanger. Moreover, it is shown that use of the model can help solve the difficult problem of calculating the effects of fouling on the loss of heat duty for exchangers with highly varying inlet conditions.

2. Approach

The conceptual framework developed to simulate refinery data is as follows:

1. Develop a high fidelity, first principle model
2. Analyze refinery data to identify unreliable data
3. Estimate model parameters from reliable data and validate model
4. Use validated model to predict behavior as function of process conditions

The model used for a tubular heat exchanger undergoing crude oil fouling in step 1 has been presented in (Coletti and Macchietto 2008; 2009). Table 1 summarizes the main model equations in each domain considered: tube side ($\Omega_{T,n}$); deposit layer ($\Omega_{L,n}$); tube wall ($\Omega_{w,n}$) and shell side (Ω_S). The model is dynamic and distributed along the length of the heat exchanger and captures the time- and space- varying effects of process variables (geometry, temperature, velocity and crude oil properties) on deposition mechanisms. For this purpose, the classic Ebert-Panchal model for chemical reaction fouling was used locally. The model accounts for important interactions between the fouling layer and fluid flow. Step 2 (refinery data analysis) and step 3 (parameter estimation) above are given in a previous paper (Coletti and Macchietto 2009) for the specific industrial application described in the following, leading to excellent match to

Table 1 Summary of main model equations. Ω is the domain considered (see text).

Ω	Equations
Ω_T	$\frac{\partial}{\partial t}\left(A_{flow}\rho e\right) = -\frac{\partial}{\partial z}\left(A_{flow}\rho u e\right) + \frac{\partial}{\partial z}\left[A_{flow}k\frac{\partial T}{\partial z}\right] + Ph_t\left(T_w - T\right) \quad \frac{dR_{f,n}}{dt} = \alpha\,\mathrm{Re}^{-0.66}\,\mathrm{Pr}^{-0.33}\exp\left(\frac{-E}{RT_{f,n}}\right) - \gamma\tau$
	$T_{f,n}(z) = T_n(z) + 0.55\ \left(T_{L,n}(z, R_{flow}) - T_n(z)\right);\qquad \tau = C_f\left(\frac{\rho u^2}{2}\right);\qquad \frac{d\delta_n(z)}{dt} = k_L\frac{dR_{f,n}(z)}{dt}$
Ω_L	$\frac{\rho_L c_{p,L}}{k_L}\frac{\partial T_{L,n}}{\partial t} = \frac{1}{r}\frac{\partial T_{L,n}}{\partial r} + r\frac{\partial^2 T_{L,n}}{\partial r^2};\qquad q_{L,n} = -k_L\frac{\partial T_{L,n}}{\partial r}$
Ω_w	$\frac{\rho_w c_{pw}}{k_w}\frac{\partial T_{w,n}}{\partial t} = \frac{1}{r}\frac{\partial T_{w,n}}{\partial r} + r\frac{\partial^2 T_{w,n}}{\partial r^2};\qquad q_{w,n} = -k_w\frac{\partial T_{w,n}}{\partial r}$
Ω_S	$\frac{\partial}{\partial t}\left(\rho_S c_{p,S} T_S\right) = \frac{\partial}{\partial z}\left(\rho_S c_{p,S} T_S u_S\right) + \frac{\partial}{\partial z}\left(k_S\frac{\partial T_S}{\partial z}\right) + \frac{1}{A_S}\sum_{i=1}^{N_p} P_{S,i}h_S\left(T_S - T_{w,i}\right)$

actual plant data. The model could predict the outlet temperatures of a shell and tube heat exchanger undergoing crude oil fouling, as a function of process conditions and time, within ±1°C.

2.1. Model implementation

The model partial, differential and algebraic equations are solved using the gPROMS™ modelling environment exploiting its hierarchical structure. A single tube model is defined once and re-used as many times as needed within desired multi-pass configurations to describe a full single shell, tubular heat exchanger unit (Figure 2). Such exchanger model is then itself defined as an object that can be easily replicated and flexibly interconnected with other units in a flowsheet (e.g. double shell unit in Figure 1). This feature is particularly handy considering that pre-heat trains can comprise up to 60 heat exchangers interconnected in a single network (Panchal and Huangfu 2000). Configuring a model requires geometric exchanger data and thermo-physical oil properties. The exchanger geometries were inputted directly from standard company data sheets, in an Excel spreadsheet, via gPROMS' built-in goEXCEL interface. This feature makes it extremely simple to set-up the model for a unit under investigation. Various thermodynamic packages accessed via a CAPE-OPEN interface allow defining oils in terms of either their gas chromatographic analysis or true boiling point curve. The thermodynamic package can then be used to calculate, at each point in time and axial length, physical properties such as density, viscosity, heat capacity and thermal conductivity of the fluids flowing in both shell and tube sides.

2.2. Case Study

The model was applied to simulate an industrial unit in an ExxonMobil pre-heat train. The unit comprises two identical shells with 4 tube pass per shell, with crude in the tube-side and residuum from the distillation column in the shell side (Figure 1). For this case study, the physical proprieties of tube- and shell-side oils where not calculated through the thermodynamic package but were assumed constant and values estimated from a short set of plant data (inlet and outlet temperatures, and flowrates). Operating conditions over 150 days after a mechanical cleaning were then simulated, with inlet temperatures and flow rates from measured plant data. The main model parameters used in the simulations are summarized in Table 2.

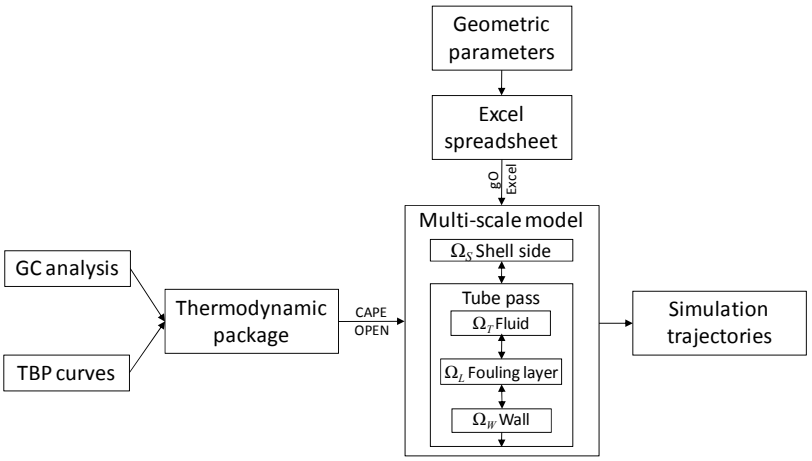

Figure 2 Implementation of the model in process simulator. Physical proprieties are calculated through a thermodynamic package which is interfaced via CAPE-OPEN. Necessary geometries are set interfacing the process simulator with an Excel spreadsheet.

3. Results

Model simulations allow tracking the trajectory of key variables over time and space. Figure 3.a shows the averaged (over length) fouling resistance, R_f, in each pass in each shell in the unit, for 150 days. The fouling resistance calculated in shell E1B is larger than that in E1A. This is expected as temperatures in the latter are lower than those in the former. An overall fouling resistance for the unit (the arithmetic average between the two shells) is plotted in the same figure as a solid line. A large difference is evident between the shells, and the unit-average resistance seriously underestimates local fouling effects (therefore occlusion and pressure loss) at the hot end of tubes. This can be observed by tracking the local thickness of the fouling layer. In Figure 3.b the foulant thickness, δ, is reported at the inlet and outlet of the unit, over time. Again, the difference in thickness after 150 days is evident. The qualitative difference in fouling behavior is also noted: at the tube inlet, foulant thickness reaches an asymptotic value whereas at the tube outlet the behavior can be assimilated to a linear fouling rate.

Table 2 Summary of main model parameters.

Parameter		Tube	Shell	
			E1A	E1B
Density, ρ	kg m^{-3}	817	880	
Viscosity, μ	Pa s	2.002×10^{-3}	-	
Heat capacity, C_p	J K^{-1} kg^{-1}	2184	2462	
Thermal conductivity, k	W m^{-1} K^{-1}	0.125	0.180	
Tube length, L	m	6.1	-	
Tube diameters, d_o/ d_i	mm	25.40/19.86	-	
Shell diameter, D_S	m		1.397	
Activation energy, E	J mol^{-1}		28931	28626
Deposition constant, α	m^{2}K kW^{-1} h^{-1}		1.689×10^{-3}	1.785×10^{-3}
Suppression constant, γ	m^{2}KW^{-1}s^{-1}Pa^{-1}		6.8×10^{-11}	2.1×10^{-11}
Pass number			4	4
Tube count, N_T			880	880

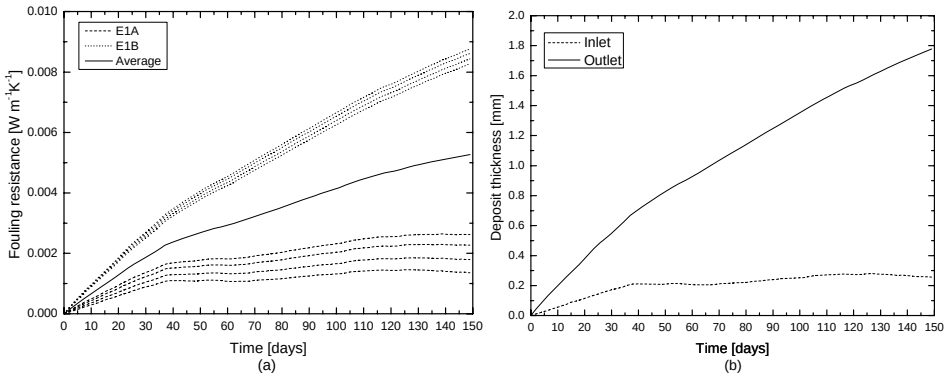

Figure 3 Fouling resistance for each tube side pass in the two shells and average value for the unit (a) and deposit thickness at inlet and outlet (b).

By repeating a simulation without fouling in the model (R_f=0) it is possible to calculate, for the given process conditions, the difference between the heat exchanged in clean and fouled conditions (Figure 4.a). At time zero (clean exchanger), there is no difference between the two scenarios. However, after few days of operations the difference becomes large. The same figure also reports the heat duty loss due to fouling calculated as the difference between the heat duties in the two scenarios considered. The maximum difference occurs after 135 days when the calculated loss in heat duty is over 2.5 MW. Losses at any one time depend on (variable) inlet temperatures and flowrates, which makes it difficult to isolate the fouling effects. The shaded area below the heat loss curve represents the energy actually lost because of the thermal inefficiencies caused by fouling and is given by the integral over time of the difference in heat duty clean and fouled. The underlying energy loss trend can be noted from a straight line linear fitting, as indicated at the bottom of Figure 4.a, or a rolling average. Figure 4.b shows the integral of the heat duty loss over time representing the cumulative energy loss. After 150 days the cumulative energy loss due to fouling is nearly 140 MJ, equivalent to a cost of extra fuel burnt in the furnace of over US$ 30,000 (considering a cost of the fuel at 27 $/KWh and 90% furnace efficiency).

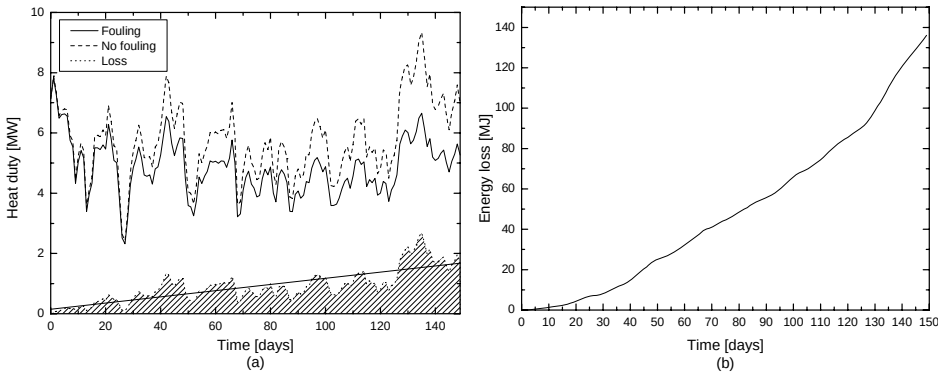

Figure 4 Heat duty from model simulations in case of fouling and no fouling over time (a). Dashed line in the bottom indicates the difference between the two. The shaded area is the energy lost due to fouling, and the straight line is obtained by linear fitting. Cumulative energy loss is given over time in (b).

4. Conclusions

A novel dynamic model for a multi-pass shell and tube heat exchanger was developed for use in refinery preheat trains, where fouling deposition results in severe energy inefficiency. It considers several aspects of the fouling phenomenon such as the local interactions between the onset and growth of the fouling layer and the crude oil flowing inside the tubes. The model allowed carrying out a detailed analysis of the related spatial and temporal evolution of thermal and hydraulic performance inside an industrial heat exchanger unit. The model was set up with the industrial unit configuration, tuned to local conditions for a clean unit, and then driven according to actual measurement of the input variables from the plant. Results showed the difference between the heat duty in clean and fouled conditions as a function of operating conditions, allowed a precise estimation of energy losses (hence extra energy and emissions duties at the furnace) and highlighted the very different performance in different parts of the exchangers.

A variety of applications are envisaged, including for improved operations (fouling monitoring of individual exchangers, energy loss calculation at PHT network scale, control mitigation applications, prediction of time to clean) and for exchanger design and retrofit. Further model improvements will include other complex phenomena such as ageing of the deposits and the effect of oil composition on physical properties.

Abstract

One of great challenges found in electric thermal plants boiler operation is to avoid the erosion problem on water wall ducts. This problem is generally caused by three different sources: flame misalignment, thermal attack and erosion due to the contact with chemicals. This work focus on investigate the effect of flame misalignment. This problem can be caused by fluid dynamics factors due the burner geometry, which can be very complex. The key part of the burner the swirler, whist working generates a spiral flow starting in the burner and following towards the rear of the boiler. The numerical simulation of this system has been developed using the commercial software of Computational Fluid Dynamics (ANSYS CFX). It has been chosen based on its robustness in mesh generation and to solver conservation equations by finite volume method. The mathematical model has been developed by two approaches: homogeneous (only air has been simulated) and heterogeneous (the coal particle trajectories inside the boiler has been calculated in the Euler-Lagrange approach). The results presented velocity profiles, pressure profiles, streamlines and other data that is helpful to understand the fluid flow phenomena inside the equipment. The coal particles trajectories simulated allow identifying where particles collide with the boiler wall. All results are in very good concordance with field observations according to engineers at UTLC from Tractebel Energia S.A.

Keywords: CFD, Boiler Simulation, Multiphase Flow

1. Introduction

Keep high efficiency of boilers in steam generation process is a great challenge for thermal power plants. The efficiency of boilers can be analyzed by reducing maintenance stops due to the expensive coasts in this equipment.
Tractebel asked ESSS to guide engineers to understand the fluid flow within the boiler using a numerical simulation. The main objective of this study is to analyze the possible causes of excessive erosion in a specific boiler wall region: the region situated near of the right burner in the third row of burners, as showed in the Figure 1.

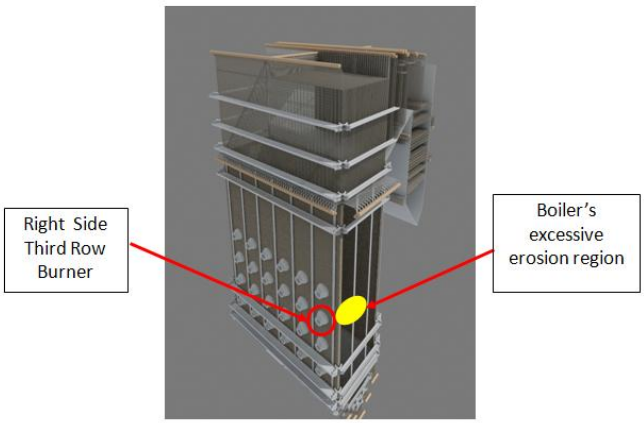

Figure 1 – Boiler region affected by excessive erosion

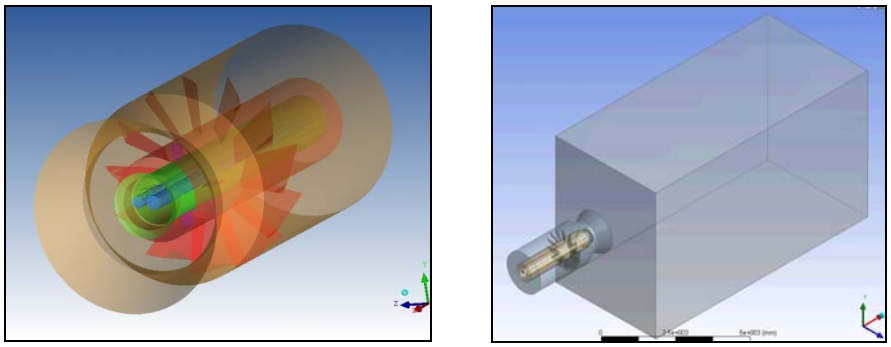
It has been previously identified that a possible origin for the excessive erosion could be due to the non-burned particles flow as a result of a misaligned flame.
The swirler promotes a spiral flow inside the equipment and is developed to stabilize the flame and the air-coal mixture flow within the burner.
The strategy to visualize the flow has been to develop a detailed air and coal mixture within the region allowing the detection of recirculation zones. This can be observed with velocity profiles and particle coal pathlines. It has been assumed that the erosion problem is associated to the particles path lines driven to the collision against the boiler wall.
This work has been developed with an adiabatic flow model. Thermal effects have not been considered since the hot air entered and no combustion model has been applied. For an additional study, these factors must be considerer to quantify the wall erosion rates, but the computational effort increases significantly. According to what has been presented, these results are qualitative, but enough to understand the boiler internal flow and wall erosion causes.

2. Methodology

The proposed boiler-burner numerical simulation has been developed using Computational Fluid Dynamics (CFD) with the commercial CFD software ANSYS CFX®. A CFD work is made of five stages: geometry, mesh, pre-processing, solver and pos-processing. These stages are detailed below.

2.1. Geometry and Computational Mesh

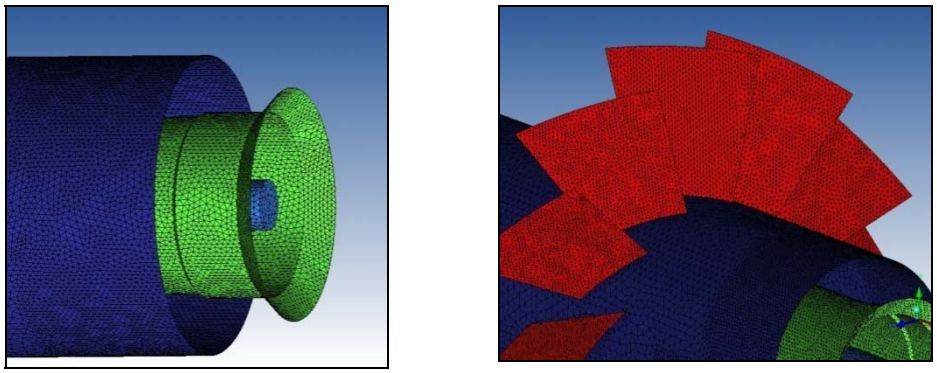
The geometry is developed using a CAD model that must specify all important details that are necessary to the correct equipment description. For this work, the initial data available has been only 2D plants and photographs.
The geometry has been build using ANSYS® Design Modeler. The final burner CAD model is showed in Figure 2(a), while the Figure 2(b) shows the computational domain.
The computational mesh is the representation of finite volumetric elements which are applied the conservation equations. In this stage, has been used the software ANSYS® ICEM CFD. To keep the correct geometry in the discretized domain, the elements sizes are established in accordance to the local length of each equipment part.



(a) (b)

Figure 2 – Burner (a) and boiler (b) geometries

Equipment computational mesh examples are shown in Figures 3, where there are two burner parts: deflector (a) and swirler (b). The final computational mesh has 2,2 millions of nodes. This size characterized a high detailed mesh which requires high computational effort.



(a) (b)

Figure 3 – Computational mesh in deflector (a) and swirler (b) regions

2.2. Mathematical Model

The main assumptions in the boiler numerical simulation are (i) steady state, (ii) isothermal, (iii) incompressible, (iv) turbulent, (v) lower solid volumetric fraction within the equipment (Euler-Lagrange).

With assumptions above, the mathematical model consists by mass continuity equation

$$\frac{\partial \rho}{\partial t} + \nabla . \left(\rho . \vec{V} \right) = 0 \tag{1}$$

and the Navier-Stokes momentum equations

$$\rho \frac{D\vec{V}}{Dt} = \rho g - \nabla p + \mu \nabla^2 \vec{V} \tag{2}$$

For the turbulence model, it has been assumed the k-□ model, the most utilized in industrial equipments with rotation. For the multiphase model, the Eulerian-Lagrangian approach calculates the particle individual track, through the integration of Ordinary Differential Equation (ODE) for particle velocity and position. The particle position can

be represented as in the Figure 4, which integrated, results the particle position within the equipment.

$$\frac{d\vec{r}_P}{dt} = \vec{U}_P \tag{3}$$

Looking Figure 4, a particle with mass m_P moves with velocity $\vec{U}_P$ and it is influenced by $\vec{F}$ force generated by continuous phase, which has velocity $\vec{U}_F$.

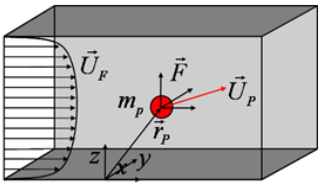


Figure 4 – Particle schematic representation

The particle velocity is obtained through the particle momentum balance, as shown equation 4.

$$m_P \frac{d\vec{U}_P}{dt} = \vec{F} \tag{4}$$

The $\vec{F}$ force acting over the particle has its origin in different phenomena, which depends of particle physical properties, continuous phase, relative velocity, gravity, turbulence, etc. In this model, it has been considered the drag force, the weight and the turbulence influence on particles tracks, through the turbulent dispersion force. To enclosure the mathematical model, the boundary conditions have been obtained through operation data at thermal unity, where has been measured the burner air flow values. The wall has considered as “no-slip” condition.

2.3. Solver

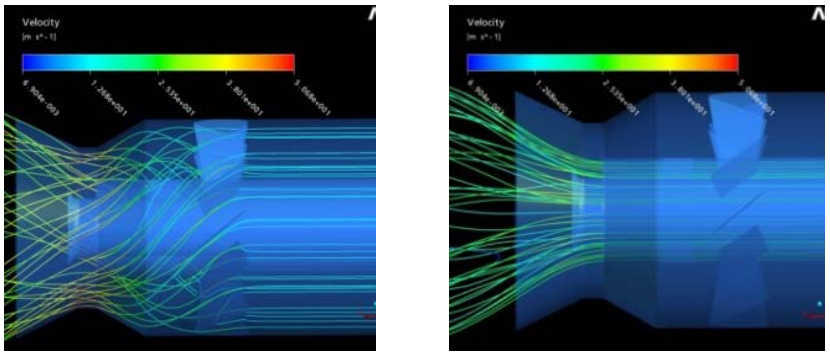
ANSYS® CFX-Solver has been applied to solve all conservation equations. It implies the method of finite volume based on finite elements. The convergence criteria has been the RMS (Root Mean Square), which has been monitored up to the residual reaches the acceptable criteria. Several monitor points throughout the equipment have been indicating velocity and pressure values aiming to guarantee the convergence stability. The third convergence criterion is the closure of mass imbalance.

3. Discussion of Results

The CFD results allow detailed flow visualization, as recirculation zones, high velocities, etc. These results are generally presented in profiles planes, streamlines or vectors, showing the flow directions and preferential paths. In this work, it has focused the velocity field and particle track. The results allowed identify the equipment erosion tendencies. The numerical solution pos-processing has been realized with ANSYS® CFX-POST.

3.1. Burner and Boiler Flow

The burner is the main boiler component and focused in this work. In it that is generated the air flow in a spiral format. Figure 5 shows the streamlines in this part of equipment. It was possible capture this phenomenon through the turbulence model.



(a) (b)

Figure 5 – Burner Geometry effects throughout the primary and secondary inlets

In the Figure 5 (a), the spiral flow starts on the blades of the swirler, promoting a spin. As mentioned before, this swirl stabilizes the flame and homogenizes the air-coal flow. The mass flow in this secondary air pipe is higher than the primary air-flow; therefore this spiral flow is predominant. Figure 5 (b) shows the streamlines of primary air pipe in contact with deflector. The radial opening homogenizes this flow with secondary air. In this duct that coal is transported. Deflection and swirlers angles are geometric parameters which can be tested with CFD, supplying tendencies of optimal configuration. The flame destabilization inside the boiler may be caused by two internal pipes in the middle of burner. These are used for flame ignition. Figures 6 and 7 show that these pipes promote a non-symmetric region.

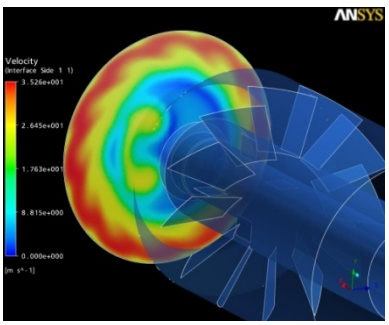


Figure 6 – Velocity Profile in the Interface between boiler and burner

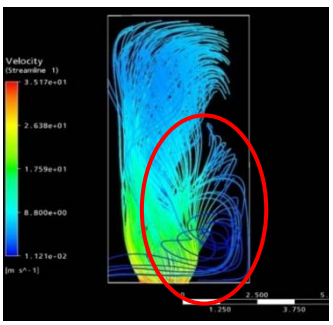

Figure 7 – Streamlines Inside the Boiler

The external annular region present an axial symmetry, however, the central region is non-symmetric. This shows that the internal pipes have significant influence in the flow. Looking towards the air flow within the boiler in a superior view in the Figure 7, it can be observed the spiral flow tendency, follow throughout the boiler. However, there are some streamlines that disengages of principal flow, going to the wall. The streamlines overtopped by the red circle can carry coal particles not burned into the wall, resulting in the excessive erosion. The causes of this disengages streamlines are unknown and it is considered that internal ignition pipes have influence on it.

3.2. Multiphase Analysis

The multiphase approach used in this work has been the Eulerian-Lagrangian, with one way coupling between the phases. With this approach only the air flow influences in the

solid flow. This simplification is possible due the low volumetric solid concentration, as explained in the mathematical model section. Figure 8 shows coal particle trajectories and collision against the boiler wall. These are few trajectories (the most part follows towards the back of the boiler), but these particles can attack the wall with erosion.

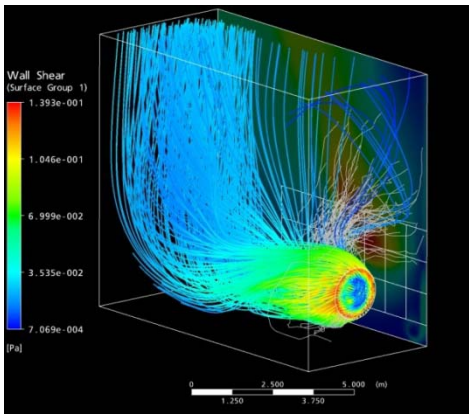

Figure 8 – Coal Particles Tracks

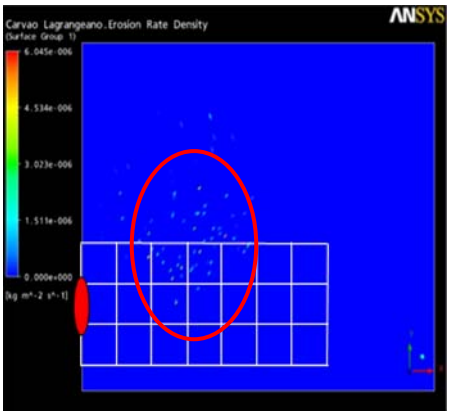

Figure 9 – Boiler Wall Erosion

Figure 9 shows wall contact of particles. The red ellipse in left side is the burner position. The white lines are only for reference. The erosion showed by colored points within the red circle are calculated through the material properties (coal–steal), velocity and collision angle between the coal particles and wall. The reds points are the more intense collision points. The region where the coal particles collide against the wall is in very good concordance with the field observations from engineers of Tractebel. The showed region is about 3.5 m of burner offset.

4. Conclusions

Erosion problem on water wall ducts of coal boilers can be analyzed by numerical simulation using CFD. In this work, it has been shown how burner swirl and deflection affect the particles and air path lines by calculating the turbulent multiphase flow with a commercial CFD tool. Velocity profile and streamlines showed the flow tendencies within the boiler with particles collision at 3.5 m of burner offset, the exact position of the highest detection of erosion. This is caused because there is no symmetry of two internal ignition pipes within the burner. This fact generates a misalignment in the spiral flow, what may promote the flame destabilization as well. A quantitative erosion analysis has not been performed at this stage, but it can be developed with addition of thermal and chemical effects like combustion. The qualitative analysis provided good results is real agreement with the problem at Tractebel Energia Power Plant validating the proposed model of this work.

Optimization of Transformations for Convex Relaxations of MINLP Problems Containing Signomial Functions

Andreas Lundell and Tapio Westerlund

Process Design & Systems Engineering
Åbo Akademi University, Biskopsgatan 8, 20500 Turku, Finland

Abstract

In this paper, a method for determining an optimized set of transformations for signomial functions in a nonconvex mixed integer nonlinear programming (MINLP) problem is described. Through the proposed mixed integer linear programming (MILP) problem formulation, a set of single-variable transformations is obtained. By varying the parameters in the MILP problem, different sets of transformations are obtained. Using these transformations and some approximation techniques, a nonconvex MINLP problem can be transformed into a convex overestimated form. What transformations are used have a direct effect on the combinatorial complexity and approximation quality of these problems, so it is of great importance to find the best possible transformations. Variants of the method have previously been presented in Lundell et al. (2007) and Lundell and Westerlund (2008). Here, the scope of the procedure is extended to also allow for minimization of the number of required transformation variables, as well as, favor transformations with better numerical properties. These improvements can have a significant impact on the computational effort needed when solving the transformed MINLP problems.

Keywords: deterministic global optimization, signomial functions, MINLP problems, convex relaxations.

1. Introduction

MINLP problems containing signomial terms which can be transformed to a relaxed convex form using the transformation techniques in this paper are of the form

$$\begin{aligned} &\text{minimize} && f(\mathbf{x}), \qquad \mathbf{x} = (x_1, x_2, \ldots, x_I), \\ &\text{subject to} && \mathbf{Ax} = \mathbf{a}, \quad \mathbf{Bx} \le \mathbf{b}, \quad \mathbf{g(x)} \le \mathbf{0}, \\ & && \mathbf{q(x)} + \boldsymbol{\sigma}\mathbf{(x)} \le \mathbf{0}, \end{aligned} \tag{1}$$

where the functions f, g, and q are convex, σ is signomial and the variables x_i are positive reals or integers. A signomial function is defined as the sum of terms consisting of products of power functions multiplied with real constants, i.e.,

$$\sigma(\mathbf{x}) = \sum_{j=1}^{J} c_j \prod_{i=1}^{I} x_i^{p_{ji}}.$$

Signomials appear in many different types of optimization problems. In the special case when the constants c_j are positive, the function is called a posynomial. Posynomials can be found for example in geometric programming, where often exponential transformations are used to solve the optimization problem. In the more general case, when a MINLP problem is of the form in Eq. (1), i.e., contains linear, convex and signomial constraints, the exponential transformation is no longer suitable. Such problems are difficult to solve, since simple signomial terms such as bilinear and trilinear terms can make the problem nonconvex, possibly with several locally optimal solutions.

2. The transformation procedure

The transformation procedure consists of two steps. In the first step, the signomial terms are convexified using single variable transformations on the individual variables. This does, however, not transform the MINLP problem to a convex form, since nonlinear equality constraints defining the inverse transformations must also be added. Therefore, in the second step, the inverse transformations are approximated by piecewise linear functions (PLFs) in a way so that the feasible region of the original MINLP problem is overestimated by a convex relaxed region. The whole procedure has been described previously in several papers, e.g., in Lundell et al. (2007) and Westerlund (2005). The scope of this paper is the first step of the transformation procedure only, i.e., the transformations of the signomial terms themselves.

Depending on the sign of the signomial terms, different transformations can be used; for positive terms the exponential and the power transformations (ET and PTs) are valid. The PTs can further be classified into two different types – the positive and negative power transformations (PPT and NPT respectively). Negative signomial terms are transformed using PTs only. In the ET the transformations $x_i = \exp(X_i)$, and in the PTs the transformations $x_i = X_i^{p_i Q_i}$ are respectively applied to the individual variables. Different values for the transformation power Q_i are used in the different PTs. Note also that whenever the transformation power Q_i is equal to one, no transformation occurs.

2.1. Convexifying positive signomial terms

When convexifying positive signomial terms, all variables x_i with positive powers must be transformed by either an ET or a PT. A general signomial term is then transformed according to

$$c\prod_i x_i^{p_i} \rightarrow c\prod_{i:p_i>0} e^{p_i X_i} \cdot \prod_{i:p_i<0} x_i^{p_i} \quad \text{(ET)} \quad \text{and} \quad c\prod_i x_i^{p_i} \rightarrow c\prod_{i:p_i>0} X_i^{p_i Q_i} \cdot \prod_{i:p_i<0} x_i^{p_i} \quad \text{(PTs).}$$

For the ET no additional conditions are required, but for the NPT all transformation powers Q_i must be negative. In the PPT the requirements are that one transformation power is positive (and larger than or equal to one), the rest negative, and that the sum of the powers is larger than or equal to one. For details see Lundell et al. (2007).

2.2. Convexifying negative signomial terms

For negative signomial terms, PTs with $Q_i < 0$ are used for variables with negative powers and $Q_i > 0$ for variables with positive powers. Thus, all powers $p_i Q_i$ in the transformed term are positive. Additionally, the sum of the powers must be less than or equal to one. Therefore, a negative signomial term is transformed according to

$$c\prod_i x_i^{p_i} \rightarrow c\prod_{i:p_i\neq 0} X_i^{p_i Q_i}.$$

3. The optimization method for the transformations

In this section, the method for optimizing the set of transformations is presented. This method is based on formulating a MILP problem, where different strategy parameters determine what transformations are favored for use on the individual variables in the signomial terms. Since the same variables can occur in several signomial terms in the problem, it may be possible to use the same transformations and, hence, also reuse the same transformation variables. Because each transformation variable is approximated with different PLFs, this can have a large impact on the solution time of the transformed MINLP problem. Other aspects to be considered when choosing the transformations are, e.g., their numerical stability and what types of transformations are preferred.

The objective function of the MILP problem for optimizing the set of transformations for convexifying the signomials in the MINLP problem described in Eq. (1) is

$$\begin{aligned}\text{minimize}\quad & \delta_{\mathrm{R}} \sum_{i:x_i \in R} r_i B_i + \delta_Z \sum_{i:x_i \in Z} r_i B_i + \delta_I \sum_{i=1}^{I} \sum_{j_1=1}^{J_T} \sum_{\substack{j_2=1 \\ j_1 \neq j_2}}^{J_T} \gamma_{j_1 j_2 i} \\ & + \sum_{i=1}^{I} \sum_{j=1}^{J_T} \left(\delta_{NT} b_{ji} + \delta_{NS} \Delta_{ji} + \delta_{ET} b_{ji}^{ET} + \delta_{PT} b_{ji}^{PT} + \delta_P \beta_{ji} \right).\end{aligned}$$

For simplicity, all signomial terms in the problem have been renumbered according to $j=1,\ldots,J_T$ (where J_T is the total number of signomial terms in the problem), since it does not matter in the transformation step in what constraints the terms are. The impacts of the different parameters δ in the objective function are described in Table 1 and the variables in Tables 2 and 3. The parameter r_i penalizes transformations of variables with large domains and can for example be calculated as follows for $x_i \in [x_{L,i}, x_{U,i}]$:

$$r_i = \begin{cases} 1+\varepsilon(x_{U,i} - x_{L,i}), & \text{if } x_i \in R, \\ 1+\varepsilon(x_{U,i} - x_{L,i} - 1), & \text{if } x_i \in Z. \end{cases}$$

In addition to the objective function, the additional linear constraints described in the rest of this section, are also included in the problem formulation. The following linear conditions – used to express the relation between the binaries b and B – are included for all variables x_i, $i=1,\ldots,I$:

$$\forall i: \quad \sum_{j=1}^{J_T} b_{ji} \leq J_T B_i \,.$$

In the MILP formulation two additional parameters are used: a large positive value M and a small positive value ε. The parameter ε can, e.g., be calculated as $\varepsilon = 1/M$. Because the convexification requirements are different for positive and negative terms, the constraints guaranteeing transformations resulting in convex terms are different depending on the sign of the term. The additional constraints needed for negative and positive signomial terms are described in Sections 3.1 and 3.2 respectively.

3.1. Additional constraints for negative terms

For a negative signomial term, the condition for convexity is that all powers in the terms are positive, and that their sum is between zero and one. Therefore, all variables with negative powers must be transformed but not necessarily all with positive powers

(whenever $Q_i=1$). When a variable x_i is transformed in the j^{th} term the binary b_{ji} should be one, and otherwise zero. Furthermore, the sum of the powers in the transformed terms should be less than or equal to one. These conditions can be written as

$$\forall i: p_{ji} > 0: \quad 1 - b_{ji}(1-\varepsilon) \le Q_{ji} \le 1 - \varepsilon b_{ji}, \quad \forall i: p_{ji} < 0: \quad \begin{cases} -M \le Q_{ji} \le -\varepsilon, \\ b_{ji} = 1, \end{cases} \quad \text{and}$$

$$\sum_{i=1}^{I} p_{ji} Q_{ji} \le 1.$$

To obtain transformations with good numerical properties, i.e., not to small powers in the transformations, the following expressions are included for each variable in a negative signomial term:

$$\forall i: p_{ji} \ne 0: \quad \begin{cases} \Delta'_{ji} \ge \left| p_{ji} Q_{ji} - \frac{1}{I_j} \sum_{i=1}^{I} p_{ji} Q_{ji} \right|, \\ \Delta_{ji} \ge 1 - \sum_{i=1}^{I} p_{ji} Q_{ji} + \varepsilon \Delta'_{ji}. \end{cases}$$

The parameter I_j, specifies the number of variables in the j^{th} signomial term. Note that the expression with the absolute values can be rewritten as two different expressions with different signs on the right-hand side.

3.2. Additional constraints for positive terms

The convexity requirements for positive signomial terms allow for more freedom in choosing the transformations than those for negative terms since we have three different types of applicable transformations, the ET, NPT and PPT. When using the first two, no restrictions on the sum of the powers in the transformed term is required for convexity, however, when using the PPT the sum of the powers in the transformed term should be greater than or equal to one. Furthermore, in the PPT only one of the powers should be left positive after transformation. These requirements can be formulated as

$$\sum_{i=1}^{I} p_{ji} Q_{ji} - M \sum_{i=1}^{I} \alpha_{ji} + M \sum_{i=1}^{I} b_{ji}^{ET} \ge 1 - M \quad \text{and} \quad \sum_{i=1}^{I} \alpha_{ji} - M \sum_{i=1}^{I} b_{ji}^{ET} \le 1.$$

For variables x_i with positive powers, the following conditions are added to guarantee correct transformations:

$$\forall i: p_{ji} > 0: \quad \begin{cases} -M + (M+1)\alpha_{ji} \le Q_{ji} \le M\alpha_{ji} - \varepsilon(1-\alpha_{ji}), \\ b_{ji}^{PT} \ge 1 - \alpha_{ji}, \\ \varepsilon(Q_{ji} - 1) \le b_{ji}^{PT} \le (1-\varepsilon) Q_{ji} + M(1-\alpha_{ji}), \\ b_{ji}^{ET} \ge \frac{1}{I_j} \sum_{i=1}^{I} b_{ji}^{ET}, \\ b_{ji}^{ET} + b_{ji}^{PT} \le 1, \\ b_{ji} = \max\{b_{ji}^{ET}, b_{ji}^{PT}\} \Leftrightarrow b_{ji} \ge b_{ji}^{ET}, b_{ji} \ge b_{ji}^{PT}\}. \end{cases}$$

No transformations are needed for variables with negative powers in positive terms, so the variables are fixed to the following values:

$$\forall i : p_{ji} < 0 : \quad \begin{cases} Q_{ji} = 1, \\ b_{ji}^{ET} = b_{ji}^{PT} = b_{ji} = \alpha_{ji} = \beta_{ji} = \Delta_{ji} = 0. \end{cases}$$

Similarly to the case with negative signomial terms, conditions favoring numerically more stable powers in the PTs should be added. Here, the preferred values for the powers in the PPT and NPT are set using the parameters $P_{POS} \geq 1$ and $P_{NEG} < 0$ in the following conditions:

$$\forall i : p_{ji} > 0 : \quad \begin{cases} M(\beta_{ji} - 1) \leq p_{ji} Q_{ji} \leq M\beta_{ji}, \\ \left| p_{ji} Q_{ji} - P_{POS} \right| \leq \Delta_{ji} + M(1 - \beta_{ji}), \\ \left| p_{ji} Q_{ji} - P_{NEG} \right| \leq \Delta_{ji} + M\beta_{ji}. \end{cases}$$

3.3. Favoring identical transformations for the same variables

The variables γ indicates whether the same transformations are used for the same variables in different terms (see Table 3). The same transformation variable and PLF can be used for the same variable in different terms if the transformations are equal. Since this results in transformed problems of less combinatorial complexities, the number of different transformations has a direct impact on the time required to solve the problem. Since we want $\gamma_{j_1 j_2 i}$ to be equal to one if different transformations are used for the variable x_i in the j_1^{st} and j_2^{nd} term, the following conditions are included:

$$\forall i : \forall j_1, j_2 \in \{1, \ldots J_T\} : (j_1 \neq j_2) \wedge (p_{j_1 i}, p_{j_2 i} \neq 0) \wedge (\operatorname{sgn} c_{j_1} = \operatorname{sgn} c_{j_2}) :$$
$$Q_{j_1 i} - Q_{j_2 i} + b_{j_1 i}^{ET} - b_{j_2 i}^{ET} - M(1 - b_{j_1 i}) - M(1 - b_{j_2 i}) \leq M\gamma_{j_1 j_2 i} \quad \wedge \quad \gamma_{j_1 j_2 i} = \gamma_{j_2 j_1 i}.$$

4. Conclusions

In this paper, the MILP method for optimizing the set of transformations was extended to provide some important additional features: favoring identical transformations of the same variable in different terms and numerically more stable transformations. The main use for the optimization method presented here, is to include it as a preprocessing step in a global optimization solver for MINLP problems containing signomial functions. Thus, creating a solver being able to solve problems of the mentioned form to global optimality without requiring the user to do the transformations manually.

Abstract

In this work a model-based methodology to solve an integrated process design and control (*IPDC*) problem for a bioethanol production process is presented. The *IPDC* problem is formulated and solved such that the economic performance is optimized in terms of a cost effective design and controllable process. The concepts of attainable region (*AR*) and driving force (*DF*) are used within this methodology, to determine the optimal design-control of the process as well as to generate feasible alternatives. Based on this methodology, the optimal solution to the design-control problem is found by locating the maximum value of *AR* and *DF* for reactor and separator, respectively. The use of *DF* and *AR* concepts are shown to provide an optimal design with respect to energy consumption for the downstream separation units and with respect to controllability for the simultaneous saccharification and fermentation (*SSF*) bioreactor unit, respectively, used in the bioethanol production process.

Keywords: bioethanol, integrated process design and control, model-based methodology, attainable region, driving force.

1. Introduction

The production of bioethanol as a fuel from renewable resources has recently attracted much interest. However, the production process is complicated, and bioethanol has therefore only become a viable and realistic product in the energy market due to rising environmental concerns and the increase in oil price. The economic competitiveness of bioethanol as a liquid fuel depends strongly on the resources used during its production and also the plant operability. Furthermore, the production of fuel ethanol from biomass generates large volumes of wastewater, which must be processed in order to minimize the environmental impact. Therefore, the development of a cost-effective, sustainable, and controllable process for bioethanol production is a priority for many research centers, universities, and private companies.

The starting point for our work is based on a bioethanol production process which has been documented by the National Renewable Energy Laboratory (*NREL*) [1]. The main unit operations are highlighted in Figure 1. The feedstock, in this case hardwood chips, is delivered to the feed handling unit. It is then sent to the pretreatment process where the biomass is decomposed into cellulose, and hemicellulose sugars are solubilized. Subsequently, the hydrolysate slurry is separated into liquid and solid fractions. The liquid fraction undergoes detoxification to eliminate inhibitory compounds and the pH is adjusted with lime. The liquid and solid fractions are recombined to be sent to the

simultaneous saccharification and co-fermentation (*SSCF*) process. In the *SSCF* process two different operations are performed, saccharification of the remaining cellulose to glucose using enzymes and fermentation of the resulting glucose and other sugars into ethanol using microorganisms. Finally, effluent from the fermentor is sent to the downstream separation process.

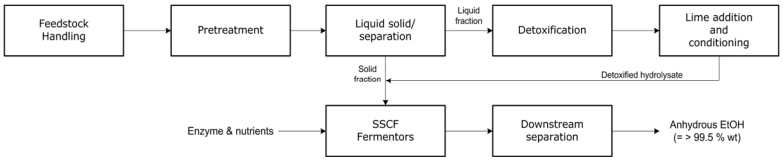

Figure 1. Bioethanol production process flowsheet from lignocellulosic biomass based on the NREL process [1].

The process flowsheet (base case design) was simulated using the PROII® simulator, and simulation results were analyzed in terms of process economic feasibility and sustainability. As a result, an improved bioethanol production process in terms of sustainability was obtained [2]. To further improve the economics of the process, the design-analysis of the downstream separation is considered by using the driving force (*DF*) based-method [3]. However, as the bioreactor, where enzymatic hydrolysis and fermentation occurs, has the inconvenience that the optimal conditions for hydrolysis and fermentation are different, implying thereby a difficult control and optimization of process parameters [4], it is worth investigating the question of integrated process design and control for this bioreactor unit. This paper therefore highlights the use of a model-based methodology for the integrated process design and control (*IPDC*) of the bioreactor and the downstream separation units for the bioethanol production process.

2. Methodology

2.1. Integrated process design and control methodology

The model-based methodology for *IPDC* aims at identifying the optimal operating point where both design and control objectives are best satisfied [5]. The *IPDC* problem is decomposed into four sequential hierarchical stages based on the formulation of a mixed-integer dynamic optimization problem to find the optimal point which gives the best performance (economic, operability, etc.): (1) pre-analysis, (2) steady-state analysis, (3) dynamic analysis, and (4) evaluation stage. Stage 1 in this model-based approach defines the design-control targets by locating the maximum values of the attainable region (*AR*) and driving force (*DF*) for design feasibility (reaction or separation are not possible if the *AR* or *DF* is zero). In stage 2, the established target is validated by finding the feasible values of design-control variables (candidates) that match the target. In Stage 3, the selected optimal operating point identified in the previous stage together with the corresponding design-control variables are analyzed in terms of performance indices such as controllability. The objective here is to verify that at the selected point the performance of the system is best satisfied at the minimum value of the derivative of *AR* or *DF* (minimum value of derivative determines the sensitivity and controllability). The last stage analyzes the economic performance of the process in terms of energy or cost. Therefore, design-control of a reactor and/or separator at the largest total *AR* and/or *DF* leads to lower sensitivity, better controllability, and the minimum energy consumption/cost process.

2.2. Design of a bioreactor through the attainable region approach

The starting point for the design of a single reactor are the reaction rates, visualized in the attainable region diagram, where the concentration of the desired product is plotted as a function of the concentration of the reactant as shown in Figure 2a.

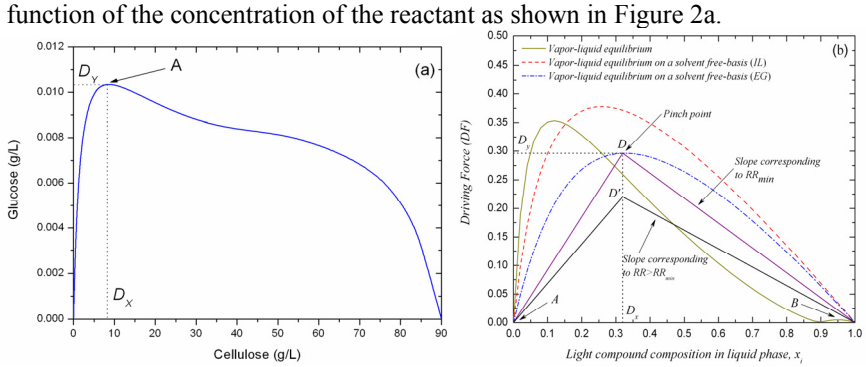

Figure 2. a: Attainable region diagram; b: Solvent-free basis driving force diagram for ionic liquid and ethylene-glycol with illustration of the design parameters.

The design steps involve the following: 1) Develop the attainable region diagram; 2) Identify the maximum value (point *A*) of the attainable region diagram and its corresponding point D_X and D_Y; 3) Compute the reaction temperature, *T* (if applicable) and residence time, τ_R from their respective models; 4) Compute the reactor volume ($V=F/\tau_R$); 5) Compute the real reactor volume ($V_R=1.1V$).

2.3. Design of a separator through the driving force approach

The starting point for *DF*-based methods is the availability of phase composition data, and secondly the graphical representation of the phase composition data as shown in Figure 2b. The *DF*-based method [3] has been used for the synthesis and design of the downstream separation process.

3. Results

3.1. Reactor design results

In order to have a graphical representation of the *AR* analysis for a bioreactor, kinetic models describing the *SSF* process were taken from South *et al*. [6]. The objective of this design is to obtain the highest concentration of ethanol within the range tolerated by the microorganisms (*Eth*(*w*/*v*)≤10%). Note indeed that the *SSF* bioreactor is considered instead of the *SSCF* bioreactor, due to the large uncertainties of the experimental data as well as the lack of reliable kinetic models for the *SSCF* process. Nevertheless, the design-analysis with the *AR* based method for the *SSF* bioreactor model serves the purpose of illustrating the main concepts (see also section 3.3). The *AR* analysis was performed at different values of enzyme loading at two different initial cellulose concentrations (Case 1 = 1 *g/l* and Case 2 = 90 *g/l*). The results are shown in Figure 3 and 4. For Case 1, a low enzyme loading is required in order to obtain the attainable ethanol concentration at the highest concentration of glucose. The optimum ethanol concentration of 0.08 *g/l* can be obtained at 0.048 *g/l* of glucose with 45 *FPU/g* of enzyme loading as shown in Figure 3a. This is corresponding to 0.458 *g/l* of cellulose (Figure 3b). Conversely, for Case 2, a high enzyme loading is required to obtain the attainable ethanol concentration at the highest concentration of glucose. In this case (see Figure 4a), the ethanol concentration of 43.98 *g/l* is obtained at the enzyme loading of 200 *FPU/g* (see Figure 4b). Clearly, this is a very high enzyme loading, compared to the

SSCF bioreactor process in which the enzyme loading is usually between 3.5 and 15 *FPU/g* [1]. Interestingly, it can be noted that all the specifications of the *SSCF* cannot be matched with the *SSF* bioreactor. Matching the low enzyme loading leads to a low ethanol concentration at low initial concentration of cellulose, while matching the ethanol concentration leads to a high enzyme loading but for the correspondingly higher initial concentration of cellulose. The reason for this difference is that the *SSF* process model does not account for conversion of C5-sugars into ethanol. Conversion of C5-sugars is important for the process economy, since *SSCF* gives a higher reported ethanol yield from cellulose than *SSF* and requires lower amounts of enzyme [1].

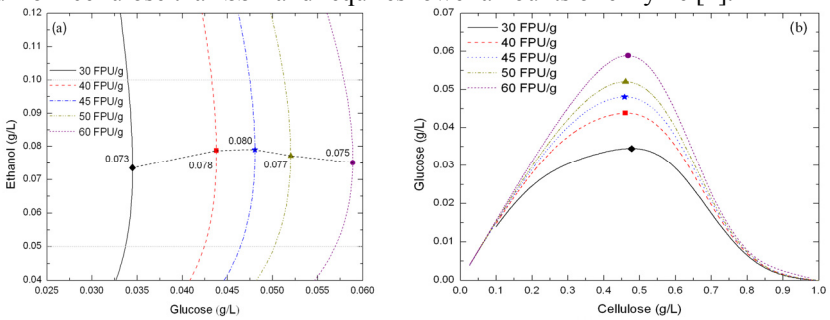

Figure 3. *AR* space-concentration diagram for a: Ethanol-Glucose and b: Cellulose-Glucose at initial concentration of cellulose of 1 *g/l* (Case 1).

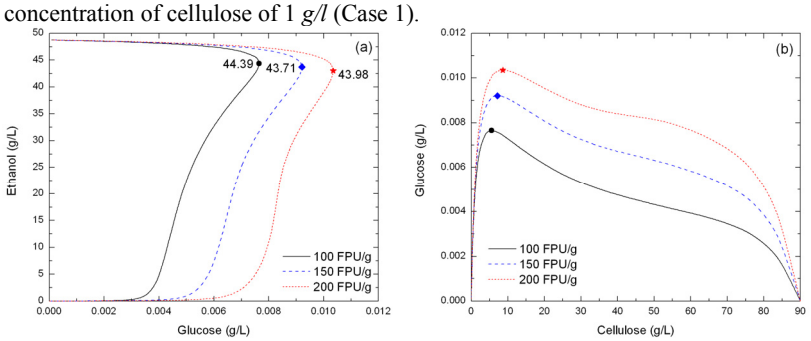

Figure 4. *AR* space-concentration diagram for a: Ethanol-Glucose and b: Cellulose-Glucose at initial concentration of cellulose of 90 *g/l* (Case 2).

3.2. Separator design results

The downstream separation process objective is to obtain anhydrous ethanol from an ethanol-water mixture. A solvent-based separation process has been considered by using ethylene-glycol (*EG*) in order to highlight the *DF*-based method for synthesis and design of separation processes. Table 1 summarizes the results with respect to process design variables.

Table 1. Downstream separation design results

	Distillation column	Extractive column	Recovery column
Number of stages	32	30	15
Feed stage	17	22	5
Reflux ratio	3.2	0.52	0.54
DF_{max}	0.35	0.48	0.59
Energy consumption	1633 $kcal/kg_{Eth}$		

The process separation scheme has been validated by rigorous simulation to evaluate performance in terms of energy consumption. For the base case design, an energy

consumption of 1743 $kcal/kg_{Eth}$ is obtained, whereas the obtained energy consumption for the solvent-based separation process is 1633 $kcal/kg_{Eth}$, a reduction of 6.3 % with respect to the base case design. The reason for this reduction is that the solvent-based separation process is now designed at the maximum value of *DF*. Designing separation processes at the largest *DF* leads to more energy efficient separation processes.

3.3. Integration of design and control

In this section, results of the *IPDC* analysis for the *SSF* reactor unit (Case 2) are presented. As explained in the previous section, a reactor should be designed at the maximum point of the *AR*. For control, at the selected point the controllability performance of the system is best satisfied. In order to show that, the absolute value of derivatives of glucose with respect to cellulose is plotted for the sensitivity analysis as shown in Figure 5. At this point the derivative of glucose with respect to cellulose has a minimum value. In Figure 5 also, there are two other points (B and C) representing two alternative operating points which are below the maximum *AR* point. From a design point of view, they are not feasible since point B generates a lower ethanol concentration and point C requires larger residence time. Thus, from an integrated design-control point of view, only the control issues will be highlighted. Since the derivative at point A is smaller than at points B and C, the process sensitivity of point A is low. From a control point of view, any changes in cellulose will give smaller changes in glucose at point A compared to points B or C. Therefore, by maintaining the cellulose at point A, the desired glucose can more easily be obtained (controlled) than for the other points. Consequently, the corresponding ethanol concentration can easily be controlled. In order to maintain cellulose at its desired value, one option is to manipulate the enzyme loading (manipulated variable).

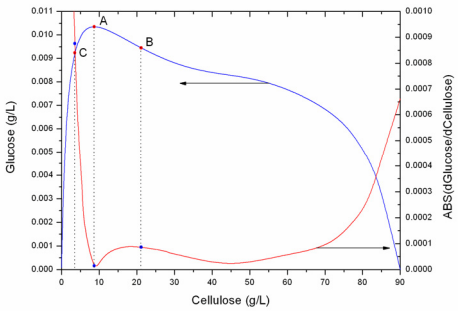

Figure 5. *AR* space-concentration diagram for Glucose-Cellulose and its corresponding derivative (in absolute value) with respect to Cellulose for Case 2.

Let us suppose a disturbance (-5% change in input cellulose) moves cellulose away from its set points (points A, B, C). According to Figure 5, any changes in the cellulose concentration at points B and C will easily move the glucose concentration away from its steady state value and as a result, it will be more difficult to maintain the ethanol concentration at these points than at point A. Figure 6 shows the output response of cellulose, glucose, ethanol and its corresponding control actions to reject a step disturbance (-5% input cellulose) using a P-controller. Although, there is some off-set in the output cellulose concentration at point A (see Figure 6a), the off-set in output for glucose is negligible while the off-set in output for ethanol is quite small (see Figure 6b and 6c). Notably, point A shows better performance in terms of off-set than other points. From a design point of view, design at point A is feasible since it satisfies the design criteria of ethanol concentration, whereas points B and C are not. From a control point of view, candidate A has better controllability performance in terms of disturbance

rejection (see Figure 6d). Consequently, candidate A is the optimal bioreactor design that satisfies design and control objectives.

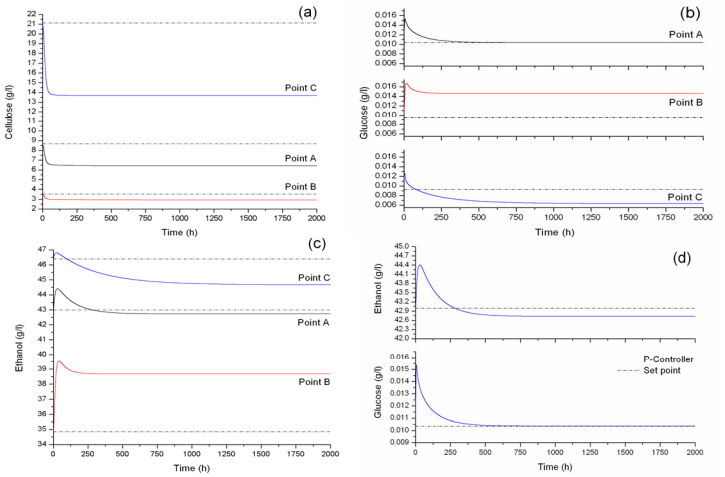

Figure 6. Rejection of a step disturbance (-5% input cellulose) for Case 2 using a P-controller: Output responses of all points for (a) cellulose; (b) glucose; (c) ethanol; and (d) ethanol and glucose at point A.

The same analysis is also valid for the *DF*-based separation design and control analysis since the graphical concept of *AR* and *DF* regions are similar. Design of the separation system should be performed to maximize the total *DF*. If the separation becomes more difficult, the operation and control become more expensive.

4. Conclusion

In this paper, a model-based methodology provides useful information related to the solution of the integrated process design and control of a bioethanol production process. By taking the maximum value of the *AR* or *DF*, the optimal solution with respect to the design, control and economic performance can be estimated before the rigorous simulation is attempted. For bioreactor design, we successfully demonstrated the implementation of the *AR* concept to provide an optimal design with better dynamic performance. Numerical simulation results indicated that the resulting reactor design is able to maintain its steady state conditions with better dynamic performances. For the downstream separation unit, the use of the *DF*-based concept is shown to provide an optimal design with respect to energy consumption. Current and future work is focused on applying this methodology considering the *SSCF* process, as well as adding design-control analysis for all unit operations of the bioethanol production and other processes involving reaction and separation.

New generic approach for the analysis of energy conversion system models

Raffaele Bolliger, Helen Becker, François Maréchal

Industrial Energy Systems Laboratory (LENI), Ecole Polytechnique Fédérale de Lausanne, CH-1015 Lausanne, Switzerland

Abstract

This paper proposes a new approach in the field of energy conversion systems analysis and synthesis. The method is based on a generic and multi-platform description syntax, that clearly separates the information concerning the physical behavior of the modeled technology (e.g. mass and energy balances and chemical reactions) from the information necessary to apply one or more system analysis methods (e.g. process integration, Life Cycle Impact Assessment, thermo-economic evaluation,...).
The description syntax also contains other informations about the model, namely about its history, quality, scope or documentation.
The approach encourages the development of reusable models, which can be easily assembled to create large superstructures from which optimal system configurations can be extracted. By dissociating technology models from the analysis and synthesis method, the approach allows the independent development of analysis methods and the consistent data transfer between models of different scales.
The study of a fine chemical industry waste incineration system is presented to demonstrate the flexibility of the approach.
Keywords: Energy conversion system analysis computer aided process engineering process design process integration

1. Introduction

The design of energy conversion systems is based on models which describe the mass and energy balances for the different process units and their integration into the whole system. These models generate the data needed to analyze the overall system efficiency and to establish performance indicators, using for example exergy analysis, process integration with pinch analysis, life-cycle assessment or thermo-economic evaluation. The increasing complexity of the system, the highest degree of integration and the increasing number of energy conversion options together with the demand of applying different performance indicators require more systematic approaches that go beyond the use of simulation models. This paper proposes a methodology to systematically tackle the integrated system design by dissociating technology modeling from the methods for the analysis and the synthesis of integrated systems.

2. Literature review

In recent years, research activity in energy conversion system analysis and design evolved towards more complex and more integrated systems, often composed by combining smaller sub-systems. The domain covers multiple system scales from equipment design [11] to process design (e.g. biomass conversion processes [5]) to industrial processes (e.g. fine chemicals batch plants [2]) and even urban systems [10].

In order to address the problem of handling complex models, research recently focused on developing tools for exchanging informations and allow the interoperability of modeling softwares. For example, The DOME platform (distributed object-based modeling environment) [3] implements a model based co-current system design and engineering platform. It has been successfully applied to urban systems [7] allowing to interconnect versatile sub-systems models accessed from the internet using web services. The CAPE-OPEN [4] initiative on the other hand has been developed by the process engineering community to allow the interoperability of flow-sheeting tools, unit models and thermodynamic packages. Although these methods give the opportunity to construct very complex models, most of the time they are only concerned with the process flowsheet calculation problem.
The development of the system model however only solves the first part of the problem. The design of the energy conversion systems requires the application of one or more analysis and synthesis methods allowing one to deduce the performance indicators and the information about the interactions between the various technologies included in the system with a system holistic vision. Examples of such methods are energy and process integration, life-cycle analysis, thermo-economic evaluation or exergy analysis.
The major drawback of the existing approaches is that they do not separate energy and mass balances modeling from information relative to the application of system analysis and synthesis methods. Models are built in one single block containing all the information. The reuse of the same models in different study contexts becomes therefore very difficult and often requires a partial recoding of the model.

3. Proposed method

We propose a new method to handle and connect models by separating the chemical and physical models of the process units from the methods used for system-scale analysis and synthesis. The method is based on a generic syntax which describes the different sub-system models and the interfaces available to model their integration in the system. A schematic representation of the concept is shown in Figure 1.

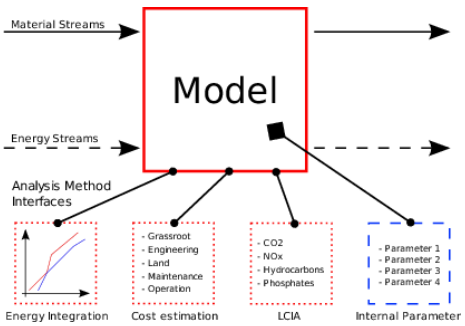

Figure 1 Schematic view of the separation of physical model from method analysis related data

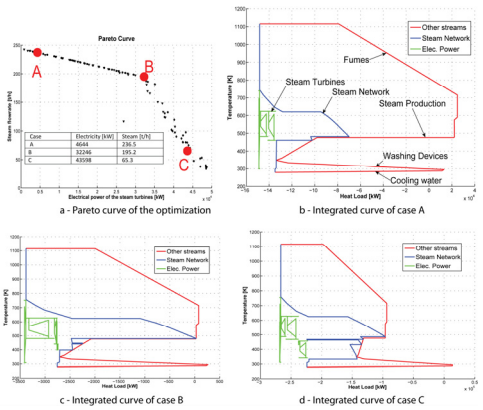

Figure 2 Case study results

The syntax provides a generic abstraction layer that describes the models independently from their modeling environment and considers their reuse in different projects. This also allows one to develop a data base of technology models that may be used to systematically develop process superstructures with interconnected technologies.
Furthermore, the use of a generic and homogeneous syntax promotes the development of analysis and synthesis methods that are independent of the technology models, hence expanding the scope of application and allowing multiscale approaches.
A model representing a technology is the combination of a set of modeling parameters used to represent the characteristics of the technology and its environment and of a set of equations that describes the thermo-physical and chemical conversion operations of the technology. Models can be connected via their input and output streams and possibly by sharing some model parameters.
Each system analysis method applied to the model has a dedicated interface, where all the required informations are stored in a structured variable. The system analysis interfaces include the extraction and the generation of the required data for the analysis methods from the model results. For process integration application, the interface includes the definition of the hot and cold streams of the technology as well as the related energy flows (electricity, water, resources,...). For the cost estimation, the interface provides the values required to estimate the cost (e.g. the size, pressure and temperature conditions, the materials, ...). For the environmental impact assessment, the model provides information about the materials used and the size of the technology that are required to compute the direct and the indirect emissions of the technology. For the exergy analysis, not only the input, output, enthalpy and entropy are given but more detailed data are also provided such as exergy losses in the chemical reactions, pressure losses, etc... The definition of the analysis method interfaces implies therefore a detailed analysis not only of the technology itself but also of how it will interact with the other technologies in the analyzed system. This analysis is however done independently of the other technologies considered and is therefore independent of the system analyzed.
The system analysis and synthesis methods will use the system analysis interfaces to generate the performance indicators at the system level considering the possible integration of each technology in the system.
The interest of the approach is the separation of tasks: the development of a new analysis method does not require the modification of the physical model and does not affect the information handled by the other methods. However, it may require specific development when particular data are needed.
The syntax also defines other data, in relation with the inclusion of the model into a shared database. These informations concern the model classification, its documentation, the history of modifications and more generally data allowing to establish the model accuracy and quality. Table 1 defines the domains covered by the syntax.

Table 1: Domains covered by EnergyTechnologies

Domain	Description
Physical model	Definition of input and output flows (material and energy) crossing the model boundaries. Description of the model parameters used to control its behavior.
System Analysis interfaces	Definition of data required to apply system analysis and synthesis methods.
Classification	Information used to place the model inside searchable database.
Files, version	Information about model content, required software, versions.
Changesets, references	Information about the authors, model changes and improvements.
Documentation	References to model documentation and bibliographic references.
Validation	Information about model quality and validation status.

The syntax defined is generic: it can be implemented in any programming language accepting structured variables; the content of the structures is suitable to describe any energy conversion technology and more generally any model which can be built with a black-box technique.

4. Case study - waste incineration system

The method has been applied to study the integration of a liquid waste incineration system composed by four units.

The first sub-system model represents the liquid waste incineration plant. The unit model includes the burner, the fumes washing devices and a deNOx. The thermodynamic model is built with a commercial flow-sheeting software.

The second model represents the steam network. It includes the heat recovery steam generator, the steam turbines and the pumps. The model is formulated as a mixed integer linear programming optimization problem, where the optimal layout of the steam network in terms of electricity production is computed according to the available heat profile in the steam generator [9, 1].

The third sub-system model represents the cooling water system, which is used to cool down the fumes and the steam in the condenser. The fourth model represents the industrial plant where the waste incineration plant is situated. The model defines the heat requirement as the amount of steam to be produced to satisfy the heat requirement of the plant. The third and fourth models are simple representations of a cold and a hot stream, defined in the energy integration interface described in Figure 1, without any model applied. When the model is available, then the unit will be substituted without having to redevelop whole model.

If a new alternative method exists for treating the liquid waste (e.g. a wet oxidation process), the model will be added to the system and the system analysis will allow one to compare the two options.

An energy and process integration analysis is performed on the system in order to study the interactions between the four models. The heat recovery opportunities will be studied in order to maximize the combined steam and electricity production.

A multi-objective optimization using an inhouse advanced evolutionary algorithm [8] is performed to find the optimal layout of the steam network in order to maximize two objectives in competition: steam and electricity production. The optimization is run in an inhouse computational platform developed to apply the proposed approach[5].
This example let us show the flexibility of the approach in terms of system integration. The process integration of the utilities is visualized by the integrated composite curves (Fig. 2 b,c and d), while the multi-objective optimization systematically generates competing technical solutions and is an extremely valuable computer aided decision tool for the engineer.

4.1. System analysis method: process integration

The objective of pinch analysis and process integration is to identify the heat recovery potential between the hot and cold streams in a system [6]. All the cold and hot streams of the process have to be identified in the various units of the process and the utilities. Based on the definition of a minimum temperature difference (ΔT_{min}) the minimum energy requirement (MER) is computed. The maximum energy recovery between the process streams is also calculated.
In the case of the proposed example, the waste incineration system and the steam requirement are defined as process units, while the steam network and the cooling water are defined as utilities whose sizes have to be optimized. The process integration model [9] computes the optimal flows in the utility system in order to satisfy the process requirement. At the same time, the mechanical power produced by the steam turbines is maximized.
The composite curves are used to analyze the solutions and to visualize the process integration. The composite curve of the hot and cold streams shows the minimum energy requirements of the process.
The grand composite curve shows if the utilities can satisfy the process requirements and displays the potential heat recovery improvements.
Integrated curves will be used to analyze the integration of a particular unit with the rest of the whole system.

4.2. Optimization results

The multi-objective optimization of the problem leads to a Pareto optimum set (Fig. 2a) which represents the best compromise between the two objective functions. Solutions appear to span over two different zones. The table in Figure 2a displays electricity production and steam flow rates corresponding to cases A to C. Figure 2a, and c display the integrated curve of the steam network for cases A to C.
The analysis of the results shows that case B corresponds to the point where the maximum steam flow is reached in the high pressure header. The increase in electricity production going from case B to case C is performed at the expense of the steam production that quickly decreases. On the other hand, steam production is only slightly affected with the increase of electricity production at high temperature, from case A to B. Solution B is therefore the best compromise in terms of steam/electricity production ratio.

5. Conclusions

The proposed approach addresses the problem of the size increase in the domain of the analysis and synthesis of energy conversion systems. In order to overcome the complexity of the models, which are often developed on a per-study bases, this paper proposes a new method, which separates the modeling of a technology from the

information necessary to apply system analysis methods. This is done by defining a generic and platform-independent syntax, which can be used to describe models built with commercial or inhouse packages.
The approach encourages the development of more generic and reusable models, which can be stored in a shared database and later on be reused in future studies. The proposed approach allows to uncouple the technology model development from the development of system analysis and synthesis methods whose models and tools become independent from the technology itself.

An Improved Quasi-Sequential Approach to Large-Scale Dynamic Process Optimization

Weirong Hong [a], Pengcheng Tan [a], Quoc Dong Vu [b], and Pu Li [b]

[a]*Institute of Process Equipment, Zhejiang University, Hangzhou 310027,China*
[b]*Institute of Automation and Systems Engineering, Ilmenau University of Technology, PO Box 100565, Ilmenau 98684, Germany*

Abstract

We present an improved quasi-sequential approach to large-scale dynamic process optimization. This new approach incorporates the quasi-sequential approach with the interior point method to handle inequality constraints. In this way the eventual optimization problem to be solved becomes a NLP without constraints. Mathematical derivations and computation schemes are developed. We first take a two-dimensional constrained optimization problem as an example; the result is compared with the simultaneous and quasi-sequential approach in terms of path solution with a graphical interpretation. A highly nonlinear reactor optimal control problem is also taken to demonstrate the effectiveness of this approach.

Keywords: Dynamic Optimization, Quasi-Sequential Approach, Interior-Point, NLP

1. Introduction

Dynamic optimization can be applied in many decision-making situations in process systems engineering. It remains as a challenging research task for high complex as well as high dimensional applications. These optimization problems are based on a rigorous model and often lead to many highly nonlinear equality and inequality constraints. Even though a solution may be found in some cases, the computation efficiency, convergence rate and initial-value sensitivity may be unsuitable for modern process industries, especially for real-time applications. The available solution approaches can be generally classified into two groups, sequential and simultaneous strategies (Biegler et al., 2002, Biegler, 2007). A new approach, the quasi-sequential approach that takes the advantages of both the simultaneous and the sequential strategies, was recently proposed (Hong et al., 2006). In this study, we extend this quasi-sequential approach by using the interior-point method to handle the nonlinear programming problem inside the solution framework. This is due to the fact that the interior-point method can efficiently handle a large number of inequality constraints. We call it interior-point quasi-sequential approach. In this new approach, state and control variables are first discretized completely as in the simultaneous approach with collocation on finite elements, so as to overcome the difficulty in the sequential approach with satisfying state path constraints. Second, model equations and state variables are eliminated in the same manner as in the sequential approach by a simulation step, so that the optimization problem is reduced to a small NLP only with inequality constraints and control variables. Finally, the primal-dual interior-point method is employed to handle the inequality constraints. In this way the final optimization problem to be solved becomes a NLP with equality constraints by adding slack variables to the inequalities. Mathematical derivations and computation schemes for the interior-point quasi-sequential approach have been developed.

Taking a two-dimensional equality constrained optimization problem as an example the resulting approach is compared with the simultaneous and quasi-sequential approaches in terms of path solution with a graphical interpretation. A highly nonlinear reactor optimal control problem is also considered to demonstrate the effectiveness of this approach. It can be concluded that this interior-point quasi-sequential approach is better than the quasi-sequential approach for solving highly nonlinear large-scale dynamic optimization problems with multiple inequality path constraints. Therefore it provides a promising solution to nonlinear model predictive control and real-time dynamic optimization of engineering processes.

2. NLP formulation

The constrained dynamic optimization problem of interest in this paper can be stated as follows:

$$\min_{x,u} j(z,u) \tag{1}$$

$$s.t. \quad F(\dot{z},z,u) = 0 \tag{2}$$

$$z_{\min} \le z \le z_{\max} \tag{3}$$

$$u_{\min} \le u \le u_{\max} \tag{4}$$

$$z(0) = z_0 . \tag{5}$$

In this formulation, $z(t)$ and $u(t)$ are state (dependent) and control (independent) variables, respectively. Eq. (2) defines a general system of DAEs, Eq. (3) and (4) describe path constraints on the state and control variables, and Eq. (5) the initial condition of the state variables, respectively. In the framework of interior-point methods, inequality constrained functions will be reformulated through the addition of slack variables with lower bounds of zero. These slack variables are added to the state variable vector. Correspondingly, the reformulated inequality constraints which are now equalities are added to the system of DAEs.

The quasi-sequential approach (Hong et al., 2006) possesses advantages of both the simultaneous and the sequential approach. It is based on a completely discretization of the state and control variables with collocation on finite elements like the simultaneous approach, and also it eliminates the state variables and the DAEs in the manner as the sequential approach. Only control variables and inequalities will be handled in the NLP solver. By using the collocation method, the differential equations of the DAE system are converted to a set of algebraic equations. The DAE model is solved successively in each element at each NLP iterate, and the sensitivities of the state variables with respect to control variables are computed in parallel with the DAE solution. We describe the interior-point quasi-sequential approach in more detail as follows. After discretization with collocation, Eqs. (1)-(5) can be represented as the following NLP problem:

$$\min_{z\in\Re^m, u\in\Re^{n-m}} f(z,u) \tag{6}$$

$$\text{s.t.} \quad c(z,u) = 0 \tag{7}$$

$$z_U \ge z \ge z_L \tag{8}$$

$$u_U \ge u \ge u_L \tag{9}$$

After the solution of model equations in the quasi-sequential framework, the problem is reduced to the form:

$$\min_{u\in\Re^{n-m}} f(z(u),u) \tag{10}$$

$$\text{s.t. } z_U \geq z(u) \geq z_L \tag{11}$$

$$u_U \geq u \geq u_L \tag{12}$$

This problem consists only of control variables as well as inequality constraints which are enforced at each collocation point. Without loss of generality, the problem formulated in (10)-(12) can be rewritten as following:

$$\min_{u\in\Re^{n-m}} f(z(u),u) \tag{13}$$

$$\text{s.t. } z(u) \geq 0 \tag{14}$$

$$u \geq 0 \tag{15}$$

We now replace the inequalities by a logarithmic barrier term that is added to the objective function and yield:

$$\min_{u\in\Re^{n-m}} j_m(u) = f(z(u),u) - m\left(\sum_{i=1}^{m}\ln(z(u)^{(i)}) - \sum_{i=1}^{n-m}\ln(u^{(i)})\right) \tag{16}$$

with the barrier parameter $m>0$. Now we have an unconstrained NLP problem to solve. For a given m, multiplier estimates, n_1 and n_2, are introduced and the optimality conditions for (16) can be written in the primal-dual form:

$$\begin{aligned} \nabla f - (\frac{dz}{du})^T n_1 - n_2 &= 0 \\ V_1 Ze - me &= 0 \\ V_2 Ue - me &= 0 \end{aligned} \tag{17}$$

where $e = [1,\ldots,1]^T$, $v_1 = mZe$ and $v_2 = mUe$, Z and U are diagonal matrices with z and u on their diagonals, respectively. The Newton method can be used to solve the system of nonlinear equations (17). Then the search direction ($d_k^u, d_k^{n_1}, d_k^{n_2}$) at iterate k ($u_k, v_{1,k}, v_{2,k}$) can be obtained as a solution of the linearization of (17), that is:

$$\begin{bmatrix} W_k & (\frac{dz}{du})_k^T & -I \\ V_{1k}(\frac{dz}{du})_k & Z_k e & 0 \\ V_{2k}e & 0 & U_k e \end{bmatrix} \begin{pmatrix} d_k^u \\ d_k^{v_1} \\ d_k^{v_2} \end{pmatrix} = -\begin{pmatrix} \nabla f_k - (\frac{dz}{du})_k^T v_{1k} - v_{2k} \\ V_{1k}Z_k e - m_k e \\ V_{2k}U_k e - m_k e \end{pmatrix} \tag{18}$$

where $W_k = \nabla^2_{uu} L(u_k, n_{1,k}, n_{2,k})$. Eliminating the $d_k^{n_1}$ and $d_k^{n_2}$ in Eq.(18) yields the search direction:

$$(W_k + \Sigma_k) d_k^u = -\nabla_m j\,(u, v_1, v_2) \tag{19}$$

where: $\Sigma_k = (\frac{dz}{du})_k^T V_{1k} Z_k^{-1} (\frac{dz}{du})_k + V_{2k} U_k^{-1}$

$$d_k^{v_1} = -v_{1k} + Z_k^{-1} m_k e - Z_k^{-1} V_{1k} (\frac{dz}{du})_k \; d_k^u$$

$$d_k^{v_2} = -v_{2k} + U_k^{-1} m_k e - U_k^{-1} V_{2k} \; d_k^u$$

3. Comparison of the solution path

We illustrate the solution path of the quasi-sequential, the interior-point quasi-sequential and the simultaneous approach with the following example. Consider the *Rosenbrock* two-dimensional constrained optimization problem:

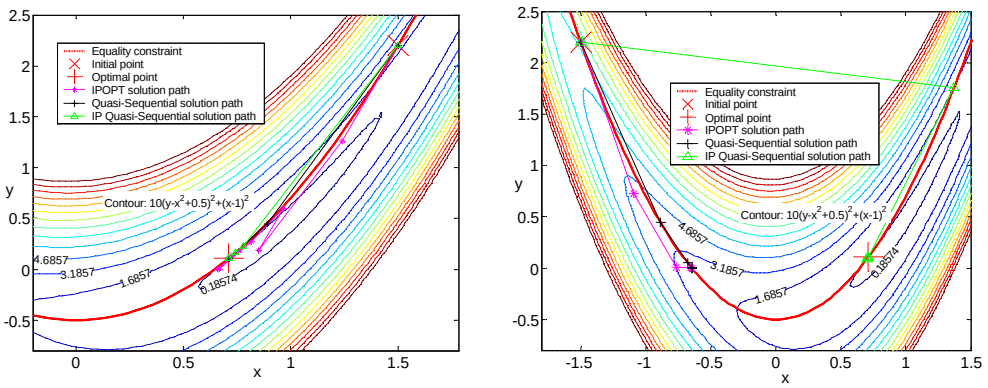
$$\min \ 10(y - x^2 + 0.5)^2 + (x-1)^2 \tag{20}$$

$$\text{s.t} \ \ y = 1.2x^2 - 0.5 \tag{21}$$

$$0 < y < 5 \tag{22}$$

In the sequential approach, the variable x is regarded as the control variable. We solve the problem by the simultaneous, the quasi-sequential approach, and interior-point quasi-sequential approach. The initial point is set at (1.5, 2.2) and (-1.5, 2.2). The optimal point should be at (0.7117, 0.1078), and the minimum objective function value is 0.18574. The solution paths of all three approaches are presented in Fig. 1 where the interior-point quasi-sequential approach is called IP quasi-sequential for short. And the program package IPOPT (Wächter, 2002) is used for the simultaneous approach.

As shown in Fig.1, when the initial point is set at (1.5, 2.2), all of approaches can converge to the optimal point. Moreover, the solution paths are almost the same. But if the initial point is changed to (-1.5, 2.2), only the IP quasi-sequential approach can converge to the optimal point. The IPOPT and quasi-sequential approaches fail, and terminate at the bound of y = 0. The IP quasi-sequential approach shows the different solution path and a better algorithm convergence.



(a) the initial point from (1.5, 2.2) (b) the initial point from (-1.5, 2.2)

Fig. 1. Solution path with respect to different initial point

4. Optimal control of a CSTR

A continuous stirred tank reactor (CSTR), in which an exothermic, irreversible, first order reaction A → B occurs in the liquid phase and the temperature is regulated with external cooling, is considered for optimal control. This example is taken from Pannocchia and Rawlings (2003), Henson and Seborg (1997) with the assumption that the liquid level is also a state variable. Mass and energy balances lead to the following highly nonlinear state model:

$$\frac{dh}{dt} = \frac{F_0 - F}{p \cdot r^2} \tag{23}$$

$$\frac{dc}{dt} = \frac{F_0(c_0 - c)}{p \cdot r^2 \cdot h} - k_0 \cdot c \cdot \exp(-\frac{E}{R \cdot T}) \tag{24}$$

$$\frac{dT}{dt} = \frac{F_0(T_0 - T)}{p \cdot r^2 \cdot h} + \frac{-\Delta H}{r \cdot C_p} \cdot k_0 \cdot c \cdot \exp(-\frac{E}{R \cdot T}) + \frac{2U}{r \cdot r \cdot C_p}(T_c - T) \tag{25}$$

The controlled variables are the level of the tank, h, and the mole fraction c. The third state variable is the reactor temperature, T. The manipulated variables are the outlet flow rate F and the coolant liquid temperature T_c. Moreover, it is assumed that the inlet flow acts as a disturbance.

We consider an operation situation that, at time t = 10 min a disturbance enters the plant, which is an increment of 10% on the inlet flow F_0. Here the objective is defined as to minimize the offset caused by the disturbance by controlling outlet flow rate F and the coolant liquid temperature T_c over a time horizon of t_f = 50 min. Thus the problem is formulated as follows:

$$\min \int_0^{t_f} \left[(h - h^s)^2 + 100(c - c^s)^2 + 0.1(F - F^s)^2 + 0.1(T_c - T_c^s)^2 \right] dt \tag{26}$$

$$s.t.\ \ DAE \text{ model (23)-(25)} \tag{27}$$

$$85 \le F \le 115 (l/\min); 299 \le T_c \le 301 (K) \tag{28}$$

where h^s, c^s ,F^s,T_c^s are the values at the desired steady-state operating point. This leads to a typical constrained dynamic optimization problem. We divide the time horizon t_f into 50 subintervals, and discretize the problem with the 3-point-collocation in each time interval. The two control variables are represented as piecewise constant. Consequently, there are 2×50=100 control variables and 3×3×50=450 state variables after the discretization.

In implementing the three approaches for comparison, the bounds are imposed only on control constraints. All three approaches, the simultaneous, quasi-sequential and IP quasi-sequential, are coded in FORTRAN (the simultaneous approach directly using the IPOPT Fortran package). At the optimal solution, the three approaches provide the same profiles for control variables as shown in Fig.2. The iterations and CPU time are given in Table 1. The results show that the IP quasi-sequential approach requires less iteration numbers, but much computational cost compared with the quasi-sequential approach. We should point out, however, that the comparison is affected by a number of implementation details. In the quasi-sequential approach, the SQP subroutine DNCONG in the IMSL Library is used as the NLP solver. The IP quasi-sequential approach is coded by the authors, where a lot of implementation parameters should be refined. Moreover, the IPOPT used here is an old version; it is being developed or renewed constantly.

Table 1. Comparison of different approaches to the CSTR problem

Disturbance F_0 (*l/min*)	IP Quasi-Sequential (Iter/CPU(s))	Quasi-Sequential (Iter/CPU(s))	IPOPT (Iter/CPU(s))
100? 110	10/0.7031	17/0.5513	44/1.4219

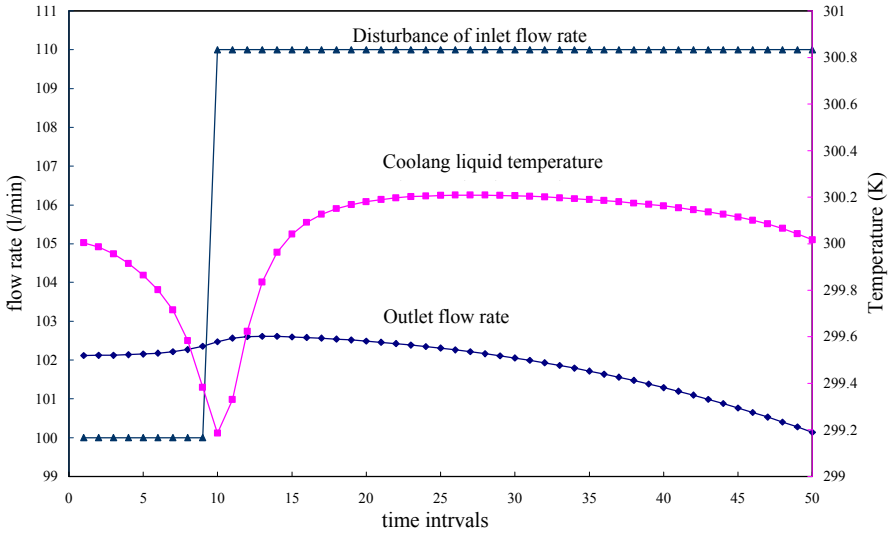


Fig. 2. Optimal trajectories of control variables

5. Conclusions

The quasi-sequential approach would be not very effective for problems with many active constraints, like the most active-set methods for inequality constrained optimization. Here we presented and analyzed an improved quasi-sequential approach, the interior-point quasi-sequential approach, to utilize the ability of interior-point methods for efficient handling a large number of inequalities. The results of the taken examples show that the new approach has advantages of the solution path and higher convergence rate compared with the quasi-sequential approach. But its implementation parameters, such as the update of barrier parameters, should be improved. Finally, the interior-point quasi-sequential approach to handle very large optimization problems with more inequality constraints needs to be studied in the further research.

A Branch and Cut Framework for Multi-Stage Stochastic Programming Problems Under Endogenous Uncertainty

Matthew Colvin, Christos T. Maravelias

Department of Chemical and Biological Engineering, University of Wisconsin-Madison, 1415 Engineering Dr, Madison, WI 53706, USA

Abstract

To ensure that decisions in multi-stage stochastic programming (MSSP) formulations do not *anticipate* future outcomes, it is necessary to introduce nonanticipativity constraints (NACs). In the case of endogenous uncertainty, NACs grow very quickly making all but the smallest multi-stage stochastic programming models computationally intractable. To address this challenge, we first present a number of theoretical results that allow us to formulate substantially smaller and tighter MSSP models. Second, we discuss a branch and cut algorithm where necessary inequality NACs are removed from the starting formulation and added only if they are violated. Our theoretical results coupled with the proposed algorithm allow us to generate and solve problems that were previously intractable. The methods were applied to the resource-constrained scheduling of clinical trials in the pharmaceutical research and development pipeline.

Keywords: branch and cut, stochastic programming, endogenous uncertainty.

1. Introduction

Optimization problems under uncertainty can be addressed using different methods, from robust optimization to fuzzy programming, and from simulation-based optimization to stochastic programming (Sahinidis, 2004). In stochastic programming (SP), which we consider in this paper, uncertain parameters are assumed to follow discrete distributions (i.e. each parameter has a finite set of outcomes), and uncertainty is represented via a set of scenarios. In two-stage SP, a subset of decisions are made before the realization of uncertainty (1st-stage decisions) and a subset of decisions play the role of recourse after uncertainty is observed (2nd-stage decisions). In MSSP formulations, uncertainty is observed *gradually* at different stages, leading to a formulation where decisions are also made at different stages. Thus, optimization decisions x_{ts} in MSSP models are defined for all stages, $t \in \mathbf{T}$, and over all scenarios, $s \in \mathbf{S}$. However, decisions made at different scenarios have to be *nonanticipative* of future outcomes. In other words, decisions in two scenarios which at the current stage have identical realizations of uncertain parameters should be the same.

For any pair of scenarios, (s,s'), there exists a stage, $t^{s,s'}$, at which scenarios s and s' become *distinguishable*. Since our knowledge in these two scenarios until stage $t^{s,s'}$ is the same, optimization decisions in scenarios s and s' must be the same, which can be generally expressed using the following logic (nonanticipativity) condition:

$$\left\{t < t^{s,s'}\right\} \Rightarrow \left\{x_{ts} = x_{ts'}\right\} \ \forall t, s, s' \qquad (1)$$

If stage $t^{s,s'}$ is known in advance, the condition in eq (1) can be expressed as: $x_{ts} = x_{ts'}$, $\forall s, s', t < t^{s,s}$, or (Birge and Louveaux, 1997):

$$x_{ts} \sum_{s' \mid t<t^{s,s'}} p_{s'} - \sum_{s' \mid t<t^{s,s'}} p_{s'} x_{ts'} = 0, \quad \forall t, s \tag{2}$$

where p_s is the probability of scenario s. Note that the equalities in eq (2) grow linearly in the number of scenarios and that they can be used during preprocessing for variable and constraint elimination.

When the timing of uncertainty realization is dependent upon optimization decisions, a special case of *endogenous* uncertainty, the condition in eq (1) can be transformed into:

$$-Ry_{tss'} \le x_{ts} - x_{ts'} \le Ry_{tss'} \quad \forall t, s, s' \tag{3}$$

where binary variable $y_{tss'}$ is equal to 1 if scenarios s and s' are distinguishable in stage t, and R is an upper bound on $x_{ts} \ge 0$. The nonanticipativity constraints (NACs) in eq (3) grow quadratically in the number of scenarios, quickly dominating the problem size. Furthermore, a new binary variable has to be introduced to model nonanticipativity.

The goal of this paper is the development of a) theoretical results for the reduction of the NACs in eq (3) and b) a branch-and-cut solution algorithm for MSSP models under endogenous uncertainty in which the timing of uncertainty realization is dependent upon optimization decisions. A thorough discussion of MSSP can be found in Birge and Louveaux (1997), Kall and Wallace (1994), and Ruszczynski (1997). A more thorough discussion of endogenous uncertainty can be found in Jonsbraten et al. (1999).

2. Resource Constrained Scheduling of Clinical Trials

While applicable to a broader class of problems, the methods presented in this paper were developed for and applied to the problem of resource-constrained scheduling of clinical trials in the pharmaceutical research and development (R&D) pipeline and results will be presented in this context.

Given are:

- A fixed time horizon divided into uniform time periods (stages), $t \in \mathbf{T}=\{1, 2, \ldots, T\}$
- A set of candidate drugs, $i \in \mathbf{I}$, with known potential revenues (if successfully developed)
- A set of limited resources, $r \in \mathbf{R}$.
- A set of clinical trials, $j \in \mathbf{J} \subseteq$ {PI, PII, PIII}, for each drug with known cost, duration, resource requirements, and probability of success; clinical trials have to be carried our in sequence PI $\rightarrow$ PII $\rightarrow$ PIII.

Our goal is to determine if and when each clinical trial should be performed so as to maximize the expected net present value (ENPV) of the R&D pipeline. It is assumed that when a clinical trial fails, development of the drug is halted and all investment in the drug is lost. Further it is assumed that the success or failure of each clinical trial is the only source of uncertainty.

The above problem is an optimization problem under endogenous uncertainty because our decisions determine when clinical trials are carried out and thus when uncertainty (clinical trial outcomes) is observed. For each drug $i \in \mathbf{I}$ there are up to four possible outcomes: it fails PI trials (PI-F), it fails PII trials (PII-F), it fails PIII trials (PIII-F), and it passes all trials (PIII-P). Therefore, uncertainty can be expressed in terms of a single parameter, ξ_i, with ordered sample space $\Omega_i \subseteq$ {PI-F, PII-F, PIII-F, PIII-P}. The problem at hand can be formulated as a MSSP model with a single set of independent

variables, X_{ijts}, which are equal to 1 if clinical trial (i,j) is started at stage t in scenario s. Since the timing of uncertainty observation is dependent upon our decisions, inequality NACs of the form of eq (3) must be enforced for all clinical trials, in every stage, and between all pairs of scenarios. A detailed problem statement and MSSP formulation can be found in Colvin and Maravelias (2008).

In a *naïve* MSSP formulation, an instance containing three drugs would require ~290,000 NACs compared with ~4,100 other constraints. For an instance containing six drugs these numbers grow to ~1.2×10^9 and ~250,000, respectively. Clearly, problems of this size cannot be addressed by existing optimization tools.

3. Results for Nonanticipativity Constraints

In this section, we present a number of properties that enable the formulation of substantially smaller and tighter MSSP formulations of problems with endogenous uncertainty in which the timing of uncertainty realization is dependent upon optimization decisions.

Property 1. *It is sufficient to express NACs only for pairs of scenarios* (s,s') *that differ in only a single uncertain parameter* ξ_i. .

This result is based on the work of Goel and Grossmann (2006) and can be shown using transitivity. In the case of the drug development problem, this property says that if the realizations in scenarios s and s' are different for more than one drug, then it is unnecessary to enforce NACs between s and s'. The drug whose outcome is different in scenarios s and s' will be referred to as the *critical drug*.

Property 2. *If a set of decisions must be carried out in a predefined sequence and each decision in this set can lead to the observation of a single outcome for each uncertain parameter, then it is sufficient to express NACs for scenarios* (s, s') *that differ in the outcome of a single parameter* ξ_i *and the outcomes of* ξ_i *in scenarios s and s' are associated with decisions that must be made consecutively in the sequence.*

This property leads to improvements in a smaller class of problems, in which the timing of decisions is unknown but certain decisions have to be made in a specified sequence. For example, in the planning of R&D activities, clinical trials must be carried out sequentially (PI $\rightarrow$ PII $\rightarrow$ PIII) and the outcomes after the completion of PI trials can be split into two sets {PI-F}, which can be observed, and {PII-F, PIII-F, PIII-P} which cannot be observed until additional trials are carried out. Thus, if i^* is the critical drug for scenarios s and s', then it is sufficient to express NACs between s and s' only if the outcomes of ξ_{i^*} in s and s' are consecutive elements in Ω_{i^*}.

Properties 1 and 2 allow us to apply NACs for a reduced set of scenario pairs, which we will refer to as $\mathbf{\Psi}$. The *association* of a decision variable with a specific outcome and thus the differentiation of a specific pair of scenarios leads to the following property that enables the formulation of NACs using substantially fewer variables:

Property 3. *If the stage at which scenarios s* and *s' become distinguishable is a function of a single optimization decision, then the logic condition in eq (1) can be transformed into mixed-integer constraints in terms of decisions* x_{ts} *only.*

In the scheduling of clinical trials, the completion of PI trials can only lead to the observation of outcome PI-F, because if PI is successful then we should carry out more trials before we observe another outcome. The trial that differentiates scenarios s and s'

will be referred to as *critical trial* and denoted by ($i^{s,s'}, j^{s,s'}$). Using Properties 1-3, we can express NACs as follows:

$$-\sum_{t'\le t-\tau_{i^{s,s'}j^{s,s'}}} X_{i^{s,s'}j^{s,s'}t's} \le X_{ijts} - X_{ijts'} \le \sum_{t'\le t-\tau_{i^{s,s'}j^{s,s'}}} X_{i^{s,s'}j^{s,s'}t's}, \quad \forall i,j,t,(s,s') \in \mathbf{\Psi} \qquad (4)$$

where τ_{ij} is the duration of trial (i,j). The summation of $X_{i^{s,s'}j^{s,s'}t's}$ variables is equal to 1 if the critical trial ($i^{s,s'}, j^{s,s'}$) is finished before stage t, which would mean that scenarios s and s' are distinguishable, and therefore the corresponding decisions can be different. Note that NACs are expressed for a subset of scenario pairs (Properties 1 and 2) without introducing new $y_{tss'}$ decision variables (Property 3).
Another implication of the sequencing of decisions is that decisions cannot be carried out before all prerequisites are completed, which leads to the following two results:

Property 4. *If the stage at which scenarios s and s' become distinguishable depends on a single decision which cannot be made before stage* $t^{s,s'}_{\min}$*, then nonanticipativity between scenarios s and s' in stages* $t < t^{s,s'}_{\min}$ *can be enforced using eq. (2).*

Property 5. *Non-anticipativity between s and s' for decisions that precede the decision that leads to the realization of uncertainty that distinguishes s and s' can be enforced using eq (2).*

Properties 4 and 5 lead to the replacement of a large number of double inequalities of the form of eq (3) by equalities of the form of eq (2). This leads to smaller and tighter formulations.
Finally, for all formulations employing eq. (2) with only binary decision variables, we can further reduce the number of equality NACs:

Property 6. *Let* $\mathbf{S}_t$ *be a set of scenarios that are necessarily indistinguishable at stage t, i.e.* $\mathbf{S}_t = \{s: t^{s,s'} < t, \forall s' \in \mathbf{S}_t\}$*. If* $p_s > 0$ $\forall s \in \mathbf{S}_t$ *and* $x_{ts} \in \{0,1\}$*, then NACs among all scenarios in* $\mathbf{S}_t$ *can be enforced using a single equality of the form of eq. (2).*

Nonanticipativity for decisions in scenarios $s \in \mathbf{S}_t$ is typically enforced using $|\mathbf{S}_t|$ equalities (note that eq (2) is expressed for every s). Property 6 says that in the case of binary variables nonanticipativity for decisions in scenarios $s \in \mathbf{S}_t$ can be enforced using a single equation. It is important to note here that Property 6 is widely applicable because eq (2) is used to enforce nonanticipativity in all SP models.
The reduction in the number of NACs due to properties 1, 2, and 4-6 is demonstrated in Figure 1. For an instance with six drugs number of NACs is reduced from ~1.2×10^9 to ~1.5×10^6. Furthermore, the growth in NACs is almost linear in the number of scenarios. Nevertheless, NACs could still represent the majority of all constraints.

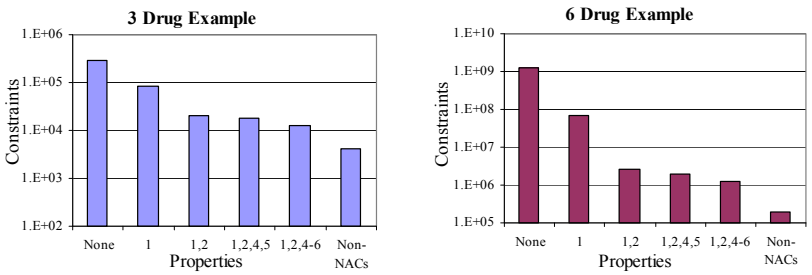

Figure 1: Reduction in NACs due to Properties 1, 2, 4, 5, and 6.

4. Branch and Cut Algorithm

Even though none of the NACs is redundant, it can be shown that only a small fraction of these constraints are active in any feasible solution. In the drug development problem in particular, it can be shown that at most 12.5% of inequality NACs can be violated in any solution, and in practice less than 4% of these constraints were violated. These observations led us to explore the development of a branch and cut (BaC) algorithm in which the initial formulation does not include any NACs represented by inequalities, though equalities (see Properties 4-6) are included. When inequality NACs are found to be violated, they are added into the formulation and kept in all descendant nodes. Note that unlike typical branch and cut algorithms, we removed *essential*, not tightening constraints.

Removing essential constraints from the formulation allows for integer solutions that are infeasible to the full model to be found feasible. To handle this, a number of modifications to the standard BaC algorithm were made. First, the heuristic solution strategy was turned off to prevent better than optimal, but infeasible, solutions to be found and used as lower bound for pruning. Second, bound updating was modified because the lower bound cannot be updated immediately upon finding an integer solution (the solution must first be checked for NACs feasibility). Finally, if an integer solution is found to violate removed NACs, it must be resolved after the addition of violated NACs (possibly leading to a fractional solution), and subsequently partitioned using standard branching.

Having successfully implemented our basic algorithm, we then sought to improve its performance in two ways: node selection rules and selection of nodes where NACs are checked. Note that in our algorithm, local search (which is the default node selection method) loses two key advantages. First, the advantage of having the basis of the previous node is diminished because hundreds or thousands of violated NACs are added, especially in early nodes. Second, with the heuristic solution turned off, a lower bound is not in place to quickly identify unproductive areas of the tree. In later nodes where fewer NACs are added and a lower bound is available, the advantages of local search are important. We found using a best first search for a fixed number of nodes, N^{max}, before using local search provided for the fasted solution times. While the optimal N^{max} shifted for each problem, it was found to be roughly proportional to the number of drugs in our example problems.

Related to the node selection rules is the decision to test for violated NACs at all nodes or at integer nodes only. Checking for infeasibilities at all nodes increases the computational cost per node substantially (because the solution is checked against a large number of NACs), but reduces the total cut additions because a cut added at an early fractional node is carried to all descendent nodes reducing the number of cuts that are added multiple times at different nodes. Testing for infeasibilities at every node outperformed testing only at integer solutions; however, when used in conjunction with our hybrid node selection rule, adding cuts in all early nodes, but only in integer nodes after a fixed depth, D^{max}, seemed to perform better than either pure approach.

5. Computational Results

The proposed algorithm was implemented in Xpress-IVE and tested on a number of instances varying in the number of drugs and scenarios. Model and solution statistics for the full-space MSSP formulation and the proposed algorithm are given in Table 1.

Table 1: Model statistics and computational results.

Example	3-drug	4-drug	5-drug	6-drug	7-drugA	7-drugB
Scenarios	64	144	288	864	2304	3456
Variables	4,512	6,192	14,112	69,216	152,256	237,600

* Model could not be generated.

First, note that the LP relaxation of the starting formulation for the BaC algorithm is almost as tight as the one of the full-space model despite removing a large number of NACs. Second, all instances are solved faster using the BaC algorithm, but more importantly, problems that were unsolvable because the corresponding MSSP model could not be generated can now be addressed.

6. Conclusions

We have presented a set of theoretical results and a novel branch and cut algorithm for the solution of MSSP formulations under endogenous uncertainty in which the timing of uncertainty realization is dependent upon optimization decisions. The proposed methods address the explosion in the number of NACs in stochastic programming formulations. They can be applied to a wide range of problems under uncertainty.

Abstract

A model for steady-state simulation in 3D of a Core-in-Drum plate-fin heat exchanger is presented in this paper. The model takes into account both the geometrical description of the PFHE, layer by layer, and the description of the external piping layout of each stream outside the core. Several steps that allow to define the entire Core-in-Drum model are presented in this case study, with in particular the mesh generation, the topological description of stream circulation, calculation constraints and, to finish, detailed results.

Keywords: Plate-Fin Heat Exchanger, cryogenics, 3D hydrothermal modelling, 3D simulation, maldistribution.

1. Introduction to Core-in-Drum Plate-Fin Heat Exchangers

1.1. General points about Plate-Fin Heat Exchangers (PFHE)

PFHE are widely used in process industries such as gas processing and petrochemical industries including cryogenic applications: industrial gas and hydrocarbon separation are the most common, but many processes use this type of equipment, including recovery of natural gas liquids, helium refrigerators and liquefiers, hydrogen purification, ammonia and ethylene processes, nuclear engineering and syngas production. Maximizing thermal efficiency with high reliability is the main purpose for such cryogenic processes. PFHEs promote exchange between many streams simultaneously (cases with more than 12 streams are common) greatly increasing energy efficiency.

1.2. Study case of a Core-in-Drum Exchanger

Most Core-in-Drum heat exchangers are used as vaporizers, reboilers, chillers or condensers to be in general associated with distillation columns. The basic principle of such heat exchangers is to permit exchange between two streams, including phase-change(s), in crossflow configuration. Figures 1 and 2 show respectively the mechanical description and the functioning principle of a Core-in-Drum PFHE.

The cold stream (called "PROP", see figures 1 and 2) enters the shell by a nozzle (item *4*) as a liquid or two-phase and submerges the core (item *6*) partially or completely. The warm stream (here called "OVHD"), fed to the core by an inlet nozzle (item *1*) and a header (item *2*), flows horizontally, away from the inlet, and cools against the vertical cold stream which vaporizes and rises by the thermosyphon effect through devoted free-opened layers, to finish with exiting through several nozzles (items *5*) . The table 1 summarizes the functioning parameters of this study case.

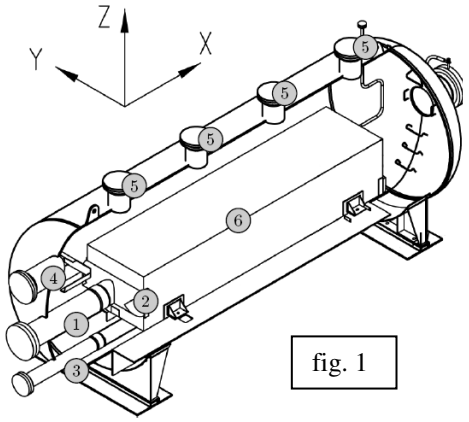

fig. 1

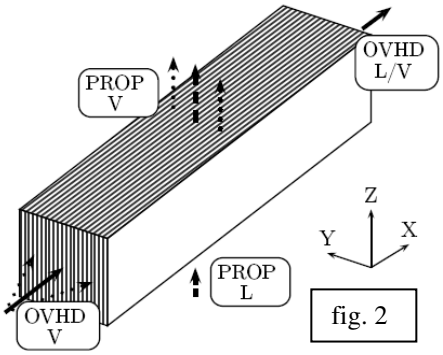

fig. 2

tab. 1

	unity	Warm stream	Cold stream
		OVHD	PROP
Gas	$kg.h^{-1}$	163109	0
Liquid	$kg.h^{-1}$	0	153250
Temperature	°C	-32.9	-35.7
Pressure	Bar	18.27	1.72
Layer		A	B
Number of layers		85	84

Figure 3 illustrates the internal structure of the two layer patterns A and B, which define respectively the OVHD and PROP circuits. The stream OVHD enters each suitable layer of the stacking arrangement by a central distributor, flows through straight fins, and finally exits by an end distributor. The stream PROP is drawn to the top through fins, which are separated by bars along the width of the layer.

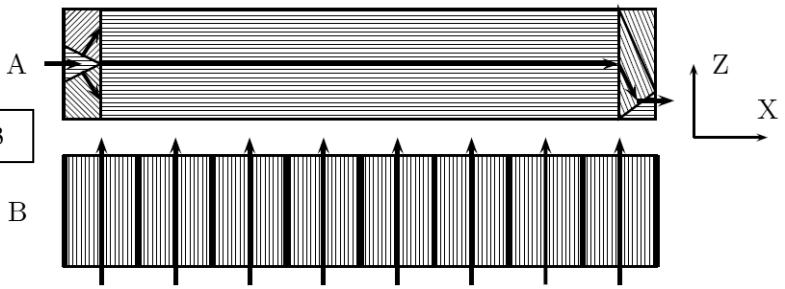

fig. 3

2. Definition of the Core-in-Drum model

The principal interest of this three dimensional model in steady-state is that the influence of flow distribution, induced by distributors and in particular by the cross-flow configuration, is integrated into the total thermal performance of the PFHE. It may result in flow imbalance (maldistribution) along the width of each circuit, disrupting the thermal behaviour of the PFHE because of the high connection between thermal and flow variables.

2.1. Meshing method

Figure 4 illustrates the specific mesh operations for the two layers. Grid is defined in order to take into account the coupling of thermal and hydraulic variables. About 220000 cells have been used to mesh the entire core-in-drum (plates and layers).

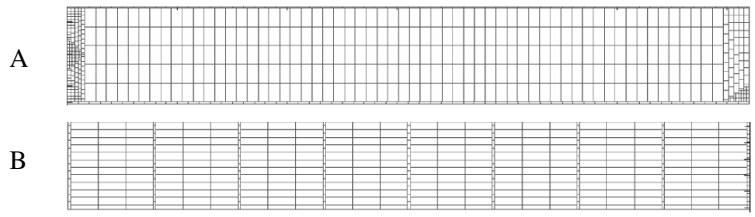

fig. 4

2.2. Flow management

The PFHE can be looked upon as a flowsheet, including specific operation units which are connected together through a flow network. All external components (manifold, nozzles, header,…) and all the meshes used to describe the internal flow circulation in each layer of the stacking pattern are integrated. Thus, the flow circulation for each stream is modelled by a devoted 3D graph, which is closely linked to each others by thermal consideration due to the particular structure of PFHE. Such a complexity needs powerful tools in order to represent the entire path followed by each stream outside the core and between covered layers. Graph theory is very useful for modelling this topological description. Figure 5 shows simply the connexions between the eight circuits of only one layer defining the PROP circulation in the stacking arrangement.

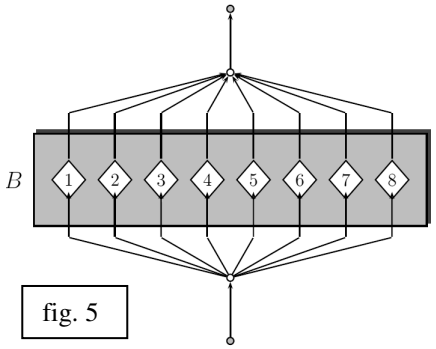

fig. 5

2.3. Calculation

All variables which define streams and all components (plates, bars) in the system are highly interconnected, increasing the complexity of the full model of the PFHE. Several million equations can be gathered in model of such a PFHE. Fortunately, each equation of the model involves few variables. Finding the solution of such a large and sparse system requires adopting specific numerical methods and tools, in particular to preserve memory requirement, improve calculation time and guarantee the quality of the solution. Consequently it would be inefficient to adopt a sequential modular strategy rather than a global approach.

Moreover, it is numerically difficult to resolve an energy conserving temperature and vapor fraction field when consecutive iterations gravitate between single and two-phase regions, because there can be an order of magnitude difference in the values of heat transfer coefficients being used to calculate the energy coefficient matrix for each iteration.

3. Results

Overall results are gathered in the table 2. The mass vapor fraction of the cold stream PROP at the exit of the core is about 0.535, while the warm stream OVHD is partially liquefied with a residual mass vapor fraction of 0.498. Notice that the pressure drop for each stream in each layer is low.

	unity	Warm stream	Cold stream
Flow	$kg.h^{-1}$	163109	153250
Mass vapor fraction	-	0.498	0.535
Temperature	°C	-33.9	-37.1
Pressure drop	mbar	11.32	9.82
Total power	MW	39.62	39.62

Outlet specifications by stream

As it is shown in figure 7, PROP temperature profiles may seem surprising : because the OVHD warm stream enters perpendicularly at the edge of the core (fig. 6), the temperatures there are expected to be significantly higher in this area than the temperatures in the rest of the core. It would seem that heat transfer between OVHD and PROP is reduced in this area.

fig. 6

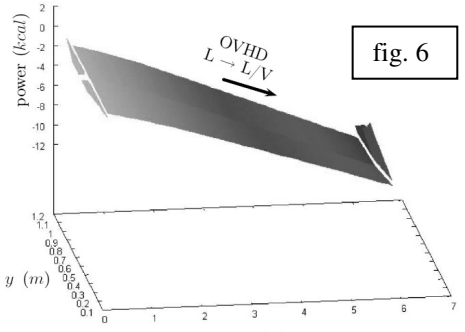

fig. 7

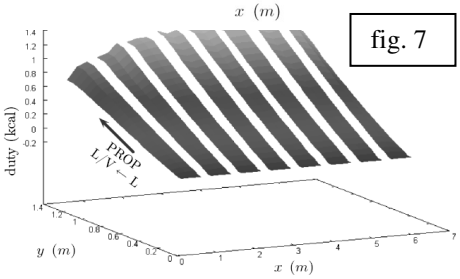

To understand this notable feature, some clue may be obtained by representing the PROP stream profiles of the relative difference between the mass flow rate calculated at a given x and the theoretical average mass flow rate evaluated by assuming a homogeneous distribution of the flow along the entire width (fig. 8). In spite of the geometric uniformity, coolant mass flow rate is not uniform across the core layer. There is a maximum flow maldistribution rate of 25%. Note that the largest flow maldistribution corresponds to the temperature imbalance described in the previous paragraph.

Consequences on the performance may be analyzed in figure 9, in which the heat transfer rate profile for PROP stream is represented. This curve is perfectly similar to the PROP mass flow rate field. Thus, the flow distribution becomes heavily involved in the thermal performance. However, the outlet vapor mass fraction, represented in the same figure, is almost continuous (0.536). The maximal gap between the two extremes of the curve is 2.3%.

fig. 8

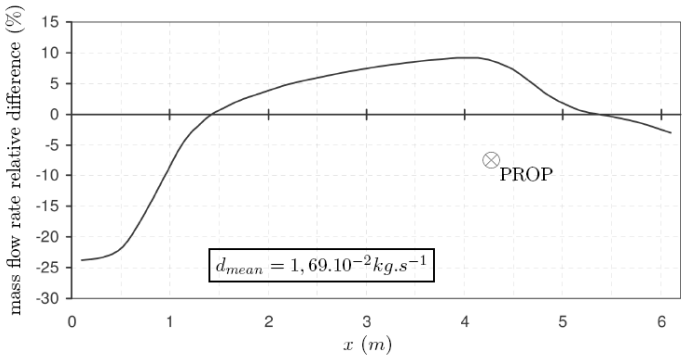

fig. 9

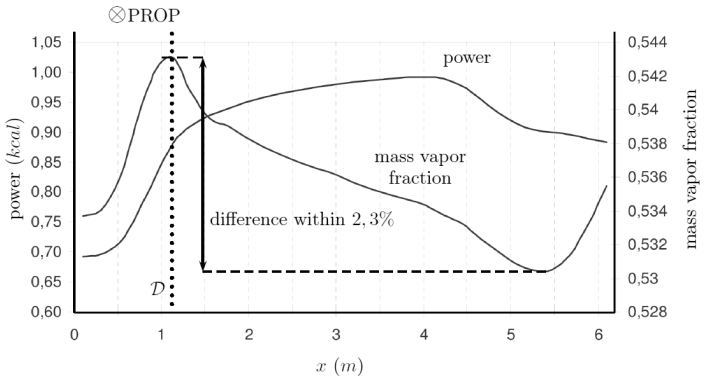

Curves plotted on the figure 10 characterize the width-wise pressure drop contributions due to both gravity and friction drag applied on the PROP stream. The gravitational term is the main constraint imposed on the vertical flow circulation (from 95.2 to 96.7 percent of the overall pressure drop) compared to the friction loss term. Physics impose the equality of the pressure drop between each vein of PROP flow, in such a way that inlet and outlet pressures are respectively uniform on each side of the core. However, thermal properties of each PROP vein evolve individually due to the changing neighboring thermal conditions imposed by OVHD thermal fluctuations. Finally, the pressure drop equilibrium along the width of the layer is obtained by the coupled compensation of frictional and gravitational terms, which allows the regulation of the flow rate.

fig. 10

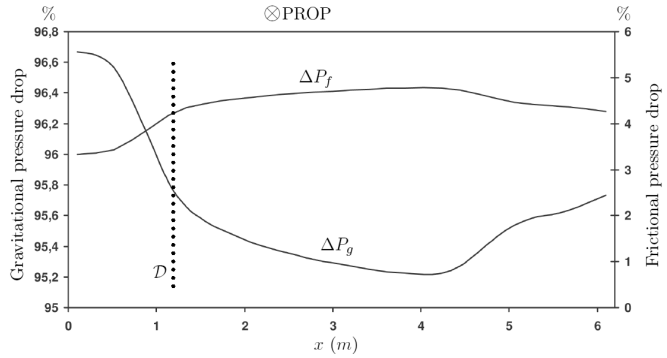

fig. 11

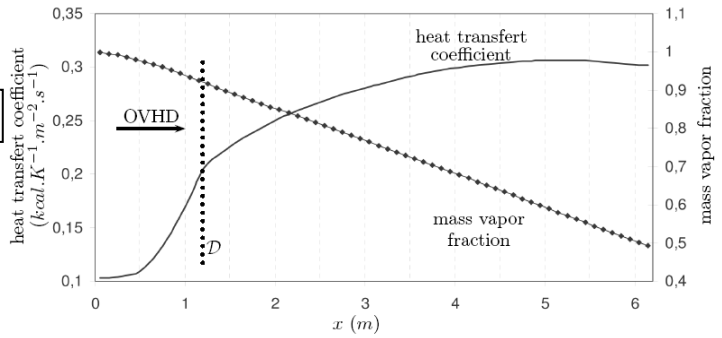
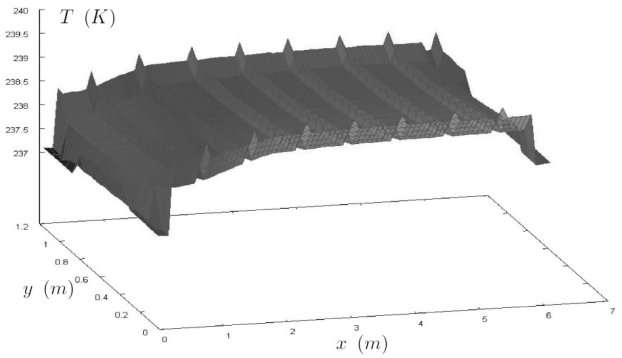


The study of the OVHD stream provides some indications concerning the understanding of the variations of mass flow and heat transfer rates of PROP stream. Figure 11 shows the heat transfer coefficient of the OVHD stream along the flow direction, with respect

to x. Logically, the heat transfer coefficient is correlated with the mass vapor fraction : this factor remains low for values of mass vapor fraction higher than 0.9 and increases regularly with a decrease of the mass vapor fraction. It is possible to visualize two distinct "rates" of heat transfer, marked by an inflexion point (at around 0.9) which is materialized by the dotted line on the figure.

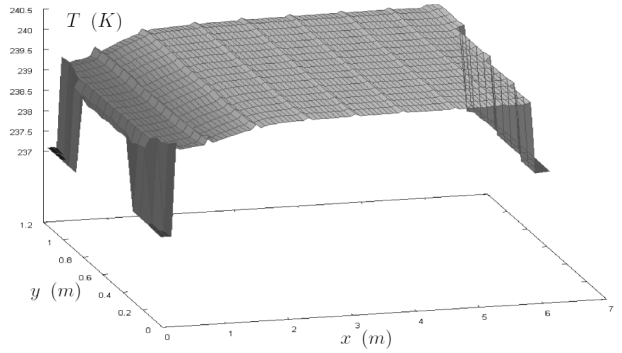
The figure 12 shows the thermal profiles of a parting sheet of the stacking arrangement, sandwiched between two distinct layers A (above) and B (below), in which circulate streams OVHD and PROP respectively. The plate closely retranscribes thermal phenomena induced by the flow circulation in each specific layer geometry. Separating-bars and dead-zones of the two distributors could be considered thermal wells, by which transit preferentially the energy.

fig. 12



The figure 13 illustrates the thermal profile of the top cap-sheet, which is directly in contact with the OVHD stream. It is interesting to observe the influence of dead zones on the two distributors implied in the description of the layer A.

fig. 13



4. Conclusion

3D modeling is a highly improved method for PFHE study. The coupling of thermal and hydraulic parameters on the global functioning of the core can be easily visualized and provides significant clues to understand such a complex system. A specific meshing grid method has been developed to take into account all kind of pattern geometries, which constitute the entire stacking arrangement. Moreover, the complex description of such PFHE involves a perfect management of flow distribution, thanks to graph theory. But calculations of such large system of equations require appropriate numerical resolutions, involving in particular numerical methods for sparse systems.

Abstract

This study demonstrates the use of (global) sensitivity analysis as a supporting tool for guiding and prioritising experimental research activities. The basic idea is to focus the experimental efforts on those factors identified as the most significant by the sensitivity analysis. Such an approach is ideal for identifying critical regions in the experimental design space (typically multi-dimensional). These critical regions can later be investigated experimentally by means of the well-established Design of Experiments methodology. The sensitivity-analysis based approach promises better use of resources by preventing wastage of valuable experimental time on investigating factors which are not influential on the system behavior. The approach requires a first-principles model of the system on which the sensitivity analysis is performed, and was tested on a dynamic fermentation model describing antibiotic production by *Streptomyces coelicolor*.

Keywords: *Sensitivity, uncertainty, fermentation, first-principles, SRC, experiment*

1. Introduction

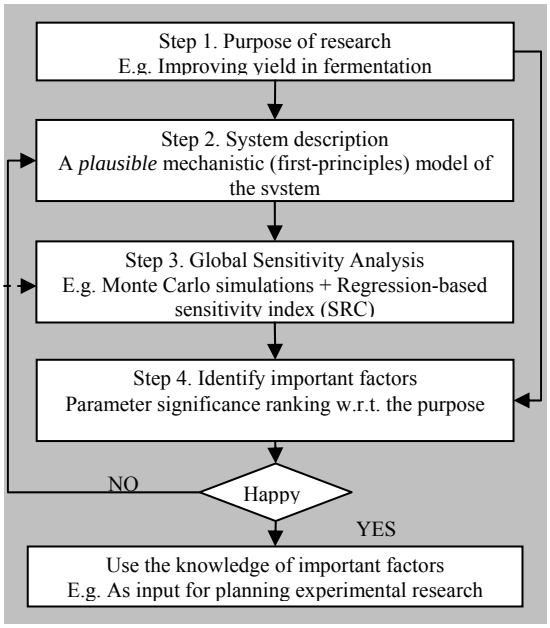
In a general sense, uncertainty exists in the predictions of any numerical model. This uncertainty stems from, among others, the numerous assumptions and simplifications made during the model-building process. Uncertainty analysis is complemented by sensitivity analysis, which aims at quantifying which of the model assumptions/input parameters causes the observed uncertainty in model predictions. The result of sensitivity analysis is a parameter significance ranking on model predictions. Such information is valuable for a number of purposes: (i) identify critical regions in the input parameter space, (ii) defend the credibility of a model, (iii) test hypotheses (Saltelli *et al*., 2008; Helton and Davis, 2003).

Traditionally sensitivity analysis is performed using differential analysis –typically by taking the first order derivative of a model output with respect to a parameter. This method however is local and may not be applicable for non-linear models – representing the majority of the engineering models. In a previous study, Sin *et al*. (2009) evaluated global methods for sensitivity analysis, namely regression-based (i.e. standardized regression coefficients, SRC) and screening-based (i.e. Morris method) approaches. The results showed that the global methods particularly perform better with respect to assessment of the significance of model parameters on the model predictions, especially when the degree of non-linearity of the model in question is high.

Another important finding of this study is that the sensitivity methods identified only few (5 to 7) out of a total of 56 parameters to cause most of the variance (up to 95%) in the predictions. Based on these results, we suggest using sensitivity analysis for better directing experimental resources in such a way that only important factors (e.g. what causes variation in the product quality, what influences the yield etc.) are investigated. The aim of this contribution is thus to develop a methodology that uses global sensitivity analysis methods for establishing priorities in experimental research.
The proposed method is different from the traditional Design of Experiment (DoE) approaches (Mandenius and Brundin, 2008), which focus typically on a few factors and mostly use a statistical model to understand the interactions between the factors. Our method is an integrated approach which systematically screens all possible factors involved in a systems' behavior using a mechanistic (knowledge-based) model.

2. Materials and methods

2.1. Global Sensitivity Analysis for prioritizing experimental research
The framework in which sensitivity analysis is used for prioritizing the experimental efforts is shown in Figure 1.



The first step is obviously specifying the objective of the experimental research work. This could be a specific objective like improving the yield in a fermentation process. The second step is to obtain a mechanistic model describing the system behavior; the only requirement is that the model should adequately describe interactions in the system, e.g. physical, chemical and biological reactions for a fermentation system. In step 3, the global sensitivity analysis is performed using an appropriate method (Helton and Davis, 2003; Saltelli *et al*., 2008; Sin *et al*., 2009).

Figure 1 Sensitivity analysis based methodology for prioritizing experimental research

In step 4, the sensitivity results are interpreted and the important factors affecting the purpose are identified. The results are then cross-checked with the available process knowledge in order to pinpoint any possible discrepancy. In case the evaluation is positive, the experimenter can then move on and use the knowledge in his/her planning of the experimental work.

2.2. Case study: Batch cultivation of Streptomyces coelicolor for antibiotic production
As a case study, batch cultivation of *S. coelicolor* for antibiotic production was used. The model predicts glucose, oxygen, biomass, actinorhodin, and off-gas CO_2 among others, and generally describes the system behavior adequately. The model contains 56

parameters relating to biological, chemical and gas-liquid exchange processes in the system. For more information and details, the reader is referred to Sin *et al*. (2008).

2.3. Regression-based sensitivity analysis

2.3.1. Standardized Regression Coefficient

In this method, the sensitivity measures are in fact the regression coefficients obtained from the linear regression models built on the outputs generated by Monte Carlo (MC) simulations (for more information see below). This method requires scalar output, hence for the outputs of the dynamic models one needs to use proper scalar values, e.g. mean value of a dynamic output. Let the scalar model output matrix be denoted as **y** with a dimension of *KxN,* in which K is the number of outputs and N is the number of MC simulations. With that output matrix one multi-linear regression model was built for each model output k:

$$y_{ik} = b_{0k} + \sum_{j=1}^{M} b_{jk}\theta_{ij} + \varepsilon_{ik} \quad for\ i = 1,2,\ldots N \quad and \quad for\ k = 1,2....K \qquad \text{Eq. 1}$$

y_{ik} is the scalar value for the kth output, b_{jk} is the coefficient of the j^{th} input factor on y_k, θ_{ij} is the value of the j^{th} factor, M is the number of factors, and ε_{ik} is the error of the regression model. The eq.1 is re-written by scaling the outputs and the factors using the corresponding mean (μ) and standard deviation (σ) (Saltelli *et al*., 2008):

$$\frac{y_{ik} - \mu_{y_k}}{\sigma_{y_k}} = \sum_{j=1}^{M} \beta_{jk} \cdot \frac{\theta_{ij} - \mu_{\theta j}}{\sigma_{\theta j}} + \varepsilon_{ik} \qquad \text{Eq. 2}$$

β_{jk} is called the standardized regression coefficient (SRC) of the j^{th} input factor on the k^{th} model output, y_k. Its magnitude is a measure of the sensitivity of the output to the factor.

Table 1 Expert review of uncertainty of input parameters (Sin *et al*., 2008)

Uncertainty Class	**Variation factor**[1]	**Parameters** (legends explained in Sin *et al*. (2008))
1. Low	5%	Y_{SX}, MW_X, MW_S, γ_S, MW_{act}, γ_{ACT}, i_{NRED}, MW_{red}, γ_{RED}, T, pH, pK_{NH}, pK_{HCO3} pK_{H2PO4}, pKw, $k_{f,NH}$, $k_{f,CO2}$, $k_{f,H2PO4}$, $k_{f,W}$, R, V_L
2. Medium	25%	f_{XI}, i_{NX}, i_{PX}, γ_X, μ_{max}, m_S, k_d, t_{lag}, K_La_{O2}, P_{in}, P_{O2}, P_{CO2}, P_{out}, D_{O2}, D_{CO2}, D_{N2}, K_{HO2}, K_{HCO2}, K_{HN2},$V_{G,}$ Q_{Gin}
3. High	50%	K_S, K_O, K_N, K_P, Y_{SACT}, β_{ACT}, α_{ACT}, S_{ACT}^{max}, Y_{SRED}, β_{RED}, α_{RED}, S_{RED}^{max}, S^*_{NH3}, K_La_{NH3}

[1]Stands for the maximum percent of deviation from the mean value of a parameter.

2.3.2. Monte Carlo simulation

MC simulation involves 3 steps: (1) specifying input uncertainty (2) sampling from the input uncertainty and (3) performing simulations with the sampled inputs (Helton and Davis, 2003). For step 1, the input uncertainty was specified following an expert review process and the results shown in Table 1. For step 2, Latin Hypercube Sampling (LHS) was used with the sampling number fixed at 500. For step 3, the model was simulated with 500 different input samples to obtain MC simulations.

3. Results and discussions

We first take a simple purpose in step 1 to evaluate the methodology, by focusing on the factors affecting off-gas CO_2 and dissolved oxygen dynamics in the system. For step 2,

the above-mentioned model is used (Sin *et al*., 2008). The other steps are presented below.

3.1. Step 3 Global sensitivity analysis

3.1.1. Monte Carlo simulations

The MC simulation results (500 in total) of biomass, glucose, oxygen and off-gas CO_2 are shown in Figure 2. Generally speaking the larger the spread of the MC simulations, the higher the uncertainty is on the output in question. From Fig 2, one observes there is considerable uncertainty on the oxygen and off-gas CO_2.This uncertainty on the output is in fact caused by the uncertainty in the inputs (Table 1). The sensitivity analysis now aims at decomposing this uncertainty with respect to factors in the input uncertainty.

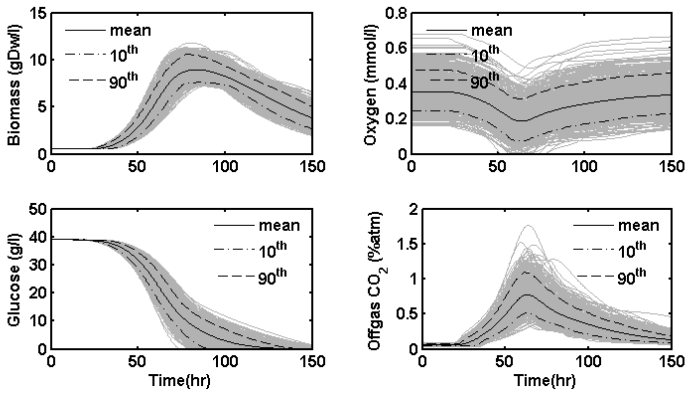


Figure 2 500 Monte Carlo simulation results for biomass, glucose, oxygen and off-gas CO_2 in a batch cultivation of *S. coelicolor* (see legend on the plots)

3.1.2. Standardized regression coefficients (SRC)

The SRC of the factors for off-gas CO_2, oxygen, glucose and biomass are shown in Table 2. The SRC take values between -1 and 1. The absolute value of the SRC indicate how significant each factor is on the output, whereas the sign indicates a positive or a negative impact of the factors on the output in question.

Table 2 Ranking importance of factors on two model outputs: oxygen and off-gas CO_2

	Off-gas CO_2		**Oxygen**		**Biomass**		**Glucose**	
Rank	Parameter	SRC	Parameter	SRC	Parameter	SRC	Parameter	SRC
1	Pout	0.58	P_{O2}	0.59	m_S	-0.67	t_{lag}	0.74
2	Q_{Gin}	-0.54	Pin	0.58	k_d	-0.42	i_{PX}	0.66
3	Pin	-0.53	K_{HO2}	0.57	i_{PX}	-0.37	μ_{max}	-0.63
4	P_{O2}	-0.11	K_La	0.12	t_{lag}	-0.26	K_P	0.54
5	V_L	0.11	μ_{max}	-0.10	Y_{SX}	0.21	pK_{H2PO4}	-0.40
6	R	0.11	K_P	0.06	pK_{H2PO4}	0.19	m_S	-0.36
7	i_{PX}	-0.08	t_{lag}	0.03	K_P	-0.13	K_S	0.12
8	m_S	0.07	γ_S	-0.03	μ_{max}	-0.11	Y_{SX}	0.12
9	P_{CO2}	0.07						

3.2. Step 4-Identification of significant factors

One observes that the majority of the factors in fact has negligible impact on the outputs, while only few have a significant influence (e.g. 9 factors have SRC value higher than ±0.03 on the off-gas CO_2 and 8 factors on the oxygen in the fermenter). The significant factors affecting the off-gas CO_2 and oxygen are mainly related to the aeration process (partial pressure of oxygen and CO_2, air flow-rate, etc) and to a lesser

extent to the microbial metabolism (Sin *et al*., 2009). On the other hand, the significant factors affecting the glucose and biomass in the system are mainly related to microbial metabolism (growth rate, maintenance, etc). This sort of information is crucial in focusing the experimental efforts in line with the purpose of the experiment (see below).

3.3. Step 5-Experiments (verification of the concept)

Since the purpose of the experiment was set to investigate off-gas CO_2 and oxygen in the fermentation system, the information provided above by importance ranking of factors thus helps narrowing down the experimental degrees of freedom to focus only on the aeration process in the system.

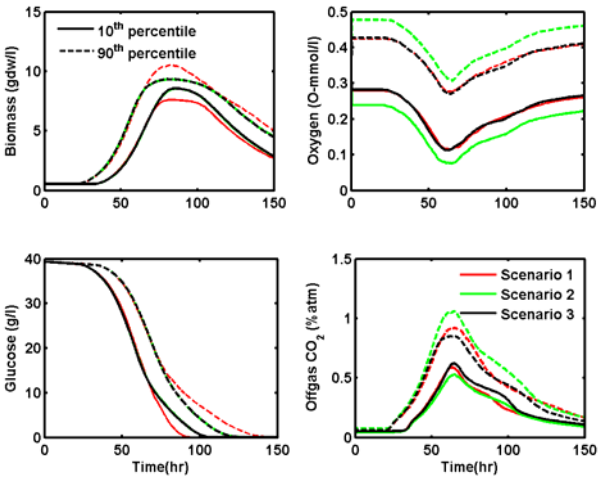

Figure 3 Virtual experiments: uncertainty reduction in three scenarios (see text)

To verify this concept, we do a simulation study using the above described model (Sin et al 2008). We assume that three experiments have been performed with the system (i.e. three hypothetical experiments) that focused on measuring the parameters of (i) the aeration (P_{out}, Q_{Gin}, P_{in}, P_{O2}, P_{CO2}, K_La), (ii) the biomass metabolism (i_{px}, m_S, μ_{max}, K_P), or (iii) both. One also assumes that the experiments are of good quality, hence providing measurements with only a 5% error. With that information, we update the input uncertainty in Table 1 (by assigning class I uncertainty to the measured parameters), and perform 3 sets of MC simulations. The uncertainty in the model outputs for each hypothetical experiment is then evaluated (Figure 3) and summarized in Table 3.

The calculated variance indicates the lack of information on the state of knowledge; hence it is a suitable measure to compare the performance of different *(*in this case *hypothetical)* experiments Compared to the reference case, the largest increase in knowledge (largest reduction in uncertainty) on off-gas CO_2 and oxygen was obtained in scenario 1, while in scenario 2 no incremental knowledge could be obtained on these two outputs. The reason is simply that in scenario 1 the efforts were spent to better measuring the parameters with highest sensitivity on off-gas CO_2 and oxygen, while in scenario 2 less influential factors were measured. Similarly, scenario 3 was able to contribute significant knowledge on the state of off-gas CO_2 and oxygen, however in this case this was at the expense of more experimental efforts (recall that more factors were measured in this scenario).

Table 3. Experimental scenario versus uncertainty estimation in four model outputs

Experiment	Off-gas CO_2	Oxygen	Glucose	Biomass
	σ^2_{CO2}	σ^2_{O2}	$\sigma^2_{glucose}$	$\sigma^2_{biomass}$
Reference	5.6e-3	14.62	2310.8	137.75
Scenario 1	**0.38e-3**	**0.58**	2311.8	137.71
Scenario 2	5.9e-3	14.5	1415.1	47.98
Scenario 3	**0.34e-3**	**0.59**	1391.5	47.15

Important to remark, on the other hand, is that scenario 1 did not bring any additional knowledge on the state of glucose and biomass, whereas scenario 2 did. Again the reason is simply as stated above: the factors measured in scenario 2 have significant influence on biomass and glucose. Summarizing, when one measures factors that are highly influential on the outputs in question (e.g. off-gas CO_2), one obtains significant knowledge on that state. This knowledge can help the experimenter in setting up priorities for experimental research, thereby directing the resources more effectively.

4. Conclusions

This study evaluated global sensitivity analysis as a means for establishing research priorities in experimental work. The concept was successfully evaluated using a simulation study with a system consisting of a batch cultivation of *S. coelicolor* for antibiotic production. The sensitivity analysis indeed identified that only few factors (around 8 to 10 out of 56) were influential on the behavior of the system, while the rest were of little or no significance. Using this information, several *hypothetical* experiments were performed, whose results showed indeed that experiments directed at measuring the few significant factors brought in significant additional information about the state of the system. On the contrary, when one invests resources on measuring less influential factors, one obtains no or negligible amounts of information.

Since the sensitivity analysis based-methodology was evaluated using only simulations, experimental validation would be the logical next step. Note that the methodology is expected to be valuable on its own – given that a mechanistic model describing various features of the system is available – especially since it helps screening a large number of factors involved in typical experimental work as a preliminary analysis prior to performing more detailed experiment design, e.g. DoE. This preliminary analysis is traditionally based on previous experiences and prior knowledge. The benefit of this new approach is that it makes the preliminary analysis systematic and efficient.

Abstract

The concept of time delay arises in many practical chemical engineering applications. Ideal time delay appears every time an advective transport is the solely transport mechanism present in part of the process. Due the distributed nature of pure time delay, this phenomena cannot be directly simulated by a finite dimension lumped system. The main objective of this contribution is the automatic development of rational approximations of ideal time delay transfer functions resulting in lumped systems of specified finite dimension. Different approximations were generated and their dynamic behaviors were analyzed and compared, where stability properties are the main focus of the analysis. Oscillations and inverse response appear in various time delay approximations, therefore these undesirable behaviors were minimized through the inclusion of adjustable *m*-order filters in the approximations. Data buffering is the common strategy considered in many dynamic process simulators to include pure time delays. However, this strategy is not compatible with numerical time integration that uses variable time steps in order to meet specified accuracy, because the delayed data must be interpolated compromising the accuracy of the numerical integration. Different continuous approximations were included in EMSO – Environment for Modeling Simulation and Optimization – and their performances were compared through some practical examples. The orthogonal collocation approach presented better stability properties for high-order approximations and the undesirable oscillations were well-controlled with low-order filters.

Keywords: ideal time delay, rational approximation, dynamic simulation, EMSO.

1. Introduction

The ideal time delay is present in many dynamics systems and has unstable effect in control systems. Your effect in the time response is simply to delay the exciting signal by *v* time units. For sheet lines, webs, fibers, and conveyors, the time delay is the distance between the manipulated variable and the process variable divided by the speed. For plug flow, the entire residence time is a transportation delay, that is, the time delay is the volume divided by the flow rate. The flow in pipelines, sample lines, static mixers, coils, and heat exchanger tubes can be considered to be essentially plug flow (Blevins et al., 2003). Other example of time delayed effects is the transcription of a specific gene in response to some stimulus that may lead to the production of an enzyme that ultimately changes the flux distribution within a metabolic network. However, there is a considerable time delay of maybe 15 or 20 min between sensing the stimulus and the eventual increase in enzyme activity, which is much slower than biochemical

reactions (Mocek et al., 2005). For these reasons, the mathematical modeling of time delay is very important when the original system holds such characteristic, in order to be used in control system design.

A difficulty to the time delay modeling is its Laplace transform $e^{-\nu \cdot s}$ cannot be expressed as a finite-order polynomials rate in *s* domain. Thus, an exact transfer functions representation of a system with time delay is not possible. For instance, first and second order transfer functions with time delay are not low-order transfer functions and when inserted in control systems may produce oscillations even if proportional controllers are used. However, an accurate approximation with a polynomials ratio in s domain, as Padè approximations, can be obtained.

Wang and Hu (1999) proposed a robust stability test for dynamic systems with short delays based on a 6^{th}-order polynomial, but it does not present good results for high frequencies and large time delays. Phillip et al. (1999) showed that Padè approximation for step responses presents squared and absolute errors larger than Bessel approximation, becoming unstable for system of order higher than 4. Guzmán et al. (2008) used the Smith predictor (SP) scheme to cope the problem of controlling delayed systems by an interactive tool. Their work focused on describing the problem of typical PI control for controlling time-delay systems, how the SP can be used to solve such problems, and also how it is possible to face the SP drawbacks against uncertainties, integrating systems, and unstable systems.

In simulations evaluated in the time domain, time delay can be simulated with FIFO queues (first in, first out). In this case, the stack length is directly proportional to the delay time and inversely proportional to the integration time step. Due to large delays inside the feedback loop, queue level dynamics might exhibit oscillations (Gómez-Stern et al., 2002). Other form to simulate the dead time is by series of capacitive systems (or CST – Continuous Stirred Tank), but it requires a considerable computational effort due to the large number of CST necessary to have an acceptable accuracy.

In this work, different continuous approximations, based on Taylor series and orthogonal collocation, are proposed to model the time delay and are applied in dynamic simulations on EMSO – *Environment for Modeling Simulation and Optimization* – (Soares and Secchi, 2003). The step function with time delay, which is a hard function to approximate, is used to evaluate the robustness and performance of the methods.

2. Approximation based on Taylor series

The time delay in the Laplace domain, Equation (1), was approximated in a continuous form by the ratio of two *n*-degree polynomials, the Padè approximation.

$$\frac{H(s)}{G(s)} = e^{-\nu \cdot s} \tag{1}$$

where ν is the time delay. If *f(x)* is an analytic function of *x*, in the neighborhoods of $x = 0$, then it can be expanded in a Taylor series around this point:

$$f(x) = \sum_{i=0}^{\infty} \frac{1}{i!} \cdot \left. \frac{d^i f(x)}{dx^i} \right|_{x=0} = \sum_{i=0}^{\infty} c_i \cdot x^i \tag{2}$$

Approximating Equation (2) by the ratio of two *n*-degree polynomials in *x*:

$$f(x) \cong f(0) \cdot \frac{b_0 + \sum_{i=1}^{n} b_i \cdot x^i}{a_0 + \sum_{i=1}^{n} a_i \cdot x^i} \tag{3}$$

Coefficients a_i and b_i of Equation (3) are determined to reproduce the Taylor series expansion until the order $2n$, with $c_0 = f(0)$ and $a_0 = b_0 = 1$:

$$\left(c_0 + \sum_{i=1}^{2\cdot n} c_i \cdot x^i\right) \cdot \left(1 + \sum_{i=1}^{n} a_i \cdot x^i\right) = f(0) \cdot \left(1 + \sum_{i=1}^{n} b_i \cdot x^i\right) \tag{4}$$

Evaluating the products e equaling the equipotent terms coefficients of x, results in the following linear systems:

$$\begin{bmatrix} c_1 & c_2 & c_3 & \cdots & c_n \\ c_2 & c_3 & c_4 & \cdots & c_{n+1} \\ \vdots & \vdots & \vdots & & \vdots \\ c_n & c_{n+1} & c_{n+2} & \cdots & c_{2\cdot n-1} \end{bmatrix} \cdot \begin{bmatrix} a_n \\ a_{n-1} \\ \vdots \\ a_1 \end{bmatrix} = -\begin{bmatrix} c_{n+1} \\ c_{n+2} \\ \vdots \\ c_{2\cdot n} \end{bmatrix} \quad and \quad \begin{bmatrix} a_1 & a_0 & 0 & 0 & \cdots & 0 & 0 \\ a_2 & a_1 & a_0 & 0 & \cdots & 0 & 0 \\ a_3 & a_2 & a_1 & a_0 & \cdots & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & & \vdots & \vdots \\ a_{n-1} & a_{n-2} & a_{n-3} & a_{n-4} & \cdots & a_0 & 0 \\ a_n & a_{n-1} & a_{n-2} & a_{n-3} & \cdots & a_1 & a_0 \end{bmatrix} \cdot \begin{bmatrix} c_0 \\ c_1 \\ c_2 \\ \vdots \\ c_{n-1} \\ c_n \end{bmatrix} = c_0 \cdot \begin{bmatrix} b_1 \\ b_2 \\ b_3 \\ \vdots \\ b_{n-1} \\ b_n \end{bmatrix}$$

where, respectively, coefficients a_i and b_i are determined.

Approximating Equation (1) as described above, Equation (5) is obtained.

$$\frac{H(s)}{G(s)} = e^{-\nu \cdot s} = \frac{1 + b_1 \cdot \nu \cdot s + b_2 \cdot \nu^2 \cdot s^2 + b_3 \cdot \nu^3 \cdot s^3 + \cdots + b_n \cdot \nu^n \cdot s^n}{1 + a_1 \cdot \nu \cdot s + a_2 \cdot \nu^2 \cdot s^2 + a_3 \cdot \nu^3 \cdot s^3 + \cdots + a_n \cdot \nu^n \cdot s^n} \tag{5}$$

Multiplying the numerator and denominator of Equation (5) by an auxiliary function, *X(s)*, and using the following inverse of Laplace transform:

$$L^{-1}(s^i \cdot X(s)) = \frac{d^i x(t)}{dt^i}$$

Equation (5) can be written in time domain as:

$$\begin{aligned} x(t) + a_1 \cdot \nu \cdot \frac{dx(t)}{dt} + a_2 \cdot \nu^2 \cdot \frac{d^2 x(t)}{dt^2} + a_3 \cdot \nu^3 \cdot \frac{d^3 x(t)}{dt^3} + \cdots + a_n \cdot \nu^n \cdot \frac{d^n x(t)}{dt^n} &= g(t) \\ x(t) + b_1 \cdot \nu \cdot \frac{dx(t)}{dt} + b_2 \cdot \nu^2 \cdot \frac{d^2 x(t)}{dt^2} + b_3 \cdot \nu^3 \cdot \frac{d^3 x(t)}{dt^3} + \cdots + b_n \cdot \nu^n \cdot \frac{d^n x(t)}{dt^n} &= h(t) \end{aligned} \tag{6}$$

Defining auxiliary state variables:

$$x_i(t) = \frac{d^{i-1} x(t)}{dt^{i-1}}, \qquad i = 1:n \tag{7}$$

Equation (6) can be described by the following first-order linear system of ordinary differential equations:

$$\begin{cases} \dfrac{dx_1(t)}{dt} = x_2(t) \\ \dfrac{dx_2(t)}{dt} = x_3(t) \\ \vdots \\ \dfrac{dx_n(t)}{dt} = g(t) - \left(x_1(t) + a_1 \cdot \nu \cdot x_2(t) + a_2 \cdot \nu^2 \cdot x_3(t) + a_3 \cdot \nu^3 \cdot x_4(t) + \cdots + a_{n-1} \cdot \nu^{n-1} \cdot x_n(t)\right) \end{cases} \tag{8}$$

Subject to the initial condition: $x_i(0) = 0$, $i = 1$ *to* n. The $h(t)$ function is determined by:

$$h(t) = x_1(t) + b_1 \cdot \nu \cdot x_2(t) + b_2 \cdot \nu^2 \cdot x_3(t) + b_3 \cdot \nu^3 \cdot x_4(t) + \cdots + b_{n-1} \cdot \nu^{n-1} \cdot x_n(t) + b_n \cdot \nu^n \cdot \frac{dx_n(t)}{dt} \tag{9}$$

Using the last differential equation of Equation (8) and knowing that $a_n = b_n$:

$$h(t) = g(t) + (b_1 - a_1) \cdot \nu \cdot x_2(t) + (b_2 - a_2) \cdot \nu^2 \cdot x_3(t) + (b_3 - a_3) \cdot \nu^3 \cdot x_4(t) + \cdots + (b_{n-1} - a_{n-1}) \cdot \nu^{n-1} \cdot x_n(t) \tag{11}$$

Therefore, for the simulation of the model, the following generalized system is used:

$$\frac{d\underline{x}(t)}{dt} = \underline{\underline{A}} \cdot \underline{x}(t) + \underline{b} \cdot u(t) \tag{12}$$

Figure 1 compares model predictions for two distinct polynomials with exact unitary step function with ν = 1 time unit. The model is stable for $n < 13$ presenting considerable oscillation before the step and acceptable result after the step, but for high-

degree polynomials the matrix *A* contains high truncate errors besides its high density that demands great computational effort.

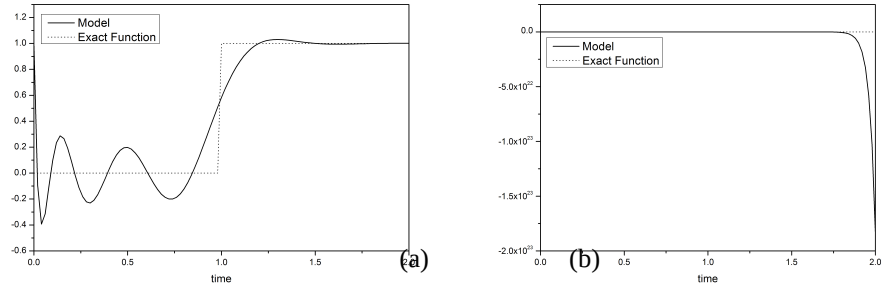

Figure 1: Approximation function of the unitary step with: (a) 6th degree polynomial with 100 discretization points and squared error of 1.8555; (b) 13th degree polynomial and 100 discretization points (unstable).

3. Approximation based on orthogonal collocation

An alternative to solve the problem of high truncate errors in the approach described in the previous section is to apply the orthogonal collocation method (Michelsen and Villadsen, 1972). Choosing the Jacobi polynomials $P_n^{\alpha,\beta}(x)$ of degree *n* and appropriate values of the parameters α and β, the matrix *A* and vector *b*, Equation (12), are obtained from the matrix of first derivatives of the polynomial at the collocation points (including $x = 0$ and $x = 1$). For $n = 5$, $\alpha = 1$ and $\beta = 0$, it becomes:

Matrix A

$$\begin{bmatrix} -12.6 & -4.08 & 1.22 & -0.566 & 0.307 & -0.109 \\ 9.80 & -2.53 & -3.13 & 1.16 & -0.583 & 0.202 \\ -5.18 & 5.54 & -1.14 & -2.97 & 1.18 & -0.385 \\ 4.11 & -3.49 & 5.07 & -0.719 & -3.46 & 0.926 \\ -4.39 & 3.46 & -3.95 & 6.81 & -0.555 & -4.02 \\ 9.94 & -7.68 & 8.23 & -11.6 & 25.7 & -18.5 \end{bmatrix}$$

Roots of $P_5^{1,0}(x)$:

$$\begin{bmatrix} 0.0398 & 0.198 & 0.438 & 0.695 & 0.901 \end{bmatrix}$$

Vector b

$$\begin{bmatrix} 15.8 & -4.92 & 2.96 & -2.43 & 2.64 & -6.00 \end{bmatrix}$$

In Figure 2 it can be seen that the limitation in the polynomial approximation for Taylor series does not occur in this case, thus higher degree polynomials can be used. However, the approximation of the step function present high frequency oscillation besides the even higher density of matrix *A*.

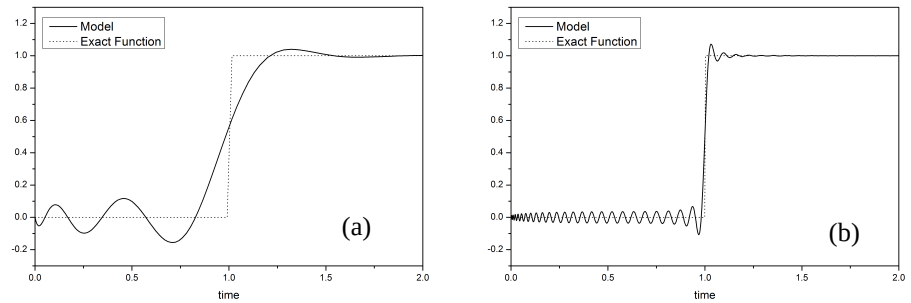

Figure 2: Orthogonal collocation approximation for unitary step function with v = 1 time unit and: (a) 5th degree Jacobi polynomial with squared error of 1.2359; (b) 50th degree Jacobi polynomial with squared error of 1.0344.

4. Approximation based on series of orthogonal collocation

In order to reduce the undesirable oscillations, the system was discretized in *N* intervals with application of Jacobi polynomial of degree 1 in each interval, creating a tridiagonal matrix *A* to solve the ordinary differential equations system:

Matrix A

$$\begin{bmatrix} -4.5 & -1.5 & 0 & 0 & 0 & 0 \\ 13.5 & -7.5 & 0 & 0 & 0 & 0 \\ 0 & 6 & -4.5 & -1.5 & 0 & 0 \\ 0 & -6 & 13.5 & -7.5 & 0 & 0 \\ 0 & 0 & 0 & 6 & -4.5 & -1.5 \\ 0 & 0 & 0 & -6 & 13.5 & -7.5 \end{bmatrix}$$

Root of $P_1^{1,0}(x)$:

[1/3]

Vector b

$$\begin{bmatrix} 6 & -6 & 0 & 0 & 0 & 0 \end{bmatrix}$$

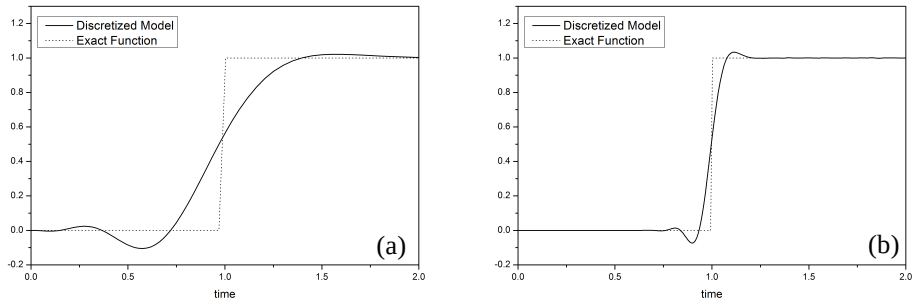

Figure 3: Series of first-degree Jacobi polynomials approximation for unitary step function with ν = 1 time unit and: (a) 3 intervals, with global order of 6 and squared error of 1.1495; (b) 24 intervals, with global order of 48 and squared error of 1.0344.

In Figure 3, a considerable reduction of the oscillation can be observed. In Figure 3a, with 3 intervals, smoother oscillations are obtained when compared with Figure 2a (global order of 11). This result is even more expressive in Figure 3b (global order of 48) when compared with Figure 2b (global order of 51).

5. Approximation based on series of orthogonal collocation with capacitive filter

In this section a filter with capacitive characteristics is applied in the system to reduce even more the oscillation in the previous section. A first-order filter is added into the system by a γ factor with range from 0 to 1, where $\gamma = 1$ prevail the orthogonal collocation and $\gamma = 0$ the capacitive filter.

In Figure 4, different time delayed simulations are plotted and compared with ideal time delay. The results show a damping in the oscillations of the previous cases, but an increase of the squared errors. Therefore, for system without inherent oscillation (Figures 4a, 4b and 4c), filtering is a resource for system with abrupt changes, reducing the oscillation generated by the approximation, otherwise the use of filter is not desired, because it attenuates natural oscillation (Figure 4d) and reduces the accuracy.

6. Conclusion

The time delay approximation based on discretized orthogonal collocation is more robust and present better performance than the usual Padè approximations. The use of capacitive filters is beneficial for systems without inherent oscillations and with abrupt

changes. The computational costs of the proposed approximation are reduced when using series of first-degree Jacobi polynomials.

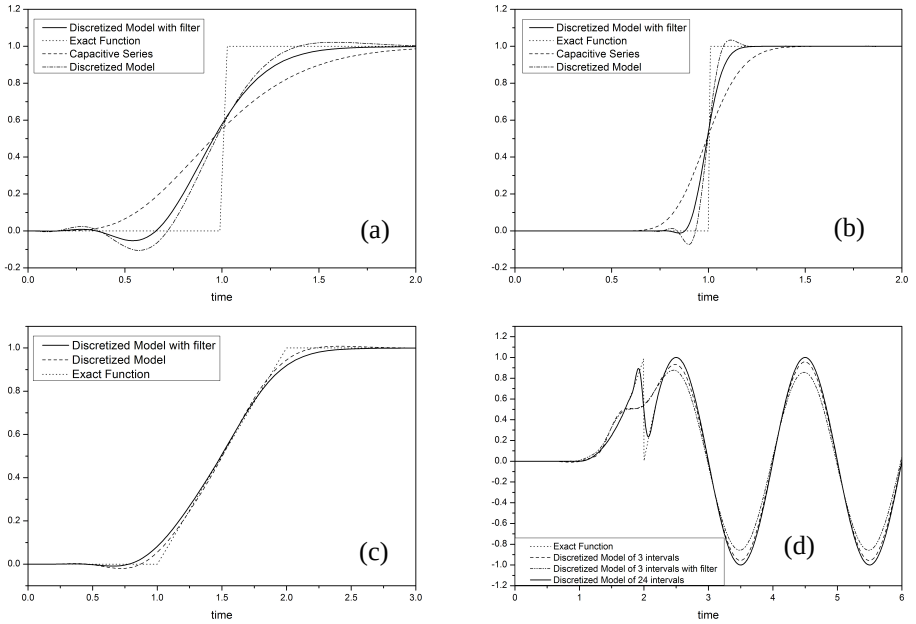

Figure 4: Time delayed simulations: (a) 6^{th} global order approximation of step function with capacitive series and discretized orthogonal collocation without and with filter (squared error of 1.2592, and $\gamma = 0.8$); (b) 48^{th} global order (with filter: squared error of 1.2669, and $\gamma = 0.94$); (c) discretized orthogonal collocation in ramp function $(t-1-(t-2)\cdot\Phi(t-2))\cdot\Phi(t-1)$ with global order of 6 and squared errors of 0.1354 (without filter) and 0.2302 (with filter) ; and (d) function $(t-1)2\cdot(1-\Phi(t-2))+(\sin(\pi\cdot(t-2)))\cdot\Phi(t-2)$ with squared errors of 1.3116 (3 intervals) and 1.3006 (24 intervals), both without filter, where $\Phi(t)$ is step function.

Abstract

A new stochastic algorithm for global optimization is proposed in this work, which is inspired in the Parallel Tempering algorithm, and is denoted as Molecular Inspired Parallel Tempering (MIPT) because it mimics the behavior of charged molecules in solution, taking into account the different forces that are exerted on each molecule. Molecules are classified into explorers and refiners. Explorers have lower friction values and are subject to repulsion forces, covering a wider region of the search space for finding the global optimum. Refiners have higher friction values, intending to make a finer search in the neighborhood of already found local minima. MIPT efficiency is tested through four challenging case studies, showing not only its capability to find the global optimum in all cases with a 100% of success ratio, but also with a comparable computational effort than other established well known stochastic methods.

Keywords: Global Optimization, Molecular-Inspired Parallel Tempering, Stochastic Optimization.

1. Introduction

The scope of Global Optimization (GO), as stated by Neumaier (2004), is to find the absolutely best set of admissible conditions to achieve an objective under given constraints. In general, deterministic or probabilistic approaches can be used for solving the GO problem. In this work, a probabilistic method is proposed, which is based on the Parallel Tempering (PT) algorithm (Earl and Deem, 2005). PT algorithms simulate various non-interacting replicas of the original system at different temperatures. Replicas at higher temperatures are able to explore wider regions, whereas those at lower temperatures are able to perform a finer sampling in local regions. A special characteristic of PT algorithms is that they exchange temperatures between different replicas, providing a global character by allowing escaping from local minima and exploring a wider search space. PT methods have been successfully applied in different fields (simulation of polymers, proteins, and general optimization problems) for more than 20 years; however, there are still open topics regarding the algorithm, and it has been suggested that temperature may not always be the best parameter to temper, and that PT can be conducted by other parameters such as pair potentials or chemical potentials. In Section 2, a Molecular Inspired Parallel Tempering (MIPT) algorithm for solving GO problems, is presented, which uses a friction factor as parameter for tempering. MIPT is easy to implement, does not need derivative information, and includes two important characteristics, global character and local refinement, which according to Törn and Žilinskas (1989), are important features that should be present in

GO methods. In Section 3, four different examples solved using MIPT are presented, and a comparison between MIPT and other well-established methods is provided.

2. Molecular-Inspired Parallel Tempering Algorithm (MIPT)

MIPT mimics the behavior of charged molecules in solution. Figure 1 shows a charged two-molecule system, in which each molecule is affected by three different forces: repulsion ($\boldsymbol{F}_{\text{rep}}$), random ($\boldsymbol{F}_{\text{Bm}}$), and friction ($\boldsymbol{F}_{\text{f}}$). Repulsion force ($\boldsymbol{F}_{\text{rep}}(i)$) exerted by molecule j over molecule i (both with the same electrostatic charge) is calculated by Coulomb's law, as inversely proportional to the square of their distance (d_{ij}). The random force ($\boldsymbol{F}_{\text{Bm}}(i)$), is responsible for the brownian motion of the molecule and it is expressed by means of a normalized Gaussian distribution with zero mean and standard deviation one ($\xi(0,1)$). Finally, the friction force ($\boldsymbol{F}_{\text{f}}(\text{i})$) has an opposite direction to the net force ($\boldsymbol{F}_{\text{net}}=\boldsymbol{F}_{\text{rep}}+\boldsymbol{F}_{\text{Bm}}$) and it is proportional by a γ-factor, to the velocity υ of the molecule. The γ-factor is a friction coefficient inversely proportional to the molecules temperature, and it is the parameter used in this approach for tempering the algorithm.

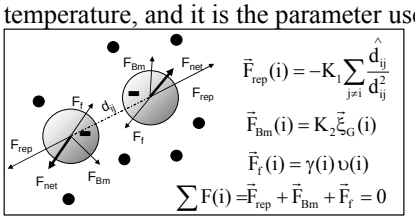

Figure 1 Forces acting on a system of electrically charged molecules. Black and gray particles represent molecules of solvent and charged solute molecules, respectively.

$$\Delta\vec{x}(i) = \frac{\vec{F}_{rep}(i) + K_2\vec{\xi}_G(i)}{\gamma(i)} \qquad (1)$$

The net force ($\boldsymbol{F}_{\text{net}}$) acting on each molecule is responsible for its displacement in the space of decision variables; such displacement is given by (1). The flow diagram of MIPT algorithm is presented in Figure 2. A key feature of MIPT is that molecules are classified into Refiners and Explorers. Refiners are always feasible points constrained to higher friction values, forcing the search to a narrow region around their current position, providing the method with a local character. These are molecules that make shorter displacements in the search region, in order to refine the search in a neighborhood that contains local optima. Explorers have lower friction values, are allowed to be unfeasible and are affected by the repulsive effect, which force them to move towards unexplored zones, providing the method with a global character. Explorers make larger moves escaping from local optima that are already being explored by refiners. The optimization starts by setting up the input data to the algorithm: the number of molecules (n_m) and decision variables (n_{dv}), the stopping criteria and the tuning parameters of the algorithm. MIPT tuning parameters include the γ-values, K_1 and K_2, the β parameter in the Metropolis condition and the minimum number of explorers (*minNexp*). It is suggested that $n_{\text{m}} \geq 2 \cdot n_{\text{dv}}$, in order to cover a wider search region. The probability of finding the global optimum increases with the number of molecules, but there is a compromise between success and computational effort. The next step is the random generation of the initial *nm* molecules (starting positions *x0(i)*). The molecules are ranked according to their objective function values and their feasibility. Then, $\gamma(i)$ is calculated and the algorithm opens two branches, one for the refiner molecules and the other for the explorers. The refiners branch starts setting the

repulsion force to zero (F_{rep}=0). Then, the random force F_{bm}(i) is calculated from a Gaussian distribution. Equation (1) is used for calculating the new position (x_{new}) of the molecule. The objective function value (f_{new}) for x_{new} is evaluated, and the Gibbs free energy change $\Delta G(i)$ with respect to the current objective function value (f_{opt}) is calculated according to (2). After calculating $\Delta G(i)$, the feasibility condition is checked again. If the new position is an unfeasible point, $x_{new}(i)$ is rejected. On the contrary, if, x_{new} is feasible and also $\Delta G(i)<0$, the new position is accepted and position for molecule i is updated to the new value ($x_{opt}(i)=x_{new}(i)$).

$$\Delta G(i) = \frac{f_{new}(i) - f_{opt}(i)}{\max(f_{opt}) - \min(f_{opt})} \qquad (2)$$

The Explorers branch begins calculating $F_{rep}(i)$ as a function of the distance between molecules. Calculation of $\Delta G(i)$ is carried out using (2). Then, the Metropolis acceptance criterion is evaluated in order to reject or accept the new position $x_{new}(i)$. If the Metropolis criterion is satisfied, the new position will be accepted and updated. Furthermore, if the new position is not only feasible but also has an optimal value lower than the objective function value for the worst refiner (that with the higher f_{opt}), it would be set as refiner, in addition, the worst refiner would be set as explorer, if and only if, the minimum number of explorers (*minNexp*) has been already reached. Finally, the stopping criteria are checked, and the algorithm stops if any of them has been met.

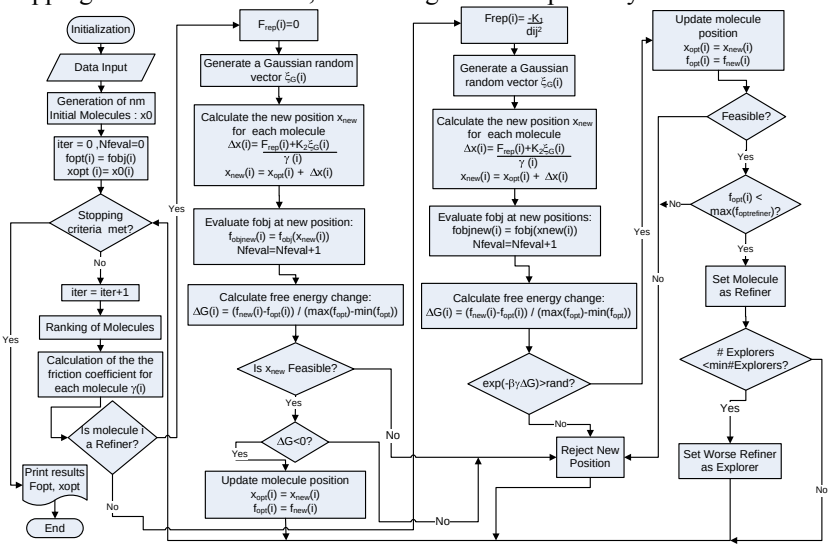

Figure 2 Molecular-Inspired Parallel Tempering (MIPT) Algorithm for Global Optimization.

3. Examples

In this section, the capability and efficiency of the MIPT algorithm for solving different GO problems is tested using four case studies. MIPT results were obtained using a PC with 1.66GHz Intel Core 2 Duo processor and 1 GB RAM.

3.1. Extended Dixon-Szegö Set

The first example is a set of 14 standard continuous GO test problems taken from the Dixon-Szegö collection. This set of functions was chosen because it is diverse enough to cover many kinds of difficulties that arise in global optimization (Hedar and

Fukushima, 2006). A description of the 14 test problems including the already known global minima values can be found elsewhere (Hedar and Fukushima, 2003). Figure 3 shows a comparison between the results obtained using MIPT, the new version of the GLOBAL method (Csendes et al., 2008) and the Continuous Grasp (C-GRASP) method (Hirsch et al., 2007). In this work, each test problem was run 100 times using MIPT (the stopping criterion was the same as the reported in Hirsch et al. (2007)), achieving 100% of success ratio. Second column in Figure 3 shows the number of decision variables for each problem. The first column of each method shows the average number of function evaluations (*Nfeval*) while the second reports the *CPU time*. It is important to notice that the comparison should be made in terms of *Nfeval*, because the three methods were run in different computers and large differences might be observed. MIPT has shown a better performance in solving the Branin, Easom, Rosenbrock-2, Shubert, Hartman-3 and Rosenbrock-5 problems, whereas the GLOBAL achieved better performance for the remaining problems except for the Zakharov-5 and the Goldstein-Price. It is remarkable that the MIPT method lies within the range of average values of the other methods, showing to be competitive in solving problems with several local minima.

Test Function	ndv	MIPT		GLOBAL		C-GRASP

$$V_{in} - V_{HK} = 0 \;;\; V_{HK} - V_{PFK} - V_{Pol} = 0$$

$$V_{PFK} - V_{GAPD} - 0.5V_{Gol} = 0;\; 2V_{GAPD} - V_{PK} = 0$$

$$2V_{GAPD} + V_{PK} - V_{HK} - V_{Pol} - V_{PFK} - V_{ATPase} = 0$$

$$V_{PK} \le 2V_{in};\; Y_{k0} \le Y_k \le Y_{k0};\quad k = 1,2,3,4,5,8$$

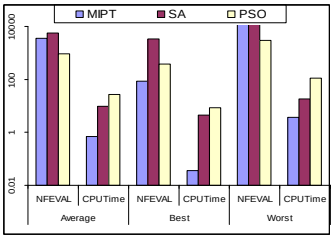

Figure 4 Case Study 2: Optimization Problem (left), Results for MIPT, SA and PSO (right).

3.2. Nonlinear Constrained Optimization Problem

The second case study is an example of the steady state optimization problem of biochemical reaction networks, which addresses the maximization of the flux of Piruvate Kinase (V_{PK}), enzyme directly responsible for ethanol production in the *Saccharomyces cerevisiae* pathway (Xu et al., 2008). This case study (Figure 4-left) consists on a nonlinear constrained optimization problem, where f represents the nonlinear steady-state model of the process, X_i the metabolites concentrations, Y_k the enzymes activities, and X_{i0} and Y_{i0} are the basal steady-state values (corresponding to an objective function value V_{Pk0}=30.1124). Xu solved the problem applying a standard iterative IOM and a modified iterative IOM approaches, finding an objective function value V_{PK}=64.828V_{PK0} and V_{PK}=64.829V_{PK0}, respectively. The same problem was solved in this work using MIPT, Simulated Annealing (SA) and Particle Swarm Optimization

(PSO). These three methods reached the same objective function value, V_{PK}= 65.022 V_{PK0}, better than that obtained by the IOM approaches. A comparison on the performance for MIPT, SA and PSO in terms of number of function evaluations (*Nfeval*) and *CPU* time for the average, best and worst cases from 100 different runs randomly initialized, is presented in Figure 4-right. Values for the IOM approaches are not reported in the original work. As can be seen, MIPT has the best performance in terms of CPU time, whereas the number of function evaluations required for reaching the global optimum lies between those needed by SA and PSO.

3.3. Mixed Integer Nonlinear Problem MINLP

The optimization problem addressed here (Figure 5-left) consists on a MINLP involving 7 decision variables. A recent work by Yiqing et al., (2007) reports results for this case study, comparing Genetic Algorithms (GA), a Simulated Annealing based algorithm (M-SIMPSA), the original PSO algorithm, and an improved PSO algorithm denoted as R-PSO. Furthermore, R-PSO algorithm was used in two variants: R-PSO_unc which updates continuous and discrete variables simultaneously, and the other, denoted as R-PSO_c that makes the mixed variables updating at difference pace. Figure 5-right shows the comparison between the mentioned stochastic algorithms and MIPT, in terms of the average number of function evaluations (*Nfeval*) and the success ratio (*NRC*), which is the percentage of runs that converged to the global optimum (f_{opt}=4.579582), in 100 executions. As shown in Figure 5, MIPT algorithm not only has reached the global optimum for all runs (NRC=100%), but also has required the less number of function evaluations, showing its capacity for dealing with MINLP problems.

$$\begin{aligned}
&\min f(x_1,x_2,x_3,y_1,y_2,y_3,y_4)\\
&\quad=(y_1-1)^2+(y_2-2)^2+(y_3-1)^2-\ln(y_4+1)\\
&\quad+(x_1-1)^2+(x_2-2)^2+(x_3-3)^2\\
&\text{s.to: } y_1+y_2+y_3+x_1+x_2+x_3\le 5\\
&\quad y_3^2+x_1^2+x_2^2+x_3^2\le 5.5\\
&\quad y_1+x_1\le 1.2;\ y_2+x_2\le 1.8\\
&\quad y_3+x_3\le 2.5;\ y_4+x_1\le 1.2\\
&\quad y_2^2+x_2^2\le 1.64;\ y_3^2+x_3^2\le 4.25\\
&\quad y_2^2+x_3^2\le 4.64;\ x\le 0;\ y\in\{0,1\}^4
\end{aligned}$$

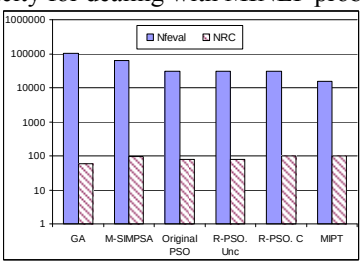

Figure 5 Case Study 3: Optimization Problem (left) and Stochastic Methods Comparison (right).

3.4. Optimization Problem in a Large Scale System

This case study consists on a two-distillation-column system for purification of a beer stream in an ethanol production process. The model consists on a total of 2411 equations, involving 241 state variables. Five control loops for controlling the pressure in both columns, and the level in the reboilers and in the partial condenser of the rectification column were included. The initial conditions for the model are the steady state values. In case of disturbance, the heat duty of both reboilers (Q_{R1} and Q_{R2}) and the heat duty of the partial condenser (Q_{C2}) can be used to optimize the economic operation of the process. The cost function (F_{opt}) to be minimized is given by equation (3), where Δt_{opt} is the optimization horizon, F_{EB1}, F_{EB2} are the ethanol flow rate in the bottoms of each column, F_{WD2} is the water flow rate in the distillate of the second column. The factors that multiply each term of (3) are penalization terms related to the ethanol price (for the three first weights), the cost of steam to the reboilers and the cost of cooling water in the partial condenser. *f* represents the nonlinear dynamic model of the process, u_{min} and u_{max} are the upper and lower bounds for the decision variables in (3) and x_{ED2} is the mass fraction of ethanol in the distillate of the second column (desired product). In order to compare the performance of different optimization algorithms in optimizing the

economic operation of this large scale system, a step disturbance corresponding to a 25% increase of the feed to the system was done. An optimization horizon of two hours was considered. The maximum number of function evaluations used as stopping criteria was 200. The results obtained using MIPT, SA, PSO and a Gradient based method (GRAD) are summarized in Figure 6-left, where the average, best and worst values from 5 randomly initialized runs for each method are compared. It can be seen that MIPT algorithm has reached the same average and best optimal values than SA and PSO, but requiring less CPU Time. In contrast, the GRAD method had the worse performance for the average and worst cases. Additionally, Figure 6-right compares the behaviour of the ethanol losses (taking as the sum of F_{EB1} and F_{EB2}), x_{ED2}, F_{opt} (instantaneous values shown), for the process with optimization (denoted as after optimization, only MIPT results are shown), and without (i.e. Q_{R1}, Q_{R2} and Q_{C2} were kept at their steady state values after the disturbance). MIPT has shown to be an efficient algorithm that can be also applied in optimization of large scale systems.

$$\min_{Q_{R_1},Q_{R_2},Q_C} \left(\int_{t_{opt}}^{t_{opt}+\Delta t_{opt}} 0.63\left(F_{EB_1}+F_{EB_2}\right)+0.63\,F_{WD_2}+6.33\left(Q_{R_1}+Q_{R_2}\right)+0.31Q_C \right) \tag{3}$$

$$\text{s.to. } f(\dot{x},x,u,d,t)=0;\ x_i(t_0)=x_{0i};\ u_{min}\le u\le u_{max};\ x_{ED_2}\ge 0.9$$

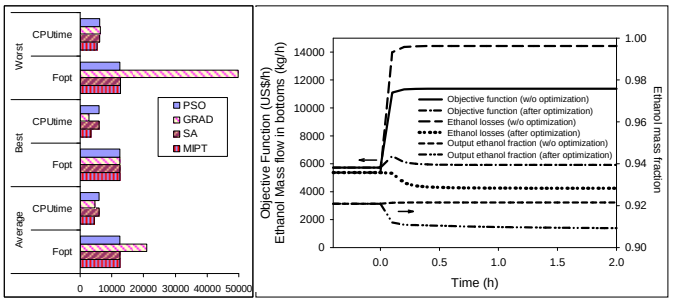

Figure 6 Case Study 4: Comparative Results for MIPT, SA, GRAD and PSO (left) and Comparison with vs. without optimization (right).

4. Conclusions

A new stochastic algorithm for Global Optimization, denoted as Molecular-Inspired Parallel Tempering (MIPT) has been proposed. Through four challenging case studies, MIPT performance was compared to well-established optimization algorithms, reaching a better performance in most of the cases. It was shown that MIPT was able to reach the global optima for a wide range of problems, including constrained NLP, MINLP and highly multimodal functions; with a high success rate and a reasonable number of function evaluations, showing to be suitable for solving global optimization problems.

Molecular-scale modeling of the degradation of phenol in Advanced Oxidation Processes reaction media

Bruno Ramos, Antonio Carlos S. C. Teixeira

LSCP/CESQ - Department of Chemical Engineering, Escola Politécnica da Universidade de São Paulo. Av. Prof. Luciano Gualberto, n. 380, trav. 3, CEP 05508-900, São Paulo - SP, Brazil.

Abstract

Modeling, in its diverse length and time scales, has been pointed as one of the most remarkable features responsible for the advances in Chemical Engineering science. The smallest physically relevant scale modeling deals with frozen individual molecules; an approach known as *quantum modeling* (QM): length scales of the order of Angstrons (10^{-10} m) and no time effects taken into account. Modeling in this scale is useful to obtain a large amount of data on properties which can be further applied into other modeling approaches or serve as parameters to process design and optimization. In this work, Density Functional and Semiempirical methods were used to study the degradation of phenol promoted by hydroxyl radicals, as those generated in Advanced Oxidation Processes media. The results are discussed and compared with experimental data collected by the group. A method is presented for modeling ChE interesting reactions and obtaining kinetic constant values.

Keywords: molecular modeling, phenol, AOP, kinetic

1. Introduction

One of the major tasks of a chemical engineer is to make the bridge between molecules and a desired product with specific function and structure. In fact, the change in the focus – from the process to the product – is a clear illustration of this fact. The future of Chemical Engineering, among all the driving forces that push industry through the 21st century (i.e. market demands, efficient consumption of resources, minimization of environmental impact, better use of research and human resources etc.), lies within a multidisciplinary and multiscale approach – or 3PE approach (triplet molecular processus – product – process), as labeled by J. C. Charpentier (Charpentier, 2007). According to that author, one of the major goals of Chemical Engineering, in this globalization and sustainability scenery, is the implementation of multiscale simulation and computational modeling applications to real world situations, from molecular to production scale. In order to accomplish this, some tools, divided in three fields, are fundamental: molecular modeling, scientific instrumentation and non-invasive measurement techniques, and powerful computational tools. It is only through simultaneous advances in these fields that it will be possible to understand and describe the relationships between events in nano- and micro-scale.

2. Methods

2.1. Energy evaluation

The energies were evaluated by using two different approaches: the Density Functional Theory (DFT) and the semiempirical model AM1. All calculations were carried out in Gaussian 03 (Frisch *et al.*, 2003).

Density Functional Theory (DFT)

The Density Functional Theory embraces a series of electronic structure methods that use the electron density as basic variable, and their origin trace back to the Thomas-Fermi model, in 1927 (Cramer, 2004). Basically, DFT aspires to predict *exactly* properties of many-electron systems without recourse to the wave function, using only (explicitly or implicitly) in the ground-state electron density. In this work, the functional chosen was the hybrid combination known by the acronym B3LYP (Scuseria & Staroverov, 2005):

$$E_{XC}^{B3LYP} = (1-a)E_X^{LSDA} + aE_{XC}^{\lambda=0} + bE_X^B + cE_C^{LYP} + (1-c)E_C^{LSDA}$$

This functional is a combination of the LSDA (local spin density approximation) exchange functional, the non-interactive exchange-correlation functional, the Becke exchange functional, the Lee-Yang-Parr correlation functional and the LSDA correlation functional; scaled by three empirically determined constants *a*, *b* and *c*. The explicit form of most of these functionals involves integrals whose arguments are electron densities or electron density gradients, and therefore an iterative procedure is necessary to evaluate the electron density and, consequently, the energy.

Semiempirical (AM1)

The semiempirical methods start out from the *ab initio* formalism and then introduce rather drastic assumptions to speed up the calculations, typically by neglecting many of the less important terms in the *ab initio* equations. In order to compensate for the errors caused by these approximations, empirical parameters are incorporated into the formalism and calibrated against reliable experimental or theoretical reference data. The most popular semiempirical methods are based on the MNDO model (modified neglect of diatomic overlap). The Austin Model 1 (AM1) was developed as an improvement of the basic MNDO architecture, in order to account for a correct evaluation of hydrogen bonding energies (Thiel, 2005) and, since the modeled system is rich in hydrogen bonds, this was the chosen semiempirical method for energy evaluation.

2.2. Geometry Optimization

The geometries modeled were optimized using the Eigenvector Following (EF) algorithm. The EF procedure is essentially based upon the widely known Newton-Raphson method (Cramer, 2004).

2.3 Frequency Calculation

In order to evaluate the thermodynamical properties of the chemical systems, the numerical values of the vibrational frequencies are necessary. They are also useful as an indication of the nature of a transitional state. The molecular frequencies depend upon the second derivative of the energy with respect to the nuclear positions (i.e. the Hessian matrix). A description on the followed procedure can be found at Ochsterski (1999).

2.4. Aqueous solution modeling

Polarized Continuum Model (PCM)
The Polarized Continuum Model is one of the Self-Consistent Reaction Field (SCRF) methods, which are – in essence – adaptations of the Poisson method for *ab initio* calculations. Basically, it simulates the presence of the system into a continuum of constant dielectric (Cramer, 2004). The chosen model, known by the acronym SCI-PCM (self-consistent isodensity PCM) simulates the molecule inside an isosurface of electron density (s.a. the surfaces constructed using Van der Waals atomic radii), and uses a numerical evaluation of the electrostatic potential. This potential enters the Hamiltonian for the system and, thus, returns the solvation energy.

Explicit solvation models
Instead of working with potentials, it is common to construct a structure with some of the solvation molecules around the system under scoop. These structures are known as supramolecules, and often offer a better accounting of the effects of hydrogen bonds.

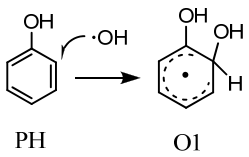
2.5. Thermodynamical and kinetic properties evaluation

In Statistical Mechanics there is a function with an equivalent status of the wave function in Quantum Mechanics. That is, a function that characterizes the system. It is called *partition function*, and it is used as an input to calculate the thermodynamical properties, i.e., enthalpy, Gibbs free energy, chemical potential etc.

The kinetic constant is evaluated according to the Transition State Theory (Ochterski, 2001).

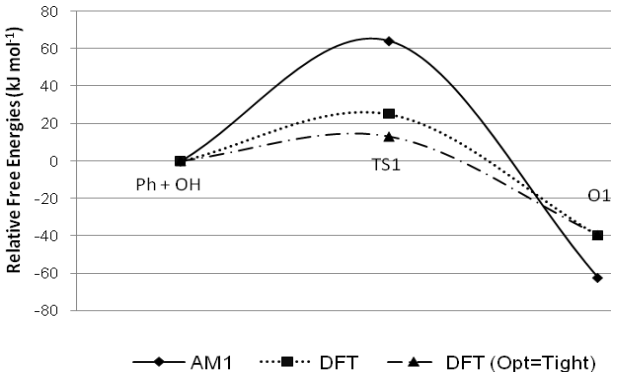
3. Results and Discussion

3.1. Reaction
The reaction was modeled as follows, using the software *Gaussian 03* for calculating and the software *GaussView 3* to generate the inputs and visualize the outputs.



PH O1

3.2. Free energy profile as a function of the theory employed
A thermodynamical evaluation at the optimized geometries of reactants (Ph + OH), product (O1) and transition state (TS1) retrieved the profile shown below. As can be seen by the relative energies, the semiempirical method has shown a larger activation free energy (defined as the difference between TS and reactant free energies) and predicted a larger exoergic behavior than the DFT functional. The transition state was also optimized by using a tighter convergence criteria. The activation free energy was found to be smaller than the one found with the standard set of convergence thresholds. By comparison with the experimental work conducted by Bonin *et al.* (2007), which found an activation free energy of ca. 16 kJ mol^{-1}, the DFT optimization with tighter criteria was found to describe better the system modeled.



3.3. Aqueous environment modeling

The aqueous environment was simulated by three different techniques: *i)* the PCM implicit model; *ii)* the supramolecular explicit model; and *iii)* by Molecular Dynamics and Monte Carlo techniques. The results suggest that the implicit solvation model is inadequate to simulate the behavior of the system in aqueous solution, possibly by not accounting correctly for the hydrogen interactions. Table 1 resumes the results.

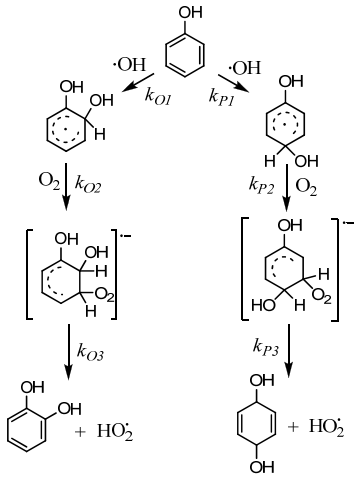
Table 1 – Solvation energies according to different solvation models.

	Total energy variation due to solvation (Hartree/particle)						
	ΔU_{solv} (PCM)	ΔU_{solv} (3W)	ΔU_{solv} (4W)	ΔU_{solv} (3W2)	ΔU_{solv} (4W2)	ΔU_{solv} (MD)	ΔU_{solv} (MC)
Phenol	-0,0301	-11,4007	-16,1264	-	-	-96,8851	-1,310
O1	0,0915	-12,0882	-	-24,1740	-32,2284	-	-

The results show a clear distinction between PCM and explicit models. Particularly for the radical O1, the PCM model predicts a lower stability in aqueous phase than in gas phase. This is an intuitively and physically erroneous conclusion. The solvation molecules stabilize the charge imbalance of the solute molecules and, therefore, improve the stabilization of the system.

3.4. Kinetic constants and comparison to experiment

The kinetic constants were evaluated for the whole mechanism of reactions leading to the formation of catechol and hydroquininone from phenol, as shown below:



For this sequence of reactions, the set of kinetic constants is shown in Table 2, and Figure 1 illustrates a simulation of these mechanisms plotted against experimental data, for a batch reaction of a media initially containing 12 mmol L^{-1} phenol and constant [·OH] and [O_2] concentrations, as taken from experiment.

Table 2 – Kinetic constants calculated and experimental values (when available)

	Kinetic constant (M^{-1} s^{-1} ou s^{-1})	
	Calculated	Experimental
k_{O1}	$3{,}33 \times 10^{10}$	$9{,}0 \times 10^{8}$ Edalatmanesh, 2008 $2{,}0 \times 10^{10}$ Friedrich, 2007
k_{O2}	$1{,}79 \times 10^{36}$	-
k_{O3}	$1{,}97 \times 10^{10}$	-
k_{P1}	$7{,}47 \times 10^{08}$	$2{,}0 \times 10^{8}$ Edalatmanesh, 2008 $6{,}0 \times 10^{9}$ Friedrich, 2007
k_{P2}	$8{,}56 \times 10^{33}$	-
k_{P3}	$4{,}17 \times 10^{10}$	-

All the kinetic constants were evaluated using DFT thermodynamical results, as was seen that DFT shows a better correlation to reality than AM1. The analysis of Figure 1 leads to the observation that phenol and cathecol general behaviour are in good agreement with experimental data: both theoretical and experimental profiles predict the complete decay of the pollutant at 500 seconds, and a maximum peak of cathecol of 4 mmol L^{-1}. The kinetic constant values found were within the margins of experimental data collected, as can be seen from Table 2.

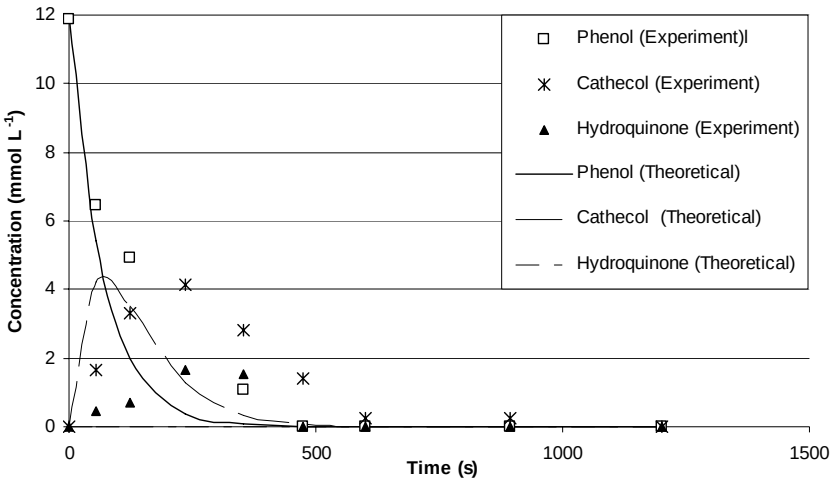


Figure 1 – Concentration profile simulation applying calculated kinetic constants in comparison to experimental data.

3. 4. Conclusion

From the results found in this work, it can be suggested that:

i) DFT plays a better role than AM1, in describing the mechanics of AOP reaction media;

ii) Implicit solvation models, such as SCI-PCM are inadequate to describe the solvation processes in the studied systems: an explicit solvation sphere is fundamental for the correct accounting of the highly stabilizing hydrogen interactions;

iii) DFT kinetic constants are in good agreement with experimental values obtained and can be used to simulate concentration profiles and provide qualitative insights on the behavior of the reactions.

A NOVEL APPROACH FOR THE PREDICTION OF PSD IN ANTISOLVENT MEDIATED CRYSTALLIZATION

Massimiliano Grosso [a], Omar Galan [b], Roberto Baratti [a], Josè A. Romagnoli [a*]

[a] *Dipartimento di Ingegneria Chimica e Materiali, Università degli Studi di Cagliari, Piazza d'Armi, I-09123, Cagliari, Italy*

Abstract

A phenomenological model for the description of antisolvent mediated crystal growth processes is here presented. The crystal size growth dynamics is supposed to be driven by a deterministic growth factor coupled to a stochastic component. The evolution in time of the particle size distribution is then described in terms of a Fokker-Planck equation. Validations against experimental data are presented for the NaCl-water-ethanol anti-solvent crystallization system.

Keywords: Antisolvent crystallization, Particle size distribution estimation, Fokker-Planck equation.

1. Introduction

Antisolvent aided crystallization is an advantageous technique of separation where the solute is highly soluble or heat sensitive. The driving force in crystal formation is the super-saturation that establishes the thermodynamic equilibrium for the solid-liquid separation. The development of rigorous mathematical models describing the dynamic of crystal growth in crystallization processes is based-on population balances. At the core of the structured population dynamics, the number of crystals in a fed-batch crystallizer is increased by nucleation and decreased by dissolution or breakage. Structured population balances models provide detailed information regarding the crystal size distribution in the crystallization unit. However, they demand a great deal of knowledge on the complex thermodynamic associated with the solute and solvent properties to be adequately incorporated in the population balances. Some important contributions in this subject have been reported in the literature (Worlitschek and Mazzotti, 2004; Nowee et al., 2008).

An alternative approach to deal with particulate systems characterized by MCS and CSD is the Fokker-Planck Equation (FPE). The FPE is just an equation of motion for the distribution function of fluctuating macroscopic variables. The study of stochastic system as the Brownian motion resulted in the Fokker-Planck Equation (Risken, 1984).

In this work we propose a phenomenological model for the description of the crystal growth process, which is based on a novel stochastic approach for the prediction of MCS and CSD in a bench-scale fed-batch crystallization unit where anti-solvent is added to speed-up the crystal formation process. The crystal growth is modeled as a stochastic process ruled by a by a classic logistic equation of common use in theoretical ecology (Grosso et al., 2007) coupled with a geometric Brownian motion. The resulting

model is a continuity equation (Fokker-Planck Equation, FPE) for the probability density of the crystal size. A comparison with experimental data will be presented for validation of the FPE approach for the NaCl-water-ethanol anti-solvent crystallization system

2. Mathematical Model

The crystals are classified by their size, L and the growth of each individual crystal is assumed to be independent by the other crystals and governed by the same deterministic model. In the proposed model, fluctuations and unknown dynamics not captured by the deterministic term are modeled as a random component that has an additive action on the growth dynamics (Gelb, 1988). This random component can be thought as a Geometric Brownian Motion, GBM, (Ross, 2003) where the intensity of the fluctuations depends linearly by the crystal size. The stochastic model can thus be written as a Langevin equation of the following type:

$$\frac{dL}{dt} = \nu(L,t;\theta)L + L\eta(t) \qquad 1$$

In Equation 1, $\nu(L,t;\boldsymbol{\theta})$ is the expected rate of growth (the deterministic model introduced below), L is the size of the single crystal, t is the time, $\boldsymbol{\theta}$ is the vector parameter defined in the model, and $\eta(t)$ is a random term assumed as Gaussian additive white noise i.e., $E[\eta(t)]=0$ and $E[\eta(t)\,\eta(t+\tau)]=2D\delta(\tau)$, where D is the additive noise intensity. Equation 1 implies that the crystal size L behaves as a random variable, characterized by a certain probability density function (PDF) $\psi(L,t)$ depending on the state variables of the system, i.e. the size L and time t. From an applicative point of view, the PDF coincides with the Particle Size Distribution (PSD) that can be experimentally observed.

It should also be noted that, when the GBM assumption holds, the PDF is a lognormal distribution, at least in the limit case of constant ν value (Ross, 2003). If ν depends also on L, some distortions from the ideal lognormal case can be however expected. This feature is qualitatively observed for many (although not all) crystalline substances (Eberl et al, 1990) and in the present case.

The Langevin Equation 1 can be further manipulated as follow:

$$\frac{1}{L}\frac{dL}{dt} = \nu(L,t;\theta) + \eta(t) = \frac{dy}{dt} = \mu(y,t;\theta) + \eta(t) \qquad 2$$

The new random variable, y, can be thus described in terms of its probability density distribution, $\psi(y,t)$, at any instant of time t and should follow the Fokker-Planck Equation, FPE (Risken, 1996):

$$\frac{\partial\psi(y,t)}{\partial t} = -\frac{\partial}{\partial y}\left(\nu(y,t;\theta)\psi(y,t)\right) + D\frac{\partial^2\psi(y,t)}{\partial y^2} \qquad 3$$

In equation 3, the "pseudo-diffusion" coefficient D takes into account the fluctuations intensity in the particle growth process (Matsoukas and Lin, 2006). As it regards the deterministic part of the model, a Logistic growth process is assumed (c.f., Tsoularis and Wallace, 2002).

$$v(y,t;\theta)=ry[1-\left(\frac{y}{K}\right)] \quad 4$$

This choice is mainly motivated to the requirement for a simple model with a parsimonious number of adjustable parameters, i.e. the growth rate, *r*, and the asymptotic equilibrium value *K*. The present growth model can be regarded as the simplest model taking into account mild nonlinearities. In spite of its simplicity, this model provides the main qualitative features of a typical growth process: the growth follows a linear law at low crystal size values and saturates at a higher equilibrium value. Using the selected growth model, the FPE can be written as:

$$\frac{\partial \psi}{\partial t}=-\frac{\partial}{\partial y}\left(ry\left(1-\frac{y}{K}\right)\psi\right)+D\frac{\partial^2\psi}{\partial y^2} \quad 5.$$

along with the boundary conditions (Risken, 1996):

$$-v(y)\psi(y,t)+D\frac{\partial\psi(y,t)}{\partial y}=0 \qquad \text{at } y=0,\forall t$$
$$\frac{\partial\psi(y,t)}{\partial y}=0 \qquad \text{as} y\to\infty \quad \forall t \quad 6$$

Finally the evolution in time of the probability density is described in terms of a linear, partial differential equation depending on the parameters *r* (linear growth rate), *K* (crystal size asymptotic value) and *D* (diffusivity). Such parameters are considered constant for each experimental condition but they can change with the anti-solvent flow rate. Indeed, antisolvent crystallization kinetics is affected by the antisolvent feed rate and, the parameters appearing in the model should be related to this operating condition. The numerical integration of Equation 5 was accomplished by exploiting the routine DASPG, from IMSL, in order to solve the resulting implicit system of algebraic ordinary differential equations obtained by means of collocation on finite elements.

3. Experiments

The experimental data used in the present work are those reported in Nowee et al. (2008). They refer to an aqueous solution of Sodium Chloride (NaCl) where Ethanol was added at different constant feed rates. Four experiments were selected under three constant antisolvent feeding profiles – one experiment at a feed rate of 0.83 $ml \cdot min^{-1}$, (low feed rates, hereafter we refer to this experiment as run A), two at a medium rate of 1.64 $ml \cdot min^{-1}$ (run B) and one at a higher rate of 3.2 $ml \cdot min^{-1}$ (run C). The first acquisition time, t_0, for each run will be the initial condition used for the FP model calibration. The PSD was measured at different time instants using Mastersizer 2000 particle size analyzer.

Model calibration for the estimation of parameters in the model is carried out separately for every run. The parameters to be estimated are: $\boldsymbol{\theta} = [\log(D), r, K]$ ($\log(D)$ is used instead of *D* in order to reduce the statistic correlation between the parameters). It should be noted that direct measurements of the Particle Size Distribution are available at *N* different spatial locations and at *M* different time values for every operating condition, i.e. anti-solvent flow rate. Parameter inference is accomplished by using the least square criterion, thus searching the minimum of the objective function:

$$\Phi(\boldsymbol{\theta}) = \Phi(r, K, D) = \sum_{j=1}^{M}\sum_{k=1}^{N}\left(\psi_{\mathrm{mod}}\left(y_k, t_j; \boldsymbol{\theta}\right) - \psi_{\exp}\left(y_k, t_j\right)\right)^2 \qquad 7$$

In Equation 7, $\psi_{mod}(y_k,t_j)$ is the probability density function evaluated through numerical integration of Equation 5, at time t_j and size coordinate y_k, while the distribution $\psi_{exp}(y_k,t_j)$ is the experimental observation of the PSD for the size coordinate y_k at time t_i. The model calibration is thus carried out by comparing N point observations of the distribution (N ~ 40), monitored at M different times (M between 6 and 10, depending on the experimental run). The minimum search is carried out by the Levenberg-Marquardt method. As it regards the supplementary run at intermediate feeding rate, this was used for an a-posteriori model validation.

4. Results

Figure 1 reports the point estimations of the adjustable parameters of the model *vs* the corresponding feed rate. The error bar for the 95% confidence interval is also shown. Point and confidence estimations are carried out with traditional inference methods (e.g. Bates and Watt, 1987). It should be noted that the uncertainty in the estimation is rather small and the parameters significantly change with V_0, especially at the highest feed rate

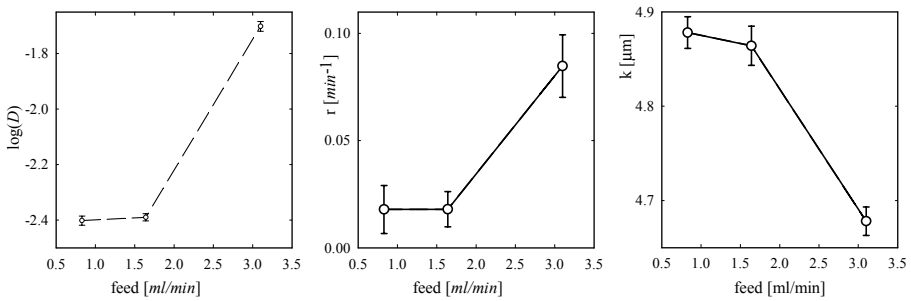

Figure 1: Parameter estimation together with the 95% confidence interval *vs* V_0.

Figure 2 reports the comparison of the PSD experimentally observed and the model prediction for the experiment at low feed rates, at the first and final acquisition time. Similar results are found at the higher feed rates, It is evident that there is a quantitative agreement between experiments and phenomenological model. In particular, the model is able to correctly capture the log-normal shape of the experimental PSD.

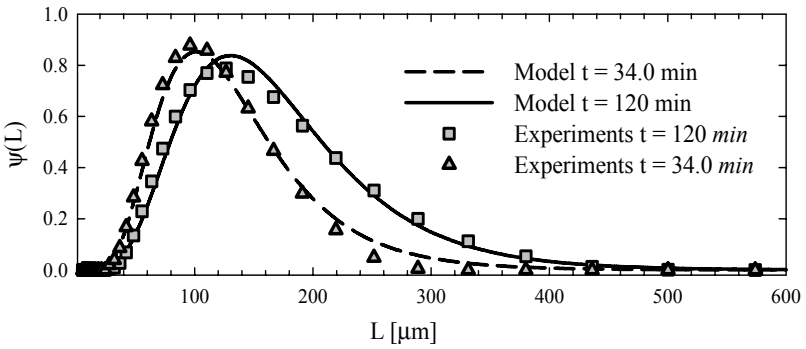

Figure 2: Comparison between model and the experimental probability density functions for the feeding rate V_0 = 0.82 ml/min: triangles are the experimental observations at t= 34 min, dashed line is the corresponding model prediction; square points are the experimental observations at t= 240 min, solid line is the corresponding model prediction.

Comparison between model and experiments is also carried out by reporting the time evolution of the experimental observations and the corresponding model prediction for first moments of the distribution, i.e., the mean, μ and the variance σ^2:

$$\mu(t) = \int_{\Omega} L\,\psi(L,t)dL \qquad o^2(t) = \int_{\Omega} [L-\mu(t)]^2\,\psi(L,t)dL \qquad 8$$

Figures 3 and 4 show, respectively, the mean and variance experimentally observed (square points) compared with the theoretical predictions (solid line) for the three runs as a function of time. The agreement is rather good at each time and the FPE model, driven by its deterministic part (the logistic growth term), correctly describes the increasing trend of the average crystal growth. In Figure 3b and 4b we also report experimental data provided by the second experimental run (cross points), (not used for the parameter inference), demonstrating that the model has also good predictive capabilities

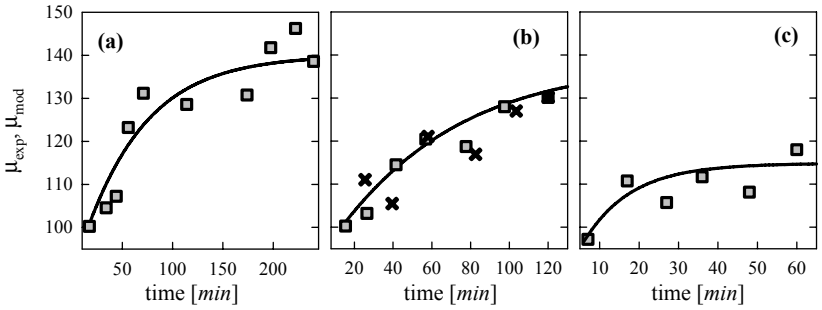

Figure 3: Mean of the Crystal Size Distributions for the three feeding rates Square points are the experimental observation, solid lines are the model predictions

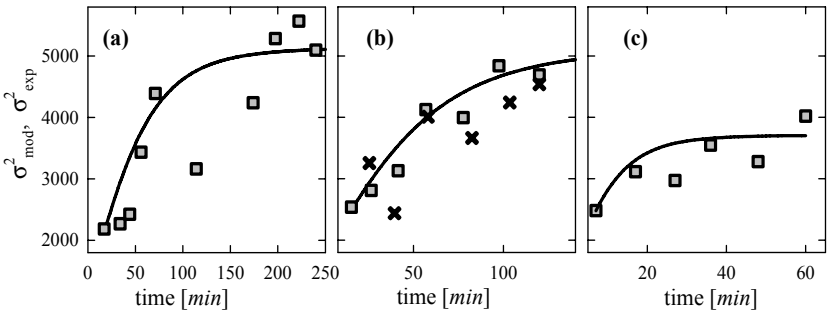

Figure 4: Variance of the Crystal Size Distributions for the three feeding rates Square points are the experimental observation, solid lines are the model predictions

5. Conclusions

A stochastic phenomenological model for the description of antisolvent crystal growth processes is here proposed. The crystal size is considered as a random variable, whose probability density evolution in time is described in terms of a Fokker-Planck equation. The model is tested on data provided in a bench-scale fed-batch crystallization unit where anti-solvent is added to speed-up the crystal formation process. The FPE formulation appears as a powerful predictive tool, as confirmed by the excellent agreement with the experiments..

Heterogeneous anaerobic biofilm reactor models Application to UASB, EGSB and AFB reactors

Mauren Fuentes, Pío A. Aguirre and Nicolás J. Scenna

INGAR Instituto de Desarrollo y Diseño (CONICET-UTN)-Avellaneda 3657 (3000) Santa Fe, Argentina

Abstract

In a previous work, a methodology developed for modeling anaerobic fluidized bed (AFB) reactors was presented. The aim of this work is to extend this methodology for modeling upflow anaerobic sludge blanket (UASB) and expanded granular sludge bed (EGSB) reactors, and compare and discuss model hypotheses and simulation results. A set of experimental data obtained by Kato et al. (2003), during the start-up of a bioreactor operating as UASB and EGSB reactor configurations, is used for model validation. A good agreement was obtained among experimental and predicted values. A simulation-based sensitivity analysis of model parameters such as the specific rate of granule rupture and the axial dispersion coefficient is performed. A decrease in the granule diameter is predicted for values of the specific rate of granule rupture higher than 1×10^{-7} m s^2 kg^{-1}. At low values of the axial dispersion coefficient, a decrease in the bioreactor efficiency is predicted. Simulation results are more sensitive when the bioreactor operates with a UASB configuration.

Keywords: dynamic modeling and simulation, anaerobic biofilm reactors: UASB, EGSB and AFB, three-phase (solid-liquid-gas) systems.

1. Introduction

Anaerobic reactors based on biofilm development such as UASB, EGSB and AFB reactors have become popular high-rate wastewater treatment systems. The anaerobic digestion is a multi-step process consisting of hydrolysis of complex organic substrates such as proteins, lipids, and carbohydrates into soluble amino acids, fatty acids, and sugars followed by the fermentation to acetate, formate, hydrogen, and carbon dioxide, which are finally utilized by methanogenic microorganisms to form methane. There are clear differences between UASB and AFB reactors, e.g. the former is based on the ability of microorganisms to form dense aggregates by autoimmobilization, and operates at a lower fluid superficial velocity than the second one, which is loaded with inert support particles for biofilm attachment. The conception of the EGSB reactor can be considered as an improvement of the UASB reactor. Inside the EGSB reactor, the higher upflow velocities, which are caused by a high recycle rate and a high height/diameter ratio, cause the sludge expansion through the whole reactor thus improving its contact with the effluent and reduce the unit dead volume.

A better understanding of the microbial and hydraulic mechanisms that regulate the system has contributed to the development of more compact and efficient units. The heterogeneous sludge distribution in UASB reactors does not make easy the application of most mathematical models developed for completely mixed anaerobic digestion systems, since these models assume homogeneous biomass distribution and hydrodynamic pattern within the reactor. The UASB reactor has being modeled as a

sum of compartments that are assumed to have ideal (mixing or plug) flow patterns, and the non-idealities of flow are described through the linkage among these compartments by bypassing and back mixing flows (Pontes and Pinto, 2006), and as a compartment using a one-dimensional dispersed plug flow model (Kalyuzhnyi et al., 2006). The adoption of some ideas from solid dynamics in a three-phase fluidized bed reactor can be used to describe the multiple solid-liquid-gas interactions that take place in UASB and EGSB reactors. In a previous work, a heterogeneous model for three-phase fluidized bed systems was developed (Fuentes et al., 2008a, 2009) and validated (Fuentes et al., 2007, 2008b). The aim of this work is to extend this methodology for modeling UASB and EGSB reactors. Some hypotheses related to the bioparticle model and hydrodynamics are discussed. Due to space restrictions, only one example is presented. It is based on the experimental results obtained by Kato et al. (2003) operating a bioreactor with UASB and EGSB configurations. A simulation-based sensitivity analysis of model parameters such as the specific rate of granule rupture and the axial dispersion coefficient is performed. A complete explanation (hypotheses and equations) of the model and other application examples could be presented in an extended version of the paper.

2. Mathematical Model

The methodology here used is based on three major modeling tasks: (1) the anaerobic digestion model, (2) the bioparticle model, and finally (3) the hydrodynamics model.
UASB and EGSB reactors are modeled as three-phase gas-solid-liquid systems. The solid phase consists of bioparticles (granules) composed by active and non-active biomass. The liquid phase is composed by the chemical species in solution (substrates, products, enzymes, ions, and water) and (active and non-active) suspended biomass, which are assumed to be as solutes. The gas phase is formed by the gaseous products from degradation stages. The global model structure is represented in Fig. 1.

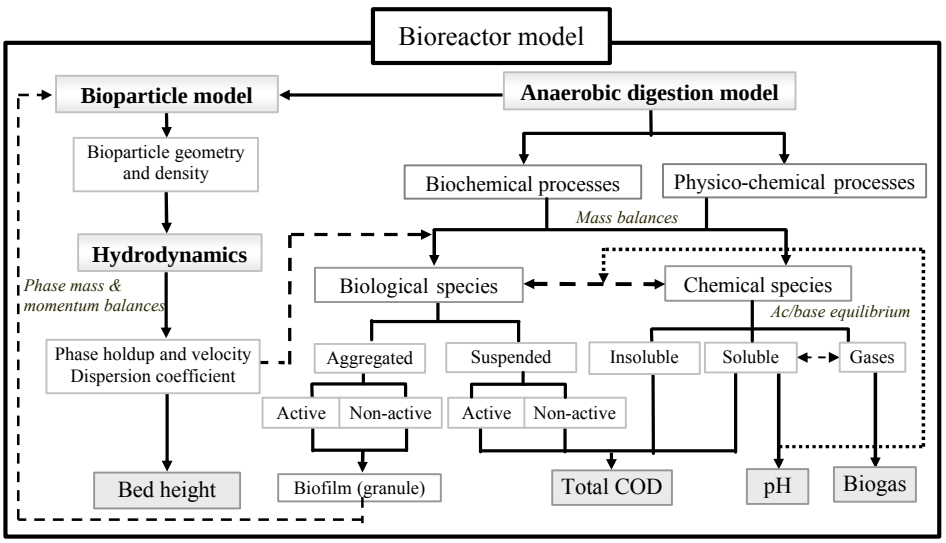

Fig. 1. Bioreactor (UASB and EGSB) model structure (modified from Fuentes et al., 2009).

A heterogeneous one dimensional (axial) dynamic model is proposed to compute the differential mass and momentum balances for the three phases and phase components

(Fuentes et al., 2008a, 2009). The bioreactor model resulted in an integral–partial derivative and algebraic equation (IPDAE) system.

2.1. Anaerobic digestion model

The anaerobic digestion model involves the biochemical (growth-uptake, death, hydrolysis and disaggregating) and physico-chemical (system charge balance for calculating pH, gas-liquid mass transfer) processes which take place in the bioreactor. The anaerobic degradation scheme proposed by Angelidaki et. al (1999) is here used. Microorganism growth kinetic expressions and kinetic and physico-chemical parameters have been previously described (Fuentes et al., 2007). The specific growth and death rates are assumed to be the same for suspended and aggregated biomass. The non-active biomass is considered as particulate material subjected to hydrolysis.

2.2. Bioparticle model

Generally, the granule composition has been described from the ash content, moisture and (active and non-active) biomass fraction. These parameters can vary during the granule formation, and thus, the dry density of granules varies. As first modeling approach, homogeneous biomass distribution on granules, constant wet biomass density and spherical geometry are assumed.

For modeling the disintegration of aggregates, some physical aspects related to the structure and compactness of granules need to be considered. Hydrodynamics affects biomass processes inside a bioreactor. These effects are more pronounced in fluidized beds than in UASB reactors, attending to the operational fluid velocity ranges (Huang and Wu, 1996; Nicolella et al., 2000). Tiwari et al. (2006) studied the influence of some factors such as temperature, alkalinity, nature and strength of substrate, and cation concentration on granule formation in UASB reactors. They concluded that: (1) a careful temperature control and an adequate alkalinity is required for generation and maintenance of granules; (2) the nature and strength of substrate in conjunction with intra-granular diffusion to a large extent determines the microstructure of the granules; and (3) the divalent cations such as calcium and iron may enhance granulation by ionic bridging and linking exo-cellular polymers. However, their presence in excess may lead to cementation due to precipitation leading to increased ash content and mass transfer limitation.

Here, the specific rate of granule rupture k_r has been defined for calculating the biomass transport phenomena. This parameter explains how the process of granulation is affected by all these environmental and operational conditions, and differs of the specific rate of biomass hydrolysis, which is related to the enzyme attack on non-active biomass. Since several factors are involved in the stability and formation of granule, and no other modeling approach has been published, the rate of granule (disaggregating) rupture is modeled as a first-order function on energy dissipation parameter (which is an upflow velocity function) and mass concentration of each microbial species present in the biomass aggregates. Parameter k_r has been assumed the same for all biological species. A sensitivity analysis of model results related to this parameter is presented in Section 3.2.

2.3. Hydrodynamics model

Characteristics of phase mixture and flow patterns are expressed by the hydrodynamic model. Generally, the flow pattern in the UASB has been described as a plug flow reactor (D_z=0) because of the low turbulence provided by the upflow velocity and gas

production. The EGSB behaves as a continuous-stirred tank reactor (D_z? 8) due to the effects of the high recirculation rate. Liquid film mass transfer resistance seems to be negligible in the EGSB but important in the UASB reactor. This could be a consequence of the different hydrodynamic conditions in the two reactors. Here, the dispersion coefficient D_z is assumed as a function of granule characteristics (terminal settling velocity and diameter) and the liquid and gas phase velocities. A sensitivity analysis of model results related to this parameter is presented in Section 3.2.

The mathematical model was implemented and solved using the process modeling software tool gPROMS (Process Systems Enterprise Ltd). The backward finite difference method (BFDM) was used to solve the partial differential equations (PDEs). Using second-order BFDM over a uniform grid of 20 intervals resulted in 3718 equations and 1140 differential variables. The total CPU time required to solve the case study described in the following section is about 37 s on an 800MHz Pentium IV PC.

3. Example

The experimental results obtained by Kato et al. (2003) are here used to calculate the application example. This work was carried out in a pilot EGSB reactor (2 dm inner diameter and 50 dm reactor height) fed with the effluent from a full-scale UASB treating municipal wastewater. The bioreactor was monitored in three different periods by varying the upflow velocity according to Table 1. During the first step-type disturbance, bioreactor operated with a UASB configuration (recirculation flow equal to zero). Average experimental values of influent chemical oxygen demand (COD) and volatile suspended solids (VSS) are shown in Table 2.

Table 1. Reactor operational conditions.

Step	Influent flow (L/d)	Recirculation flow (L/d)	Upflow velocity (dm/d)
1 (0 to 113 day)	945	0	300
2 (114 to 206 day)	945	945	600
3 (207 to 331 day)	945	1890	900

Table 2. Experimental data of the influent stream and values used in the model.

Step	Temperature (ºC)		pH		Total COD (mg/L)		Soluble COD (mg/L)		VSS (mg/L)	
	Exp.	Mod.	Exp.	Mod.	Exp.	Mod.*	Exp.	Mod.*	Exp.	Mod.*
1	29.7±1.7	30	6.9±0.1	6.9	126±53	108	56±22	56	42±27	40
2	30.3±2	30	6.7±0.2	6.9	180±50	156	79±31	78	54±29	62
3	32±1.9	32	6.9±0.2	6.9	156±48	136	55±19	56	63±30	62

* Values of 30, 30, 0, and 40 %VSS were assumed to model carbohydrate, protein, lipid and suspended biomass composition in the influent stream, respectively. Soluble COD was measured as acetic acid concentration.

3.1. Simulation results

Table 2 summarizes the values of the influent stream used for simulations. As observed in Table 3 and Fig. 2, a good agreement between experimental and predicted values of total and soluble COD and VSS concentration of the effluent stream is obtained.

Predicted values of granule diameter and solid holdup are depicted in Fig. 3 (a) and (b), respectively. Although the solid phase seems to be homogeneously distributed along the reactor height (axial dimensionless length Z^*), bioparticles with a higher diameter, and thus, with a higher terminal settling velocity, are settled at the reactor bottom.

Figure 3 (c) and (d) represents the pH and gas holdup profiles, respectively. As expected, a higher pH variation along Z^* is observed during the first step-type

disturbance, when the reactor operates with UASB configuration. A plug flow behavior is observed for the gas phase (Fig. 3d).

Table 3. Experimental and predicted values of the effluent stream.

Step	pH	Total COD (mg/L)		Soluble COD (mg/L)		VSS (mg/L)	
	Pred.*	Exp.	Pred.*	Exp.	Pred.*	Exp.	Pred.*
1	7.05	68±29	60	42±21	30	13±8	20
2	6.90	87±21	68	55±22	39	8±3	20
3	7.03	79±26	71	44±15	36	24±17	25

* The values were measured at the end of each step-type disturbance.

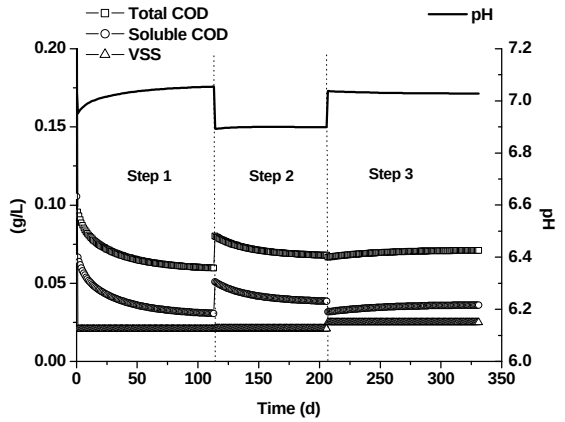

Fig. 2. Predicted values of total and soluble COD, VSS concentration and PH.

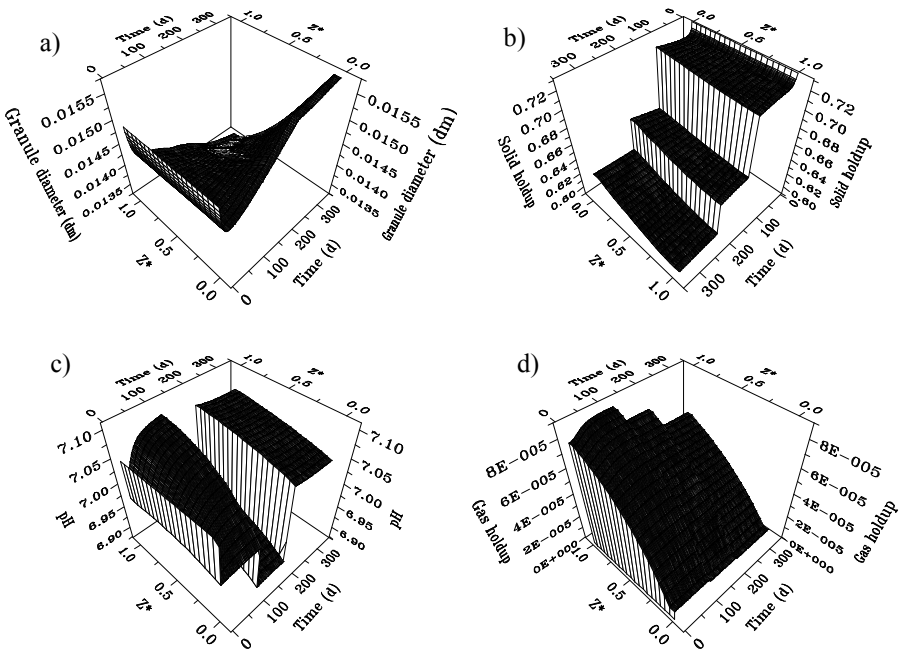

Fig. 3. Predicted values: (a) granule diameter, (b) solid holdup, (c) ph, and (d) gas holdup.

3.2. Sensitivity analysis

Figure 4 shows the sensitivity analysis of model predictions related to the axial dispersion coefficient D_z during Step 1 when the bioreactor operates with a UASB configuration. As expected, a decrease in D_z causes marked profiles along Z^*. Simulation results are less sensitive to this variation at higher upflow velocities, i.e. when operational conditions are similar to EGSB configurations. A decrease in D_z values from 800 $dm^2\ d^{-1}$ to plug flow condition (D_z=0) causes a decrease of 3% in the biogas yield and COD removal efficiency.

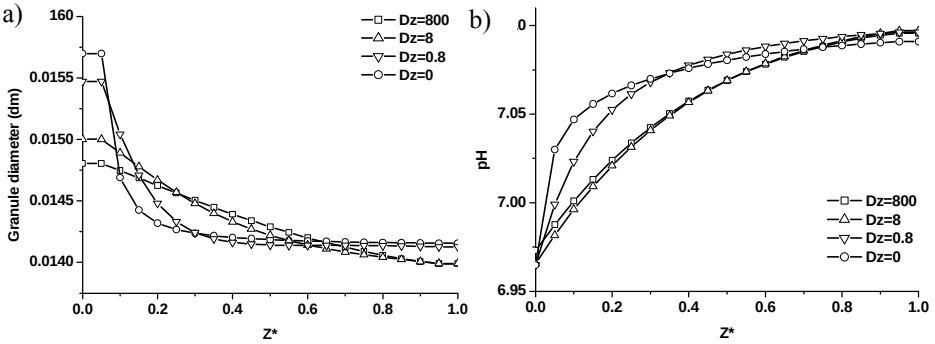

Fig. 4. Sensitivity analysis of model predictions related to the dispersion coefficient D_z ($dm^2\ d^{-1}$): (a) granule diameter, and (b) pH.

A reference value of the specific rate of granule rupture k_r equal to 2×10^{-21} dm d^2 g^{-1} (1.5×10^{-7} m s^2 kg^{-1}) is here used. Values up to $200k_r$ were evaluated. Simulation results for total COD concentration in the effluent stream is practically the same for all k_r values. However, the solid holdup decreases when parameter k_r increases, and hydrodynamic conditions vary. A decrease in the granule mean diameter, and thus, in the terminal settling velocity, causes an increase in the height of reactor. In practice, a higher concentration of suspended biomass and small granules can leave the bioreactor.

Sequencing Batches in a Real-World Pipeline Network Using Constraint Programming

Luiz Carlos Felizari, Lúcia V. R. de Arruda, Ricardo Lüders, Sérgio L. Stebel

CPGEI – Federal University of Technology – Paraná
Av. Sete de Setembro, 3165, 80230-901, Curitiba – PR, Brazil
E-mail address: felizari@cpgei.cefetpr.br

Abstract

This paper presents a new approach for sequencing of batches in a complex pipeline network by using Constraint Programming (CP) techniques. These batches are composed by oil derivatives to be transferred by the pipeline network. Although many papers found in the literature usually deal with reduced pipeline topologies, the network considered in this work is quite complex. It involves nine areas, including three refineries, one harbor and five distribution centers interconnected by fifteen multiproduct pipelines. Although this paper only focus on sequencing of batches, the final task is to provide a complete transfer scheduling for the pipeline network. This scheduling is accomplished by means of three key elements: assignment, sequencing and timing. The proposed CP model considered for sequencing of batches introduces particular features of the problem that can be used by specialized solvers. This approach aims to consider time delays introduced by the pipeline network during product transfers. Preliminary results show that a suitable ordering of batches can be obtained for improving inventory levels. Besides, results show a better performance when compared to a heuristic approach which can fail for some particular cases.

Keywords: Pipeline Network, Scheduling, Sequencing, Constraint Programming.

1. Introduction

Pipeline networks are a reliable and economical transfer way for oil and gas, especially when there is a large quantity of products to be transferred or great distances must be overcome. The distribution and transport of oil refined products involve decisions that should be taken within time periods ranging from hours to months. They include decisions about production, planning and scheduling of operations, inventory management and network utilization rate among others. Extensive reviews of optimization approaches for scheduling of pipelines have been addressed by Cafaro and Cerdá, Magatão *et al.*, Rejowski and Pinto, Relvas *et al.* and Moura *et al*. In general, most of the published works make use of decomposition strategies to reduce the combinatorial complexity for solving scheduling optimization problems in real-world pipelines. In a former work by Neves-Jr *et al.*, the same real-world pipeline network presented in this paper was modeled through MILP techniques using a decomposition approach. The scheduling problem was decomposed into three sub-problems: assignment of resources, sequencing of batches and timing allocation. The solution of assignment and sequencing problems uses constructive heuristics based on specialist knowledge about the pipeline network operation, and solution of timing problem is obtained by a continuous-time MILP model. Since solution of assignment and sequencing are hard to be obtained by a specialist, we propose to reformulate the

sequencing problem by using high-level constructs of Constraint Programming (CP). The main argument of developing MILP/CP approaches is to try to use their complementary strengths in an efficient manner (Magatão *et al*., 2005). The paper is organized as follows. The problem description and the model formulation are presented in sections 2 and 3 respectively. Computational results and analysis are provided in section 4 and conclusions are addressed in section 5.

2. Problem Description and Proposed Approach

The pipeline network represented in Fig. 1 involves nine areas, including three refineries, one harbor and five distribution centers interconnected by fifteen multiproduct pipelines. Besides, some of them can have their flow direction reverted according to operational procedures. Such complexity is dealt by considering three key elements of scheduling: assignment of resources, sequencing of activities and timing allocation for resources (Reklaitis, 1992). Each one is solved by an appropriate technique in a multilevel hierarchical structure (Fig. 2). In our former paper, assignment of resources and sequencing of activities are carried out by a heuristic algorithm. The assignment block takes into account production and demand information received from the company planning, inventory management information as well as actual inventory levels in each area. Based on this information, the assignment block calculates time windows for delivering (or receiving) each batch in each source (or destination) area. In addition, this block determines batches' priorities to be satisfied inside the pipeline network according to the previous calculated time windows. By satisfying these time windows, inventories are kept within operational levels. However, after timing allocation for resources, the obtained scheduling has shown that time windows may not be satisfied. This can be explained by the heuristic approach used for assignment and sequencing, since it does not consider time delays introduced by the pipeline network. For instance, it does not considerer the minimum time necessary to transfer a batch from its source to a final destination along to the pipeline even without bottlenecks. The main idea of this paper is present a new approach to prevent time window violations by using a Constraint Programming (CP) model for batches ordering. Constraint Programming is largely used to represent a scheduling problem in a more "natural" and compacting manner. An important CP feature is given by constraint operators, like OR, AND, IMPLICATION and EQUIVALENCE (Magatão *et al*., 2005). By developing a more formal representation of the sequencing problem, the quality of the pipeline network scheduling can be significantly improved.

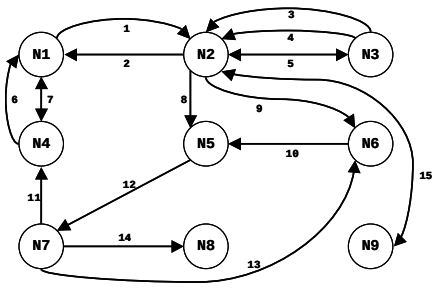

Fig.1 – Pipeline Network

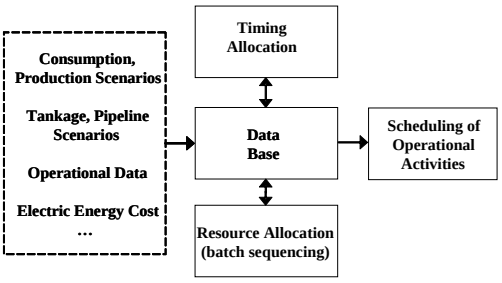

Fig.2 – Optimisation Structure

3. Mathematical Formulation

The proposed mathematical model must represent a sequence of batches that should be pumped in order to determine a minimum time window in each source and destination terminals. It is based on the OPL constraint programming framework supported by ILOG Solver and employs some specific scheduling features available in the ILOG Scheduler. Probably, the most fundamental scheduling concepts in OPL are related to built-in applications such as activity, unary and discrete resources (ILOG, 2002). The proposed CP model is described in the following.

3.1. Objective Function

The objective function in Eq. (1) is composed by time windows violations that should be minimized both in sources ($ao_{b,n}$; $do_{b,n}$) and destinations ($ad_{b,n1}$; $dd_{b,n1}$). The objective function is weighted by operational cost factors (kto; ktd).

$$\min \sum_{b\in B}\sum_{\substack{n\in N\\ n=no_b}}\left(ao_{b,n}+do_{b,n}\right)*kto+\sum_{b\in B}\sum_{\substack{n1\in N\\ n1=nd_b}}\left(ad_{b,n1}+dd_{b,n1}\right)*ktd \qquad (1)$$

3.2. Constraints

The mathematical model is composed by a set of constraints, which are expressed by equations (2) to (15). Eq. (2) establishes time start and finish of a pumping activity $op_{b,n,n1,d}$ in a source node, where vol_b and vaz_b are the volume and pumping flow rate of batch b, respectively. In addition, Eq. (3) defines the duration of activity $op_{b,n,n1,d}$ from second to last pipeline segment through the designated route. The parameter vp_d represents the volume of pipeline segment d.

$$op.end_{b,n,n1d} = op.start_{b,n,n1,d} + vol_b / vaz_b \qquad b\in B, n, n1\in N(n\neq n1), n=no_b, d\in D \qquad (2)$$

$$op.end_{b,n,n1,d} = op.start_{b,n,n1,d} + vp_d / vaz_b \qquad b\in B, n, n1\in N(n\neq n1), d\in D \qquad (3)$$

Delivery and receipt constraints are described by Eqs. (4) and (5), respectively. In each origin area, minimum pumping start time (ted_b) and maximum pumping start time (tec_b) of batch b must be respected. Similarly, the minimum receiving start time (trd_b) and maximum receiving start time (trc_b) must be guaranteed at the final product destination.

$$ted_b - ao_{b,n} \le op.start_{b,n,n1,d} \le tec_b + do_{b,n} \qquad b\in B, n, n1\in N(n\neq n1), n=no_b, d\in D \qquad (4)$$

$$trd_b - ad_{b,n1} \le op.end_{b,n,n1,d} \le trc_b + dd_{b,n1} \qquad b\in B, n, n1\in N(n\neq n1), n1=nd_b, d\in D \qquad (5)$$

Linear disjunction (6) and equivalence constraint (7) establish a precedence condition for pumping activities on shared pipelines. The binary variable $pd_{b,b1,d}$ indicates whether batch b precedes batch $b1$ at a pipeline segment d ($pd_{b,b1,d}$ = 1), or otherwise ($pd_{b,b1,d}$ = 0). The number of shared pipeline segments to batches $b1$ and $b2$ is given by the factor $kpd_{b,b1}$.

$$\left(\sum_{b\in B}\sum_{b1\in Bd\in D}\sum pd_{b,b1,d} = kpd_{b,b1}\right)\vee\left(\sum_{b\in B}\sum_{b1\in Bd\in D}\sum pd_{b,b1,d} = 0\right) \qquad (6)$$

$$pd_{b,b1,d} \Leftrightarrow op_{b,n,n1,d} \textbf{ precedes } op_{b1,n,n1,d} \qquad b,b1\in B, n, n1\in N(n\neq n1), d\in D \qquad (7)$$

Eq. (8) expresses a precedence between distinct activities of a batch during the pipeline transitions along the route.

$$op_{b,n,n1,d} \textbf{ precedes } op_{b,n1,n2,d1} \quad b, \in B, n, n1, n2 \in N(n \neq n1 \neq n2), d, d1 \in D\,(d \neq d1) \tag{8}$$

Constraint (9) determines a precedence between activities of distinct batches at intermediate nodes.

$$\begin{aligned} &op_{b,n,n1,d} \textbf{ precedes } op_{b1,n,n1,d} \Leftrightarrow op_{b,n1,n2,d1} \textbf{ precedes } op_{b1,n1,n3,d2} \\ &b,b1 \in B, n,n1,n2,n3 \in N(n \neq n1 \neq n2 \neq n3), d,d1,d2 \in D(d \neq d1 \neq d2) \end{aligned} \tag{9}$$

A pumping sequence in a source area should satisfy (Eq. 10). For this case, p_b is a product associated to batch b ($p_b \in P$).

$$\begin{aligned} &op_{b,n,n1,d} \textbf{ precedes } op_{b1,n,n1,d} \\ &b,b1 \in B, n,n1 \in N(n \neq n1), d \in D,\ p_b, p_{b1} \in P(p_b = p_{b1}) \end{aligned} \tag{10}$$

Constraint (11) uses a specific OPL construct "**requires**". It enforces that activity $op_{b,n,n1,d}$ needs a *unary resource* from the set of *unary resources* ($d \in D$). Note that this constraint enforces assignment of an activity to a specific pipeline segment as well as a sequencing of activities that have been assigned to this pipeline.

$$op_{b,n,n1,d} \textbf{ requires } d \quad b \in B, n, n1 \in N(n \neq n1), d \in D \tag{11}$$

Constraint (12) uses another fundamental concept provided by OPL for scheduling applications: *discrete resources*. In source areas, *discrete resources* may be used to model a set of pumps. Pumping activities request pump resources to be done. For instance, batches can be pumped from N7 by pipelines 11, 13, and 14. At this node there exist a limited number of pumps and only one batch is allowed to be delivered from N7 in a specific time interval.

$$op_{b,n,n1,d} \textbf{ requires } (1)\ pump_n \quad b \in B, n, n1 \in N(n \neq n1), d \in D \tag{12}$$

Eq. (13) defines a sequencing of batches according to a previous pipeline assignment. Variable ord_b indicates a relative pumping order of batch b into a list of batches. Note that only integer values are assigned to ord_b.

$$\begin{aligned} &op_{b,n,n1,d} \textbf{ precedes } op_{b1,n2,n3,d} \Leftrightarrow ord_b < ord_{b1} \\ &b,b1 \in B, n,n1,n2,n3 \in N(n \neq n1 \neq n2 \neq n3), d \in D \end{aligned} \tag{13}$$

Global constraints (14) and (15) use a predicate "**alldifferent**" which expects an array of discrete variables and holds it if all elements of this array are given a different value (ILOG, 2002).

$$\textbf{alldiferent}\ (op.start_{b,n,n1,d}) \quad b \in B, n, n1 \in N(n \neq n1), d \in D \tag{14}$$

$$\textbf{alldiferent}\ (op.end_{b,n,n1,d}) \quad b \in B, n, n1 \in N(n \neq n1), d \in D \tag{15}$$

3.3. Search Procedure

In Eq. (16), a search component consists of assignment of values for all variables ord_b, using an OPL instruction "**generate**". This generation procedure receives a discrete variable, or an arbitrary array of discrete variables, and generates values for all these variables (ILOG, 2002).

$$\textbf{generate}\ (ord_b) \quad b \in B \tag{16}$$

4. Computational Results

In this section, we compare a sequence of batches generated by the CP model with a sequence previously obtained in the assignment block (rule-based heuristic algorithm). Sequences (due to CP model and due to assignment block) are then processed by the timing block which obtains the respective timing for each sequence through a MILP model. Further details about MILP model can be found in Neves-Jr *et al*. Table 1 presents computational details for seven real-world instances (S1 to S7) considering scheduling horizons of approximately 30 days. The resource allocation block takes production/consumption plans of more than 10 different products during a month. As shown in Table 1, the sequencing model found a solution in few CPU seconds, even for scenarios with more than 80 batches. The reduced number of binary variables is function of batch conflicts in the network. For instance, variable $pd_{b,b1,d}$ is generated when batches $b1$ and $b2$ are pumped from nodes N1 and N3, respectively, and share the pipeline 8. Otherwise, the variable $pd_{b,b1,d}$ will become redundant. Similarly, the set of constraints is highly dependent of batches relationship. Forbidden product sequences, specified *a priori* by the assignment block contributes to a reduction of the number of precedence constraints and, consequently, to lower computational effort. In Table 1, this can be seen for scenarios S5 (78 bathes and 3268 constraints – 14.7s) and S6 (81 batches and 2854 constraints – 14.2s). The second part of Table 1 shows results for heuristic and Constraint Programming approaches (H/CP). A performance metric used to compare results is the total number of batches delivered or received beyond time windows computed in the assignment block. According to section 2, time windows violation is related to violations on inventory level in refinery and terminal tank farms, but it is undesirable. For instance, at the scenario S1, for the CP model, only 6 batches have their time windows violated against 19 batches to the specialist heuristic. However, in scenario S2, CP model provided a worse result than one obtained by a heuristic solution (from 4 to 5 constraint violations), but not so far.

Table 1. Results for operational scenarios

Scenario			**S1**	**S2**	**S3**	**S4**	**S5**	**S6**	**S7**
Number of Batches			49	67	67	72	78	81	84
Binary Variables			96	82	88	214	274	115	255
Continuous Variables			1652	1974	2001	2182	2381	2100	2484
Constraints			1703	2168	2184	2809	3268	2854	3442
Execution Time [s]			5.45	9.13	9.28	11.64	14.7	14.2	17.03
Time Window Violation	Delivery	Early (H/CP)	7/5	2/3	13/9	3/2	3/2	4/0	4/3
		Late (H/CP)	0/0	0/0	0/0	0/0	3/1	1/0	7/0
	Receipt	Early (H/CP)	2/0	1/0	0/0	3/2	1/0	0/0	0/0
		Late (H/CP)	10/1	1/2	12/6	4/1	3/0	0/0	6/3
	Total Violation (H/CP)		19/6	4/5	25/15	10/5	10/3	5/0	17/6
Makespan [days] (H/CP)			31/31	34/35	33/31	31/33	32/32	27/29	32/33

The proposed CP formulation was implemented and solved in ILOG OPL Studio 3.6.1 using ILOG Solver 5.3 and ILOG Scheduler 5.3 on Intel-Core2Duo 2.13GHz with 2GB of RAM.

5. Conclusions

We have developed a Constraint Programming (CP) model for sequencing of batches in a pipeline network. The incorporated approach has been tested with real-world scenarios, that covered monthly time horizons involving more than 80 batches. In order to achieve feasible solutions in acceptable computational times, a decomposition approach was used. This decomposition relied on a multi-level hierarchical structure involving the assignment, the sequencing, and the timing sub-problems of scheduling. Since the ordered sequence of pumped products has an important impact over the final short-term scheduling, the activities ordering heuristic used by the assignment part can fail for particular cases. Compared to the approach discussed in a previous work addressed by Neves-Jr *et al.*, this paper has aimed to reformulate the sequencing part using the high-level constructs of Constraint Programming (CP). In general, the proposal CP model obtained satisfactory solutions with a low computational effort (up to 70% reduction in the number of time windows violation). Furthermore, the model results can present a better level of inventory during the time horizon. Finally, for future work over the sequencing model, a more detailed formulation would enable to obtain optimised sequences with reduced product interfaces.

Optimal Experimental Design for the Determination of Protein Ion-Exchange Equilibrium Parameters

Tilman Barz, Verena Löffler, Harvey Arellano-Garcia, Günter Wozny

Chair of Process Dynamics and Operation, Sekr. KWT-9
Berlin Institute of Technology, D-10623 Berlin, Germany

Abstract

Despite the fact that batch experiments directly establish equilibrium conditions, they still have some main disadvantages, which make the determination of equilibrium parameters a challenging task. These drawbacks are among others the lack of direct measurement of the key variables, the impossibility of setting a desired equilibrium point without a perfect process model, and the high laboratory effort for the preparation and analysis of the experiments. To overcome these problems, a systematic approach based on optimal experimental design is proposed. Here, the inclusion of practical restrictions in the optimization problem formulation is crucial such as the maximal protein amount available, the maximal solubility of protein and salt, or the special characteristics of peak area determination during the measurement of protein concentrations using an analytical HPLC. The efficiency of the developed parallel/sequential design approach is demonstrated by theoretical and experimental results for the multi-component (two proteins/salt mixture) system.

Keywords: optimal experimental design, steric mass ion-exchange, adsorption equilibrium.

1. Introduction

The exact determination of adsorption equilibrium parameters still remains a challenging task. The knowledge of the thermodynamic equilibrium between the mobile phase, the stationary phase, and the components of the mixture to be separated is the fundamental basis for e.g. modeling and simulation of chromatographic applications. In this work, optimal batch experiments are designed in order to determine protein ion-exchange equilibrium parameters. In comparison to conventionally planned experiments, the optimal experimental design (OED) method allows minimizing the experimental effort to be spent for the preparation and analysis of experiments. Furthermore, a quantitative measure for the quality of a certain set of experiment decision variables is provided, which gives insight about the quality and identifiability of the estimated parameters. For this purpose, the size of the parameter covariance matrix is used as a common criterion. Moreover, different metrics are adopted in order to quantify the parameter quality (Franceschini & Macchietto, 2007). However, prerequisite for the model based experimental design is that an appropriate and valid model without structural uncertainties is at hand. Furthermore, in order to cope with parameter uncertainties, different strategies such as parallel, sequential, and parallel/sequential design of experiments can be adopted (Franceschini & Macchietto, 2007). The sequential strategy is commonly adopted, which is based on an iterative

refinement of the estimated parameter set, and thus, it is reliable even for bad initial guesses of the parameters to be estimated. In this work, it will be shown that for the considered batch experiments here, a strictly sequential strategy is not feasible for two reasons: first, it would boost the experimental effort at a maximum, and secondly, it also does not guarantee identifiability of the parameter set for the very first batches. The chosen case study in this work is the separation of bio-molecules from milk whey products. Under the commercially interesting products are the proteins β-Lactoglobulin A and B (βLgA, βLgB), which can be separated by anion-exchange chromatography (Pedersen, Mollerup, Hansen & Jungbauer, 2003). Generally, the wide range of retentivities of the whey proteins makes it difficult to separate them under isocratic conditions. Thus, the application of gradient elution to preparative- and large scale chromatography is the most common mode of operation (Natarajan, Ghose & Cramer, 2002). In gradient elution, a modulator concentration in the liquid phase is adjusted in order to influence the eluent strength, and thus the retentivities of the eluites (Gu, Truei, Tsai & Tsao, 1992). For the treatment of βLgA and βLgB, Cl^- ions (salt) are used as modulator in order to optimize the protein separation. Therefore, the salt is considered as an additional component in the equilibrium model.

1.1. Estimation and Modeling of Protein Ion-Exchange Equilibria

A general overview about typical methods for the determination of adsorption isotherms is given in (Seidel-Morgenstern, 2004). Using batch experiments means a tedious and fault prone laboratory work, but in comparison to alternative methods, no additional effects like transport or kinetic phenomena have to be considered in order to determine the adsorption equilibrium (Seidel-Morgenstern, 2004). For the explicit consideration of non-isocratic operation in chromatographic protein separation, Brooks and Cramer developed a steric mass (SMA) ion-exchange equilibrium formalism, which explicitly accounts for the steric hindrance of salt counterions upon protein binding in multicomponent equilibria. The SMA formalism can be represented in analogy to the variable coefficient in multicomponent Langmuir isotherms (Brooks & Cramer, 1992):

$$q_j^* = f\left(c_j^*, \boldsymbol{\theta}\right); \quad \text{with } \boldsymbol{\theta} = \left[\Lambda, k_{1,j}, \nu_j, \sigma_j\right]^T \text{ and } j = \{2,...,N_C\} \tag{1}$$

where N_C=3 is the number of components, c_j^* and q_j^* represent the liquid and the adsorbed equilibrium concentration, respectively. For the first component, here the salt, the parameters are fixed, and thus it does not need to be determined. Furthermore, since the proteins βLgA and βLgB have a similar structure, the steric factor of the proteins, σ_i, can be assumed to be equal for both proteins (σ_2=σ_3). Thus, there are 6 adsorption model parameters, $\boldsymbol{\theta}$, to be estimated by the available measurement.

2. Experimental Design problem formulation

The experimental design aims to adjust the initial amount of solutes and adsorbent in the batch in order to establish a certain equilibrium point. However, the decisions in order to obtain an specific equilibrium point are not obvious, which is basically due to the diminution of the initial protein concentration to the equilibrium concentration (Seidel-Morgenstern, 2004). It is obvious that using a model these decisions can be calculated, but unfortunately the model's accuracy will then depend directly on the quality of the initial estimate of the equilibrium parameters, $\boldsymbol{\theta}$. Moreover, critical for the formulation of the experimental design problem is the inclusion of practical restrictions in the optimization problem formulation. Therefore, the manual steps for preparing and analyzing batch experiments are first briefly discussed. Following this, a suitable model for the OED problem formulation is derived.

2.1. Experimental Setup, Batch Preparation and Measurements

For each batch preparation four different liquid volumes are arranged, where several decisions have to be made (see also Fig 1):

- volume, V^{sl}, and adsorbent amount, ε_{tot}^{sl}, for the adsorbent slurry
- volumes, V_2^{std} , V_3^{std}, and concentrations, $c_{2,2}^{std}$, $c_{3,3}^{std}$, for the protein standards
- and finally the concentration, $c_{1,1}^{std}$, for the salt standard, and the required volume, V_1^{std}, so as to get a desired total batch volume, V^{bt}

Furthermore, some additional parameters which result from the special pre-treatment of each batch preparation are considered, where c_1^{el} and $q_1^0 = \Lambda$ represent a constant free salt concentration, and the amount of salt in the beginning. The adsorbent is loaded with the maximal amount of salt at the start.

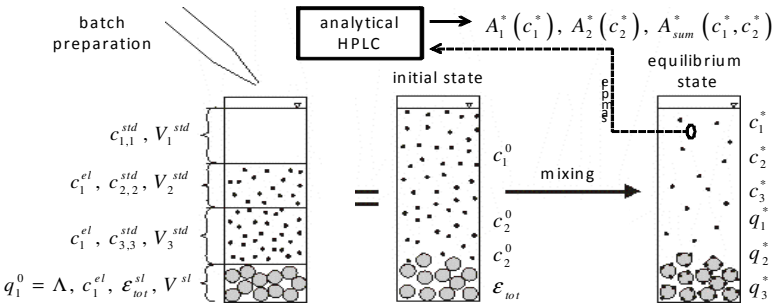

Figure 1: Preparation, initial and equilibrium state of one single batch experiment.

The major drawback lies on the fact that for batch experiments only liquid concentration measurements are available. The adsorbed equilibrium amount is determined based on the difference between the initial, c_i^0, and the equilibrium liquid concentrations, c_i^*, after mixing (Fig. 1). Here, no measurement of the salt ion concentration is carried out mainly because of the fact that the small batch size (4 ml) makes it impractical to implement a conductivity measurement. Consequently, information about neither the liquid salt, c_1^*, nor the adsorbed salt equilibrium concentration, q_1^*, is available. The analysis of the protein concentration is done by peak area integration of the photometric outlet signal and a linear calibration curve using an analytical reverse phase HPLC. Here, a typical problem in the HPLC analysis is encountered, which is the no-complete-base-line separation of the two peak areas, A_2^* and A_3^*, obtained for the equilibrium liquid concentration, c_2^* and c_3^*. Thus, the separation of the connected areas is done manually in order to calculate the concentrations c_2^* and c_3^*. By including the calibration curve into the model, both the total area, A_{sum}^*, and the alienated areas, A_2^* and A_3^*, are considered. According to the fault prone separation by hand, a relatively high and a much smaller measurement accuracy is assigned to A_{sum}^* and A_2^*, A_3^*.

2.2. Analysis of the Degree of Freedom and Mathematical Problem Formulation

For the preparation of one initial batch, all the referred parameters above are rather over-determining the decision space for the experimental design (e.g. a smaller standard protein concentration as well as a smaller standard volume can give the same initial concentration). The degree of freedom for the design of one single batch experiment is: $DoF=N_C+1$. Thus, some parameters are set to constant values such as the adsorbent amount. The standard protein concentrations are set to their maximal solubility. The adjustable variables are the three volumes of the protein standards and the slurry, as well as the salt concentration. Doing so, the relatively high effort for the preparation of

one single experiment does not increase significantly for the preparation of multiple experiments. The objective function for the OED of multiple experiments reads,

$$\begin{aligned} &\min_{\mathbf{u}} \ \varphi\left\{\boldsymbol{\theta}\mathbf{V}\left(\boldsymbol{\theta},\mathbf{u}\right)\right\} = \operatorname{trace}\left[\boldsymbol{\theta}\mathbf{V}\left(\boldsymbol{\theta},\mathbf{u}\right)\right] \\ &\mathbf{u}_k = \left[V_2^{std}, V_3^{std}, V^{sl}, c_{1,1}^{std}\right]^T \ ; \ \ \mathbf{u} = \left[\mathbf{u}_1,...,\mathbf{u}_{N_{Exp}}\right]^T \\ &\boldsymbol{\theta} = \left[\Lambda, k_{1,j}, \nu_j, \sigma_j\right] ; \ \sigma_2 = \sigma_3 \ ; \ \ j \in \{2,3\} \\ &\mathbf{y}_k^{meas} = \left[A_2^*, A_3^*, A_{sum}^*\right] \end{aligned} \quad , \tag{2}$$

where the parameter-covariance matrix, $\boldsymbol{\theta}\mathbf{V}$, represents the inference regions of each of the model parameters. A measure of this region is φ, in this specific case, the trace of the matrix, which is also known as the A-criterion. The decisions of the design problem, $\mathbf{u}$, are chosen in order to maximize the expected information content from the measured data generated by these experiments. For an estimate of the parameter-covariance matrix, $\boldsymbol{\theta}\mathbf{V}$, the inverse of the Fischer-matrix, $\mathbf{F}$, is used.

$$\boldsymbol{\theta}\mathbf{V}\left(\boldsymbol{\theta},\mathbf{u}\right) \approx \mathbf{F}^{-1}\left(\boldsymbol{\theta},\mathbf{u}\right) = \left(\sum_{k=1}^{N_{Exp}} \mathbf{F}_k\left(\boldsymbol{\theta},\mathbf{u}_k\right)\right)^{-1} \tag{3}$$

For one single experiment, $\mathbf{F}_k$ is calculated from the sensitivities of the measured variables, $\partial\mathbf{y}_k^{meas}/\partial\boldsymbol{\theta}$, weighted with the inverse measurement-covariance matrix, $\mathbf{MV}_k$.

$$\mathbf{F}_k = \left(\frac{\partial \mathbf{y}_k^{meas}}{\partial \boldsymbol{\theta}}\right)^T \cdot \mathbf{MV}_k^{-1} \cdot \left(\frac{\partial \mathbf{y}_k^{meas}}{\partial \boldsymbol{\theta}}\right) \tag{4}$$

By this means that previously carried out experiments, $k=\{1,\ldots,f\}$ are considered by a constant Fischer-Matrix, $\mathbf{F}_k$, which is then part of the sum over all experiments, but with their respective experimental design variables, $\mathbf{u}_k$, not included in the decision space, $\mathbf{u}$. Nevertheless, during the adsorption process each of the three components has to fulfill the mass balance. Together with the equilibrium model and additional equations describing the batch preparation and measurements, a total number of $N_{eq}=16*N_{Exp}$ algebraic model equations is obtained. The degree fo freedom is $DoF=(NC+1)*N_{Exp}$. Additionally, linear constraints restricting the total amount of proteins available, as well as the desired batch volume, and the maximal salt concentration, $c_{1,1}^{std}$, are considered. Following the sequential optimization approach, the model equations are solved in a sub-routine during the optimization run, and thus, only the experimental design parameters, $\mathbf{u}$, and the linear constraints are considered in the optimization routine. The resulting optimization problem is (linearly) constrained, small, dense and strongly nonlinear in the objective function and can be solved efficiently using the solver NPSOL (Gill, Murray, Saunders & Wright, 1985).

3. Theoretical and Experimental Results

Prior to the solution of the OED problem, one has to decide on both the strategy to follow (sequential vs. parallel) and the number of experiments, N_{Exp}, to be planned. At first glance, a simultaneous design of experiments seems to be the first choice for the described problem as it corresponds to the standard procedure in regular lab work, where several batches are produced and analyzed in parallel. The alternative is the sequential design approach, where only one experiment is planned. Another option is a combination of both strategies, where parallel planned experiments are designed sub-sequentially.

3.1. Theoretical results regarding the sequential and parallel design of experiments

The following points are of special interest for the decision of the design strategy:

- Prerequisite for the solution of the OED problem is that for the selected number of experiments, identifiability of the model parameters, $\boldsymbol{\theta}$, is reached. Thus, the number of experiments to be planned depends on the quality of the available measurement, $\mathbf{y}^{meas}$.
- Deviations between the initially assumed parameter estimates, $\boldsymbol{\theta}^0$, (used to solve the OED problem) and the (later estimated) "true" parameter set, $\boldsymbol{\theta}^*$, can strongly influence the quality of the experimental design and consequently the inference region of $\boldsymbol{\theta}^*$ (e.g. for large deviations between $\boldsymbol{\theta}^0$ and $\boldsymbol{\theta}^*$, an iterative design and parameter estimation is advantageous).
- Parallel planned experiments can save time and experimental effort.
- Finally, it could be argued that the simultaneous consideration of multiple experiments leads to the maximum information content by perfectly "orthonormal" design conditions, whereas sequentially planned experiments do not exploit the decision space, $\mathbf{u}$, as much efficient as possible.

Figure 2, left, shows theoretical studies about the course of the A-criterion for different design strategies with fixed parameter $\boldsymbol{\theta}^0$. It can be seen that for a minimum of four batch experiments, identifiability of all six parameters is reached. Surprisingly, the sequential design strategy (4+1+…+1) and even the nearly parallel one (10+10) does not affect the course of the A-criterion.

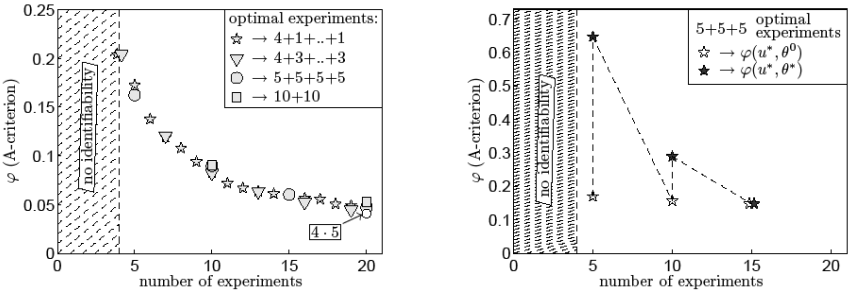

Figure 2: Course of the experimental design criterion over the number of experiments planned, here a combination of sequential and parallel design strategy is chosen, (e.g. 4+1+…+1 means: 4 parallel planned experiments and subsequently several single planned experiments). *Left figure*: theoretical results for one initial parameter set, $\boldsymbol{\theta}^0$=*const.*; *right figure*: experimental results, where the measurement data is used in order to update the parameter estimate, $\boldsymbol{\theta}^0 \rightarrow \boldsymbol{\theta}^*$, after each set of carried out optimal experiments.

Most remarkable is the result when exactly the same optimal design variables, $\mathbf{u}_k$, which were used previously for the first five experiments, are then used again in the subsequent four experiments (4*5 strategy). The A-criterion reaches the same value as for the other strategies. This can only be justified by the low information content of the measurement (see section 2.1). The decrease of the A-criterion for a rising number of experiments is because of an increased accuracy of the measured data (due to repeated measurements) rather than because of new information (e.g. analysis of the adsorption behavior at a different equilibrium point).

3.2. Experimental results for a combined sequential and parallel approach

Figure 2, right, shows the experimental results applying the (5+5+5) strategy. After each five experiments, the parameters are updated using the available measurement and

solving a parameter estimation problem, $\boldsymbol{\theta}^0 \rightarrow \boldsymbol{\theta}^*$. The updated parameters, $\boldsymbol{\theta}^*$, are then used for the subsequent OED. It can be noticed that the A-criterion is strongly affected (degradation) by an imprecise initial estimate of the parameters. With an increasing number of experiments, the quality of $\boldsymbol{\theta}^0$ also increases, and thus, this effect on the A-criterion is minimized. Figure 3 shows both conventionally planned experiments at two different salt ion concentrations (40 batches), and the optimal planned experiments (15 experiments). For the 15 already optimally planned experiments and a much smaller protein consumption, a value of φ_{opt}=0.193 is obtained instead of φ_{conv}=516.0. These values correspond to an average relative standard deviation of the parameters (σ_θ=11.7% and 615%) taken from $\boldsymbol{\theta}\mathbf{V}$, and thus highlighting the benefits of the applied method.

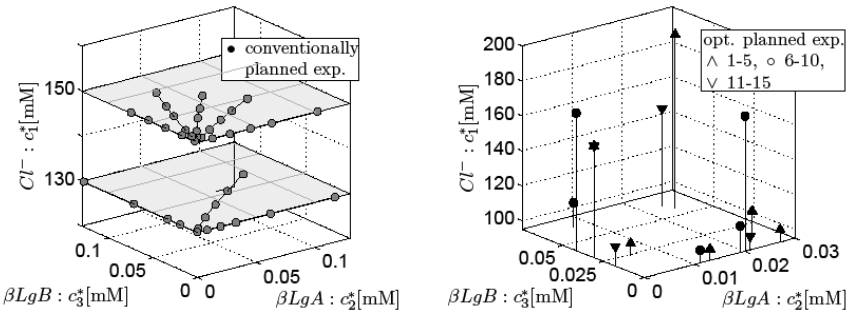

Figure 3: Liquid concentrations for the equilibrium points of conventionally planned experiments, and those which result from the solution of an OED problem.

4. Conclusions

This work proposes a systematic procedure based on a detailed model and the inclusion of design and analysis of experiments for a reliable determination of protein ion-exchange equilibrium parameters. The results show a significant improvement in terms of lab work load, number of experiments required, as well as the necessary protein amount. Moreover, it could be demonstrated experimentally that a benefit of the optimal design strongly depends on the quality of the initial guess of the parameters to be estimated. Thus, for instance, without any information about the parameter range, a sequential approach for OED is more appropriate than an entirely parallel one.

Integrating Purchase Contract Decisions with Inventory Management Optimization in the Supply Chain

M. Analia Rodríguez[a] and Aldo Vecchietti[a]

[a]*INGAR (CONICET – UTN), Avellaneda 3657, Santa Fe 3000, Argentina*

Abstract

This work addresses the optimization of material inventory management and purchase problems by linking two important players in the supply chain: material suppliers and product manufacturers. The context modeled considers a medium term horizon planning which presents a seasonal demand and a variable restricted capacity from the suppliers. Traditional mathematical constraints and disjunctive programming are used for formulating the problem. The execution performance shows the formulation efficiency and the results analyzed support the importance of solving the problem.

Keywords: inventory optimization, purchase decisions, supply chain.

1. Problem Description

The inventory management is an important problem to address in every industry due to the trade-off between customer satisfaction and capital invested. From an inventory cost perspective, the best condition would be a response-based supply chain where a zero inventory strategy is handled. However, it is rarely possible to achieve that target in practice (**Bowersox et al., 2007**). When products are made-to-stock planning the material purchase depends on the production plan while when products are made-to-order material purchase is more dependent on the demand variations. As a consequence, inventory management is much simpler in the first place than in the second one. Demand is difficult to predict and could lead to stock-out situations since suppliers could have insufficient capacity to provide the appropriate material to all manufacturers. In several industries, such as the production of paper, furniture, textile and food, among others, the use of material family is a regular practice. Companies use a set of possible raw materials (material family), in order to satisfy product demand, manufacturing a product with similar characteristics and properties. This production policy gives flexibility to production decisions allowing a set of possible formulations for the same final product. In this situation if there is no stock of the requested material according to the customer order, they satisfy the order anyway using one material of better quality, from the family, increasing the production costs, commonly called upgrade costs. In other words, the two main alternatives are whether to anticipate the demand buying the corresponding raw material increasing inventory costs; or whether to use better quality and expensive materials to satisfy the demand increasing production costs. For these reasons, decisions concerning material purchase and inventory management are really relevant and should not be considered as decoupled subjects. Another common practice in the industry is to sign provision contracts with suppliers with the purpose of decreasing costs and provision uncertainties (**Park et. al, 2006**). Diverse materials are purchased from various manufacturers signing different contract types. Contracts model

different situations in terms of prices, minimum and maximum quantities and payment conditions. Materials can be provided by various suppliers with diverse costs.
In this paper products made-to-order are studied with a very short lead time expected by the customers, modeling trade-off decision between increasing stock and upgrading production. This context is even more complicated because product demand is influenced by seasonal variations. An optimization approach to solve material purchase and inventory management problems for the supply chain is presented. The main novelty of this work is that the optimization of the inventory management is integrated to material purchase decisions handling different contract types with suppliers.

2. Model Formulation

2.1. Objective function
The objective function (1) defines the actualized profits maximization over the time horizon. The costs involved are the material purchase and the inventory costs while the revenues are calculated by multiplying the product demand and the product price.

$$Max \sum_{t} \frac{\sum_{p} Demand_{pt} \cdot price_{pt} - \left(\sum_{j} \sum_{c} \sum_{k} m_{jckt} + \sum_{f} savg_{ft} \cdot COSTavg_{ft} \cdot MS \right)}{(1+RR)^{t}} \quad (1)$$

Product demand $Demand_{pt}$ is a parameter used to calculate company revenues by multiplying it by the product price $price_{pt}$. In the second term, the money outflow is determined as the positive variable m_{jckt}. It is calculated considering material k purchased from supplier j to be paid in period t according to payment policy of contract c. This variable includes also the fixed cost assumed when selecting the corresponding contract c with supplier j. In the next term, the inventory carrying cost is calculated. For this purpose, $savg_{ft}$ is a positive variable that represents the average stock of family f in period t. The parameter $COSTavg_f$ corresponds to the average cost of family f and parameter MS indicates a percentage of the raw material average costs. This percentage estimates the average stock costs including the following major components: capital, storage, obsolescence and quality costs. As a general practice, these expenses are considered as a single inventory cost rate, represented as a percentage of the material price per unit time. In order to actualize the profits projected in the time horizon, the return rate RR corresponds to the own capital cost which is calculated with the Capital Asset Pricing Model.

2.2. Model constraints
The main constraints are presented in this section.

$$s_{ft} = s_{f(t-1)} + \sum_{j} \sum_{k \in FK_{fk}} q_{jk(t-1)} - d_{f(t-1)} \qquad \forall f \in F, \forall t \geq t_2 \in T \quad (2)$$

The initial stock of family f in period t, s_{ft}, is calculated by (2) as the initial stock of family f in period t-1 plus the quantity ordered, $q_{jk(t-1)}$, of materials k of family f to all suppliers selected in t-1 minus the material family consumption in the previous period $d_{f(t-1)}$. Note that material consumption is calculated considering the number of units of final product demand and the material consumption of each product as shown in (3).

$$d_{ft} = \sum_{p \in PL_{plf}} \sum_{l \in PL_{plf}} Demand_{pt} \cdot \alpha_{plf} \qquad \forall f \in F, \forall t \in T \quad (3)$$

A product p is formed by components l, each of which consumes one material family. It is possible that more than one component uses a certain family f. The formula (3) calculates material consumption d_{ft} according to product demand multiplying the

$Demand_{pt}$ with the parameter α_{plf} which indicates the quantity of family *f* corresponding to component *l* of product *p*, where PL_{plf} relates each component *l* of *p* with the family *f*.

$$\sum_{f} s_{ft} \leq SC \qquad \forall t \in T \qquad (4)$$

Storage capacity is actually finite; equation (4) limits the quantity in stock according to stock capacity parameter *SC*. Other constraints include the initial stock in the horizon planning, which is not null; and material average stock definition.

2.3. Modeling purchase decisions

The decision process involves several levels. Each level is modeled as a disjunction which is then associated with another level using logic equations and discrete variables.

$$\begin{bmatrix} y1_{jft} \\ \sum_{k \in FK_{fk}} q_{jkt} \leq \sum_{k \in FK_{fk}} Qmax_{jkt} \end{bmatrix} \vee \begin{bmatrix} \neg y1_{jft} \\ \sum_{k \in FK_{fk}} q_{jkt} = 0 \end{bmatrix} \qquad \forall j \in J, \forall f \in F, \forall t \in T \qquad (5)$$

Disjunction (5) expresses the selection of which families *f* are bought from each supplier *j* in period *t*. This choice represents the first level in the decision process using boolean variables $y1_{jft}$. If this variable is false then family *f* is not ordered from supplier *j* in period *t*. If it is true, the total quantity ordered must be lower than the maximum capacity of supplier *j*. In general, this quantity diminishes in high season periods. However, the reduction is not the same for all materials in the family. Cheaper materials availability tends to decrease more than the expensive ones (See model results).

$$\begin{bmatrix} y2_{jkt} \\ q_{jkt} \leq Qmax_{jkt} \end{bmatrix} \vee \begin{bmatrix} \neg y2_{jkt} \\ q_{jkt} = 0 \end{bmatrix} \qquad \forall j \in J, \forall k \in FK_{fk}, \forall t \in T \ (6)$$

In the following level given by disjunction (6), variable $y2_{jkt}$ indicates if material *k* is selected from family *f*, according to FK_{fk}, in period *t*. The set FK_{fk} defines which materials correspond to each family. In this term, the quantity ordered of material *k* in period *t* cannot be larger than the supplier capacity for that material and period. If a material *k* is not selected from family *f* then no quantity can be ordered from supplier *j* in *t*. Note that more than one material could be selected for each family. This situation will occur when the most convenient material presents lower availability ($Qmax_{jkt}$) than required. So, there is a commitment between buying material in advance increasing inventory costs and selecting materials of better quality affecting purchase value.

$$\bigvee_{\substack{c \in C \\ (c,t,t') \in TP_{ctt'}}} \begin{bmatrix} y3_{jckt} \\ q_{jkt} \geq Qmin_{cj} \\ w_{jckt} = q_{jkt} \cdot PC_{jkt} \cdot (1 - \delta_{jc}) + FC_{jc} \\ w_{jckt} = m_{jckt'} \end{bmatrix} \begin{array}{l} \forall j \in J, \forall k \in K, \forall t \in T \qquad (7) \\ \delta_{jc_1} = 0; \delta_{jc_2} > 0; \delta_{jc_3} > \delta_{jc_2}; \delta_{jc_4} < 0 \end{array}$$

Disjunction (7) selects the contract type using variable $y3_{jckt}$ for each material *k*, supplier *j* in period *t*. The first equation constrains the quantity of material that at least must be ordered from the supplier. This quantity $Qmin_{cj}$ depends on the contract and the supplier also. Note that while $Qmax_{jkt}$ represents an upper bound for variable q_{jkt}, in this case, parameter $Qmin_{cj}$ determines a lower bound for the order quantity.

The second constraint calculates the costs w_{jckt} of purchasing material *k* according to the amount bought q_{jkt}, price PC_{jkt} and corresponding contract discount ($\delta_{jc} > 0$) or interest rate ($\delta_{jc} < 0$). This cost also includes the fixed cost FC_{jc} to be faced whenever contract *c* is signed with supplier *j*. In the third constraint, positive variable $m_{jckt'}$ determines the amount to be paid for buying material *k* from supplier *j* in period *t'* according to the

payment policy of contract c. In this case, the set $TP_{ctt'}$ establishes that the purchase ordered in period t must be paid in period t' according to contract c. Note that when $t=t'$ there is no financial benefit but when $t<t'$ the financial benefits is given by the difference between them. In the first three contracts, period t is equal to t', however, the fourth one has a longer payment term. Although variable $m_{jckt'}$ could be calculated directly in the second constraint avoiding the use of w_{jckt}, this formulation is considered worthy in order to distinguish the cost concept given by the second equation and the effective money outflows calculated in the last one.

The first contract modeled the purchase with neither requirements nor benefits. For that reason, the minimum quantity requested is zero and the cost is calculated using the regular price with no discount. The second contract type presents a minimum quantity to order given by $Qmin_{c2j}$. It also has a discount applied to the total amount ordered. The third one has a bigger minimum quantity to order, $Qmin_{c3j}$, and a bigger discount too. With the aim of longer business relations with the suppliers, the model constrains the selection of this contract type only in case this material k has already been ordered from supplier j in the previous period. In the last contract type, the minimum quantity required $Qmin_{c4j}$ is the highest and due to the payment term offered, the second equation considers an interest rate ($\delta_{jc4} < 0$). This contract type is the only in which there is a possibility of paying later than the moment the actual purchase is made.

There are logical constraints related to material selection and some others equations guaranteeing coherence in the decision process not shown due to space reasons.

3. Model Results

The formulation was posed in GAMS system with the aim of showing model performance and solution suggested. It was executed over a PC having an Intel Pentium D 2.8 GHz processor. Disjunctions were modeled using LogMIP (**Grossmann et al., 2005**). Table 1 summarizes execution performance. The objective value was 5686.51.

Table 1. Solution performance.

	Equations	Postive Variables	Discrete Variables	Execution Time
Solution performance (Optimal solution)	2593	1777	822	13.906 sec

The main result is represented by variable q_{jkt} shown in Table 2. The lack of material availability during high season forces the company to accumulate materials in previous periods. This increases inventory handling and financial costs but not production costs.

Table 2. Material quantity decision.

q_{jkt}	j_1k_1	j_1k_2	j_1k_4	j_1k_5	j_1k_8	j_2k_1	j_2k_4	j_3k_1	*Quantity ordered*	**Qmax active** (Equation (5))
t_1	**500**	538	**400**			**450**	**420**		**2308**	
t_2	**200**	**300**	**200**	281	***85***	**200**	**200**		**1466**	***Qmin active*** (Disjunction (7))
t_3			**150**	**200**	175				**525**	
t_4		**200**	185	***110***	120			**200**	**815**	

According to these results, in many occasions equation (5) actually restricts the solution while in only two cases the first equation of disjunction (7) is also active. Stock capacity is not a limitation since SC is equal to 5000 and the maximum quantity ordered is 2308.

Considering that material costs are incremented from k_1 to k_{10} as shown in Figure 1, it is remarkable that there is priority to use cheaper materials from each family although they are ordered beforehand due to suppliers availability (see Figures 2a-2c). With the aim of clearing this, material ordered in each time period is compared with material use due to product demand. As an example, in Figure 3 the solution for family f_1 is presented. It shows that the biggest quantities ordered are placed in the first periods while consumption is actually in the third one. The main reason is that material availability of

the least expensive materials (k_1 and k_2) is limited in the third period and additionally, purchase costs for all materials are incremented in peak periods too (Figure 1). Material k_1 is the most ordered, which is the cheapest from family f_1. Material k_2 is requested in minor quantities and material k_3 is not ordered.

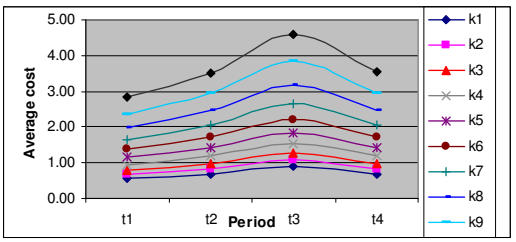

Figure 1: Material average costs

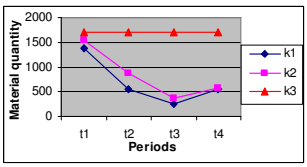

Figure 2 a: Suppliers availability for f_1.

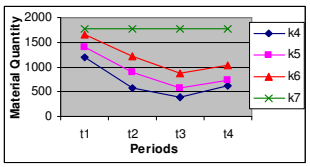

Figure 2 b: Suppliers availability for f_2.

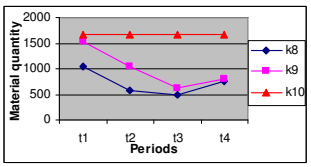

Figure 2 c: Suppliers availability for f_3.

As mentioned before, buying materials in advance causes an increase in stock and financial costs. However, there are two main reasons for using this strategy. In some cases, suppliers cannot provide enough material to satisfy the demand in peak periods. In others, although suppliers can provide certain material from the family, its cost is too expensive in high season thus rising production costs.

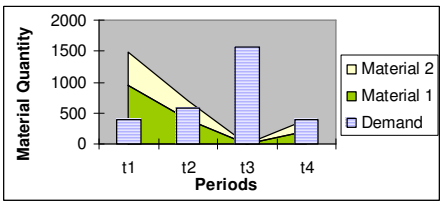

Figure 3: Demand and material purchase for family f_1.

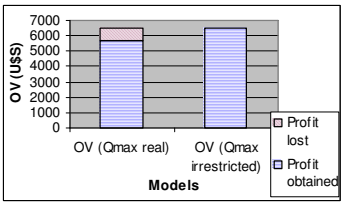

Figure 4: Objective value comparison.

Additionally, there are some other factors contributing to bigger ordered quantity: a) there is a fixed cost per contract signed; b) quantity flexibility contracts promote different discounts according to the amount purchased. In order to analyze the impact of these decisions in the objective value, financial costs of the material bought in advance should be determined. Two different strategies are presented to estimate the value of the financial costs. In the first place, it is possible to change the supplier availability considering unrestricted capacities for all periods.

Table 3. Material quantity decision for the fictitious case.

q_{jkt}	j_1k_1	j_1k_4	j_1k_8	j_2k_1
t_1	***170***	451		
t_2	700	700	***85***	
t_3	700	700	175	618
t_4	400	295	120	

Qmin active (Disjunction (7))

Table 3 shows that the solution obtained presents a few number of materials ordered before they were required. They are selected not because materials are insufficient in peak demand periods but because material costs increase in this period. The difference

between the objective value in the real case (5686.51) and the objective value in this fictitious one (6539.15) gives an approximate idea of the profit lost due to the financial costs paid caused by the supplier restricted capacity (Figure 4).

From another point of view, the quantity ordered in advance in each period according to the corresponding demand is estimated. The present discounted cost of the material acquired in periods before its actual consumption is calculated for each material family handled, representing the capital invested in stock. These two perspectives show how the solution is conditioned by supplier availability changes.

Table 4. Material purchased in advance and the corresponding actualized costs for family f_1.

Family f_1		Material k_1						Material k_2		Initial stock	Total quantity purchased	Quantity in advance	Costs in advance
		Supplier j_1		Supplier j_2		Supplier j_3		Supplier j_1					
Period	Demand	Quantity purchased	Cost	Quantity purchased	Cost	Quantity purchased	Cost	Quantity purchased	Cost				
t_1	383	500	0.5	450	0.55	0	0.6	538	0.6	350	1488	1455	803.8
t_2	580	200	0.6	200	0.7	0	0.75	300	0.72	-	700	120	128
t_3	1575	0	0.85	0	0.9	0	0.92	0	1.02	-	0	0	0
t_4	400	0	0.6	0	0.76	200	0.7	200	0.72	-	400	0	0
i = 8%											**Actualized total cost**		**854**

Table 4 shows the demand for family f_1 and the quantity bought from each supplier in the horizon planning. It also shows the cost of each material according to the supplier and period. The total quantity purchased is the summation of all materials purchased from all suppliers while the quantity in advance is calculated subtracting the demand to this quantity. The cost in advance is estimated using the materials purchased in advance and multiplying it by the corresponding material cost.

4. Conclusion

The problem tackled in this paper shows how several important decisions can be handled together so as to optimize the company global operation. In this sense, inventory optimization is considered jointly with purchase planning decisions. A new disjunctive model is proposed for solving the integration of inventory management and material purchase including also the selection of providers, specific materials and contract policies. Seasonal demand and material availability make this problem even more interesting since purchase and inventory decisions play an important role in the company profits.

With the intention of showing the problem solution, results are presented and analyzed in the previous section. This analysis shows that the quantity purchased is restricted by supplier availability in several occasions. In fact, there is a trend towards buying cheap materials in advance and stock them until they are needed. For that reason, financial costs were estimated using two different techniques showing the impact of these decisions on the company profits. The case study presented and the results obtained strengthen the relevance of the approach proposed.

Abstract

Mixtures stability analysis is a calculation procedure to determine whether a mixture will exist as a homogeneous phase or as multiple phases in equilibrium, for an established condition. The mathematical problems related to this analysis generally represent a great challenge with respect to the use of optimization methods, due to the occurrence of great number of local minima. The Adaptive Random Search (ARS) method is a stochastic global optimization method that has revealed superior to other stochastic methods such as genetic algorithm and the Particle Swarm Optimization. In the present work the hybridization of the ARS method with an algorithm for the solution of nonlinear equation systems is proposed, aiming to achieve the following characteristics: i) capability of covering the whole search space without being attracted to local minima, ii) small dependence on the initial guess, and iii) low computational cost. The methodology for stability analysis using hybrid ARS was implemented for three different equations of state - Soave-Redlich-Kwong (SRK), Peng-Robinson (PR) and PC-SAFT (Perturbed Chain – Statistical Associating Fluid Theory) - and tested on some mixtures for which data are available in the literature. The results of the original and hybrid versions of the ARS method were compared to those obtained with deterministic methods: a quasi-Newton method with BFGS approximation of the Hessian and with the DIRECT, which is another deterministic global search method that has been used in stability analysis problems. The hybrid ARS method allowed determining the correct thermodynamic condition (i.e., stable or unstable) of all tested mixtures. Additionally, in the cases where multiple local minima were present, this method has provided more than one solution in a single run, which is very useful for the solution of the phase equilibrium problem. In this sense, the composition values obtained by solving the stability analysis with the hybrid ARS were used to initialize the algorithm that solves Rachford-Rice equation (flash problem). Furthermore, the hybrid ARS method was able to validate all the solutions found when solving flash problem, for both stable and unstable mixtures.

Keywords: stability analysis, global optimization, phase equilibrium.

1. Introduction

When solving a phase equilibrium problem using equations of state, the most important practical aspects is to know if the tool performs stability analysis and, if so, how are the performance and reliability of the stability analysis method.

The most used stability analysis formulations were proposed by Michelsen (1982) and are based on the Gibbs tangent plane criterion. Implementation of Michelsen's stability analysis formulations requires the use of optimization methods or methods to solve nonlinear algebraic equations systems. The main difficulty found in applying these methods to this specific problem is related to the possible existence of multiple solutions besides the trivial one or the occurrence of several local minimum. Therefore, the method used to solve stability analysis problem should be able to scan the solution space effectively.

Due to complexity of the numerical problems involved in stability analysis and although several optimization methods have been tested for this task, only a few have

presented satisfactory performance. Interval Newton method (Tan and Radoz, 2002), the tunneling global search (Nichita et al., 2008) and DIRECT (Saber and Shaw, 2008) can be mentioned as examples of optimization methods successfully applied to stability analysis. Nevertheless, the development of methods to solve stability analysis problems is still a subject of great interest, both from the scientific and industrial points of view. The method should be able to meet the following features: i) capability of covering the whole search space without being attracted to local minima, ii) small dependence on the initial guess, and iii) low computational cost.

In this context, a method that has great potential for use in stability analysis problems is the Adaptive Random Search (ARS) method of Secchi and Perlingeiro (1989). In the present work the ARS method was modified to solve mixture stability problems, taking advantage of its ability to scan the search space and determine the maximum number of possible solutions, and introducing a local search algorithm for refinement of the generated points and minimizing with this the probability of failures when the determination of unstable or stable mixtures.

2. Methodology

The methodology for stability analysis by the modified ARS method was implemented for three different equations of state - Soave-Redlich-Kwong (SRK) (Soave, 1972), Peng-Robinson (PR) (Peng and Robinson, 1976) and PC-SAFT (Perturbed Chain – Statistical Associating Fluid Theory) (Gross and Sadowski, 2001) – and tested using mixtures data found in literature. The performance of modified ARS method for the chosen mixtures stability problems was compared with the original ARS, a quasi-Newton method (FMINUNC with BFGS, Coleman *et al*., 1999), and DIRECT (Saber and Shawn, 2008), which is a global optimization method and make search inside of the specific space.

2.1 Adaptive Random Search

The ARS method is a global optimization method, based on a memorized random search, with asymmetric distribution and systematic reduction of a hyper-ellipse of samples (Secchi and Perlingeiro, 1989). In each stage of the method random points are generated inside of the hyper-ellipse using the following expression:

$$x_{i,j}^{k+1} = x\_ot_i^k + \frac{R_i}{\delta}\left[B_i\left(A_i\Psi_{i,j} - 1\right)\right]^{\delta} \qquad i = 1, NCOMP\ ;\ j = 1, NSAMPLE \qquad (1)$$

where *NCOMP* is the number of variables (in stability analysis problems is equal to the number of components), *NSAMPLE* is the number of generated random points for the search, in the step k+1, inside of hyper-ellipse, $x_{i,j}^{k+1}$ are the search points, $\underline{x}\_ot_i^k$ are the coordinates of the best point in k-th step of the algorithm (or the starting point for k = 1), $\Psi_{i,j}$ are random numbers between zero and one, R_i are the hyper-ellipse axes sizes, δ is a parameter that attributes the samples distribution form, whereas for δ = 1, the distribution is uniform. A_i is the distribution asymmetry vector (A = 2 means symmetrical distribution) and B_i is a vector that gives the direction of the asymmetry. Designating *F_ot* as the value of objective function at the point $\underline{x}\_ot_i^k$, the ARS method is executed in the following steps:

1 – Evaluate the objective function in the initial point and store this value in *F_ot* (this variable is responsible for storing, always, the best value of objective function);

2 – Generate a set of random values, inside of the hyper-ellipse space, with respective evaluation of the objective function, and store these values. This step is repeated *NSAMPLE* times, generating a vector of objective functions (F_t_j).

3 – Compare the objective function values (F_t_j) calculated in step 2 with *F_ot*. If F_t_j has at least one value better than *F_ot*, $x_{i,j}^{k+1}$ is considered promising for the global minimum search. Otherwise set $x_{i,j}^{k+1}$ is discarded and returns to step 2. If after a specified number of attempts no set of coordinates are found with the objective function value better than *F_ot* the search is finished;

4 – Since $x_{i,j}^{k+1}$ has been considered promising, *F_ot* receive the best value of F_t_j and $\underline{x}\_ot_i^k$ get their coordinates;

5 - Check whether the old value of $\underline{x}\_ot_i^k$ must be discarded or not. This is done by evaluating the distance (Equation 2) between the coordinates of the old and the new points, comparing this distance with a metric *M* given by Equation 3.

$$Dm = \|x\_ot^k - x\_ot^{k+1}\| \quad (2)$$

$$M = 0.2c[\sum_i (R)^2]^{\frac{1}{2}} \quad i = 1,2,\dots,n \quad (3)$$

where *Dm* is the distance between coordinates of iterations *k* and *k* +1 and c = 0.5 in this step. If *Dm* < *M*, x_ot^k is discarded, otherwise this point is stored too.

6 – Verify if any other point $x_{i,j}^{k+1}$matrix coordinates. is located in promising regions of the search space. However, in this step only the distances between these points are evaluated using Equation 4.

$$Dp = \left[\sum_i \left(x_{i,j}^{k+1} - x_{i,l}^{k+1}\right)^2\right]^{\frac{1}{2}}, \quad for\ j \neq l \quad (4)$$

where *Dp* is the distance between the points randomly generated. The criterion to accept a set of points is also done using the metric *M,* Eq. 3, but at this step *c* = 1.

7 - Reduce the hyper-ellipse radius by increasing the parameter δ (δ = 1, 3, 5,... when δ = 1 means uniform distribution) and return to step 2. These steps are repeated until the hyper-ellipse radius becomes less than a given tolerance, when an optimum is located. If there are still points stored, a new starting point is recovered from memory and the steps 2 to 7 are repeated, restarting with a uniform distribution.

2.2 Mixtures Stability Analysis

The procedure for a mixture stability test presented here was developed above the following consideration: if the original mixture is stable, there is no composition of a new additional phase that leads to decrease the global mixture Gibbs energy. Based on that, many formulations were developed and the most used in literature were presented in Michelsen (1982). In this work the following formulations presented by Michelsen (1982) were used:

$$lnY_i + ln\hat{\phi}_i(\boldsymbol{y}) - h_i = 0 \quad (5)$$

$$TPD(Y_i) = 1 + \sum_i Y_i\left(lnY_i + ln\hat{\phi}_i(\boldsymbol{y}) - h_i - 1\right) \quad (6)$$

where $h_i = \ln(z_i) + ln\hat{\phi}_i(\boldsymbol{z})$, $\hat{\phi}_i$ is the fugacity coefficient of component *i*, z_i are the molar fractions of the mixture for which the stability are being tested, $\boldsymbol{z}$ is the vector that contains z_i values, Y_i is an independent variable that has as unique restriction that their values must be greater than zero, $\boldsymbol{y}$ is the vector containing y_i values (molar fraction of trial phase), which are obtained by the following relationship:

$$y_i = \frac{Y_i}{\sum_i Y_i} \quad (7)$$

These equations were obtained through algebraic manipulation of the free Gibbs energy expressions, in order to obtain a final mathematical formulation which can deal more efficiently with the infinitesimal amounts of the trial phase. Complete description of the algebraic development can be found in Michelsen (1982). The values of Y_i that minimize Equation 6 are also the roots of Equation 5. In order to determine the mixture stability, it is necessary to solve just one of these equations, however, both were used in this work because the modification in ARS method was made by inclusion of an algorithm for solving nonlinear algebraic systems. The mixture instability condition is that the global minimum of Equation 6 has TPD (Y_i) < 0. The minimums of Equation 6 (or roots in Equation 5) are called stationary points and these values are, generally, found near the composition of phases in equilibrium, when a mixture is unstable.

2.3 Modifications in ARS method for determining mixtures stability

The goal of the proposed modification is to use the ability of the ARS method in generate promising values in search space together with the high convergence rate of the Newton method. This is done by using the stored coordinates as promising (determined using Equation 6), eliminating the stage of solution refinement in the ARS method (reduction of the hyper-ellipse radius by increasing the parameter δ) and using these values to solve the problem represented by Equation 5 using the Newton method.

As the only restriction for the decision variables is the positiveness, it was also proposed the following modification to generate random points avoiding negative values:

$$x_{i,j}^{k+1} = x\_ot_i^k \times exp\left\{\frac{R_i}{x_{ot_i}^k \delta}\left[B_i\left(A_i \Psi_{\mathrm{i,j}} - 1\right)\right]^{\delta}\right\} \quad (8)$$

Bringing the specific variables from stability problem to optimization problem, $x_{i,j}^{k+1}$ represents $Y_{i,j}^{k+1}$ which by Equation 7 is directly related with the molar fractions. As the molar fractions exist within a defined range it is more advantageous to use these values (y_i) instead of those (Y_i) to calculate the metric M, becoming a more robust criterion to evaluate the coordinates generated at each iteration k.

2.4 Performance indicators

When using stochastic methods, the number of objective function evaluations and the obtained solution can be different for each run the method is applied. Thus, for comparative analysis of different stochastic methods, efficiency and robustness indicators were used, as defined below, respectively.

1 – Average number of objective function evaluations and its standard deviation;

2 – Robustness (η): the robustness indicates the percentage of success to determine the global minimum of the problem.

$$\eta = 100\,\frac{n}{N^*} \quad (9)$$

where n is the number of times that the method correctly solved the problem, finding the global minimum, and N^* is the number of tests for each problem.

2.5 Solving the Flash problem

To solve multiphase and multicomponent flash problem from Rachford-Rice equation, routines have been implemented using the successive substitutions method, as shown by Leibovici and Neoschil (1995). An important point in this topic is the initial guess used in numerical procedures; as mentioned by Heidemann and Michelsen (1995), this method can be very unstable, especially for very asymmetric mixtures such as water and oil and polymer-solvent mixtures. In this work, it was used the coordinates of the minimum found in the stability problem to start the numerical methods. As the mixtures treated in this work are cases where the stability problem presents many minima, the implemented algorithm with the numerical procedures for resolution of the flash problem was started with different combinations of these coordinates.

3. Results

The optimization methods discussed previously were tested with a series of mixtures stability problems. Due to the paper length limitations, only two cases are discussed here:

Mixture 1: Methane-hydrogen sulfide at 191.15 K and 40.53 bar with 50% in molar fraction (Michelsen 1982; Nichita *et* al., 2008; among others). This problem has been formulated with PC-SAFT equations of state, with a global minimum of -0.0779 whose coordinates in molar fraction are [0.9809 0.0191] and with SRK whose minimum is -0.0766 with coordinates in molar fraction of [0.9791 0.0209]. The values of *kij* parameter were obtained, for the PC-SAFT model, in Nichita *et* al. (2008) and for SRK in Harding and Floudas (1999).

Mixture 2: Ethanol, acetic acid, ethyl acetate, water and carbon dioxide at 333.15 K and 58 bar, with composition in molar fraction of [0.2027 0.2026 0.1611 0.1617 0.2719] (Solórzano et al., 2004). This problem was formulated using PR equation of state for which the global minimum is -2.5783 with coordinates in molar fraction of [0.39110 6.7 × 10-05 7.74 × 10-07 0.60767 0.00115]. The values of *kij* parameters were obtained in Solórzano *et* al. (2004).

In both cases many local minima can be observed, this characteristic makes these problems a challenge to optimization methods. Table 1 presents the performance of the original and hybrid ARS methods for 300 tests with each problem (examples 1 and 2).

Table 1: Performance of ARS and hybrid ARS (HARS).

Case	Example 1				Example 2	
Model	SRK		PC-SAFT		PR	
Method	ARS	HARS	ARS	HARS	ARS	HARS
Robustness	52.33	99.33	32.00	95.67	97.33	97.00
Evaluation avarege number	397.88	218.14	380.88	162.94	3405.30	1599.19
Standard deviation	42.31	31.35	38.97	37.51	545.33	307.00
Minimal number of evaluations	325	151	319	99	2296	1015

The number of evaluations computed for HARS method is number of evaluations for generating promising values plus the number of iterations to solve the equations system represented by Eq. 5 with all generated promising points. As shown in Table 1, the hybridization of the ARS method decreased the required evaluations number for solve stability problem in both examples. Moreover, except for example 2, in which both methods had gotten good robustness, robustness of the HARS method for example 1was very superior to ARS for both equations of state. An important thing is that in all cases and tests presented, the initial guesses were always the trivial solution coordinates. This aspect shows that both, ARS and hybrid ARS, are not influenced by initial guesses values. Another important point is that when the mixture is stable, the trivial solution is the global minimum of the problem ($TPD = 0$).

Regarding the FMINUNC method, this solved the stability problem of the Mixture 1 with 112 objective function evaluations. However, this method has led to a local minimum with a value of -0.06598. The DIRECT method, even found the global minimum, needed 1289 evaluations to determine it. For Mixture 2, the FMINUNC method again established a local minimum, whose value is -0.04567 with 156 objective function evaluations. The DIRECT method needed 1431 objective function evaluations and found the global minimum.

Regarding the phase equilibrium problem, both mixtures are cases where exists, beyond the correct solution, another numerical solution that satisfies the equilibrium criteria (equality of the chemical potentials in all phases and mass balance restrictions), however, in terms of the Gibbs free energy, this solution does not represent a global minimum. Because of this, the stability analysis is used to validate the solution, showing the local minimum solution is unstable and the global minimum is stable. Tables 2 and 3 present these solutions for the two mixtures.

Table 2: Solutions of the phase equilibrium for Mixture 1.

Equation of State	Equilibrium type	Molar Fraction		Z = PV/RT	Condition
SRK	LL	0,91097	0,08903	0,1627	unstable
		0,12518	0,87482	0,0939	
SRK	LV	0,97838	0,02162	0,5502	stable
		0,12441	0,87559	0,0939	

Table 3: Solutions of the phase equilibrium for Mixture 2.

EOS	Equilibrium	Molar Fraction					Z = PV/RT	Condition
		Ethanol	Ac. Ac	Ethyl Ac.	Water	CO_2		
PR	LL	0,4955	0.00116	$1{,}18\times10^{-5}$	0,49465	0,00869	0,1458	unstable
		0,0631	0,29863	0,23788	0,00300	0,39735	0,0855	
PR	LLV	0,4963	0,00126	$1{,}37\times10^{-05}$	0,49442	0,00796	0.0857	stable
		0,0661	0,31538	0,25107	0,00323	0,36419	0.1482	
		0,0024	0,00141	0,00471	$4{,}29\times10^{-05}$	0,99141	0.7442	

The stability of the solutions in the flash problem was tested using hybrid ARS method, which correctly indicated stable and unstable solutions. For both mixtures, the

flash procedure was initialized with different values for each phase compositions related to some solution of the stability problem.

4. Conclusions

In this work a modification for the ARS method was proposed, named as hybrid ARS. The performance of the hybrid ARS method in stability analysis problems was compared with the conventional ARS method, a quasi-Newton, and DIRECT. Hybrid ARS method showed to be a trustworthy method with great applicability potential for this kind of problem. This method showed high robustness in all analyzed examples, which can be characterized as being of high complexity. Moreover, the hybridization of the ARS method significantly decreased the average number of objective function evaluations needed to find global minimum, being more efficient, also, than DIRECT method. Although FMINUNC establish a solution with few evaluations of objective function, this type of method is not reliable due to its dependence on initial guesses. The ARS and hybrid ARS method did not show this feature so that even the trivial solution can be used as initial guesses of the variables in the stability analysis procedure. Another important point is that these characteristics of reliability and performance delivered by the hybrid ARS method were observed for the three types of equation of state: Soave-Redlich-Kwong (SRK), Peng-Robinson (PR) e PC-SAFT (Perturbed Chain – Statistical Associating Fluid Theory).

Abstract

The monitoring of polymer properties is frequently performed through sampling and off-line measurement of quality parameters in lab scale. Because of the long time required to perform off-line analyses, off-line data are generally inadequate for control purposes. As impurities cannot be detected in-line and can exert significant influence on the polymerization kinetics, modifications of some important quality parameters (such as the morphological characteristics of PVC particles) can only be detected at the end of the polymerization, causing major production losses. In the present work it is shown for the first time that it is possible to monitor some of the morphological properties of PVC (such as the bulk density, BD, the cold plasticizer absorption, CPA, and the average particle diameter D_p) *in situ* and in real time with the help of near infrared spectroscopy (NIRS) in suspension polymerization processes.

Keywords: Near Infrared Spectroscopy (NIRS), Suspension Polymerization, Poly(vinyl chloride) (PVC), Polymer Particle Morphology, Real Time Monitoring.

1. Introduction

Development of tailored polymer resins is required for several applications in different fields. In order to achieve the production of a polymer resin with specified end-use properties, the availability of efficient control techniques is of fundamental importance. A gap between the polymerization process and the control technique must be bridged with accurate and robust instrumentation for on-line and in-line monitoring and calculation. The lack of instruments that are able to measure and monitor the quality of the polymer resin has been recognized by many authors as the most important problem in the field of polymerization reactor control. The complex nature of typical polymerization systems is one of the main difficulties for development of adequate monitoring instruments. Despite the huge efforts invested for development of reliable and robust monitoring techniques in recent years, important polymer properties cannot be measured on-line. On the other hand, off-line measuring of polymer properties can be very laborious and take a lot of time. Besides, there is a difficult task of relating molecular properties (which can usually be evaluated remotely in the laboratory, such as

‡ Current Address: Instituto de Química, Universidade de Brasília, *Campus* Universitário Darcy Ribeiro, CP 04478, 70910-900, Brasília, DF, Brazil, E-mail: fmachado@unb.br

the average molecular weight, average particle size, and copolymer composition, among others) and final end-use properties (such as brightness, thermal and mechanical resistance, stiffness, etc.), whose quantification is much more complex and usually determined for final products only (Santos et al., 2005).

Sampling devices intended for on-line applications are often sophisticated and complicated, requiring careful design and installation procedures, which very frequently cannot be performed in real industrial sites. Additionally, several available monitoring instruments are so expensive that installation and maintenance costs can be prohibitive for most industrial facilities. According to Santos et al. (2005), it is not surprising to observe that there is an enormous gap between the control applications developed in the research laboratory and the actual control applications implemented industrially.

A major breakthrough in the area of on-line polymer reaction and quality monitoring was achieved when conventional sensing techniques were coupled to fiber optics, making *in situ* measurements and remote analysis possible for a large number of applications (Kammona et al., 1999). Among them, monitoring techniques based on the NIRS are very useful for a number of practical applications in the field of polymer reaction engineering. When quantitative analyses are necessary, NIRS monitoring technique provides process information, which is used to determine the calibration model that after validation with actual process data is employed to infer the final polymer properties. In this context, it is shown for the first time that it is possible to monitor some of the morphological properties of PVC (such as the bulk density, BD, the cold plasticizer absorption, CPA, and the average particle diameter D_p) *in situ* and in real time with the help of near infrared spectroscopy (NIRS) in suspension polymerization processes.

2. Experimental Procedure

2.1. Polymerization Reactions

The experimental apparatus consists of stainless-steel autoclaves with volumes of 0.001 and 0.1 m^3 and maximum working pressure and temperature of 20 bar and 250ºC, respectively. A thermocryostatic bath was used to control the reaction temperature. The agitation speed could be varied in the range of 0 to 2400 rpm and a Pt 100 thermocouple probe was used to monitor and control the reactor temperature.

NIR spectra were collected with the help of a NIRS-6500 equipment from NIRSystems Inc, configured to scan the spectral region ranging from 400 to 2500 nm, in reflectance and interactance mode. The instrument was connected to the bench scale reactor by using a bundle of optic fibers terminated with a 1-in diameter probe. The NSAS software (*Near-Infrared Spectral Analysis Software*) was used for data acquisition, spectral mathematical treatments, and partial least square regression. The acquisition interval of NIR spectra was adjusted to 300 seconds.

The main process variables were varied and coded based on a three-level factorial design, as illustrated in Table 1. The polymerization reactions were carried out in accordance with a factorial Taguchi planning, as shown in Table 2. A standard recipe consisting of poly(vinyl alcohol), used as a suspending agent, initiator, water, monomer and additives was charged into the reactor to perform the polymerization reactions. The detailed recipe will not be presented for confidential reasons. The agitation speed was selected as one of the design variables because it modifies the mechanism of break-up and coalescence of VCM droplets, which changes the average particle size and the PVC morphology (Jahanzad et al., 2005; Johnson, 1980; Lyoo et al., 2005 and Vivaldo-Lima et al., 1999). The temperature was selected to control the resin K-value (an indirect

measure of the average molecular weight and the processability of the PVC resins) (Burgess, 1982). The initiator amount (A) was selected as a design variable because it can be used to control the rate of reaction and the rate of heat production. The suspending agents (B and C) act on the suspension stability and on the particle size distribution (Burgess, 1982; Alexopoulos et al., 2007; Kichatov et al., 2003; Saeki and Emura 2002). At each particular experimental condition spectra were collected in the spectral regions of visible and near infrared in order to observe the effect of the process variables on the final properties of PVC resin.

Table 1 – Three-Level Variable Values

Variable	Unity	Level 1	Level 2	Level 3
X_1 - Speed ω	rpm	X	1.58X	2.16X
X_2 - Temperature	°C	Y	1.05Y	1.10Y

2.2. Results and Discussion

2.2.1. Polymerization Analysis

The spectra presented in Figure 1 indicate spectral changes during the polymerization in the near infrared region between 1400 and 2100 nm. According to Santos et al. (1998, 2000), the region between 1600-1700 nm is sensitive to modification of the average size of the suspended droplets. As batches were performed at very different conditions, as shown in Table 1 and 2, this can possibly indicate that the PVC particle morphology can be changed along the reaction course; however, these changes could also be generated by others factors, instead of particle morphology. Thus, the influence of morphology on the NIR spectrum should be analyzed with the help of mathematical and statistical

techniques, such as partial least squares (PLS). The development of most NIR-based monitoring and control applications in suspension polymerization processes only becomes possible because of reflection, refraction and scattering of light on the surface of the suspended particles. The large intensity of scattering (usually considered as a disadvantage in most applications), when compared to absorption, is fundamental for determination of the morphological features of polymer beads in these systems. In the particular case of MVC suspension polymerization, it is important to notice that the average diameter of the pores of the final PVC particles has the same magnitude of the wavelengths in the NIR region (ranged from 1 to 2 μm). Thus, light scattering can be strongly influenced by the particle structure.

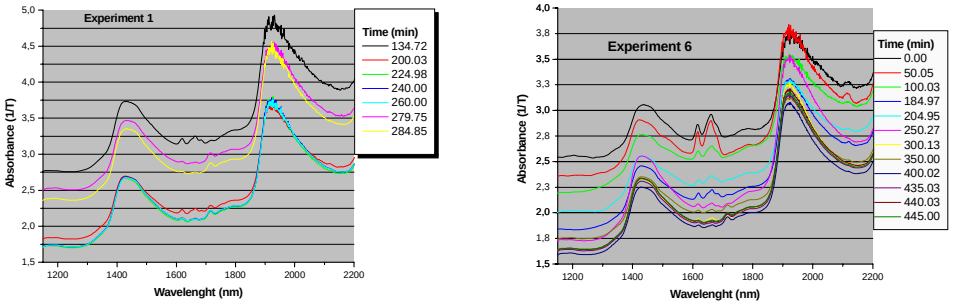

Figure 1 - Spectral Evolution along the Polymerization Time.

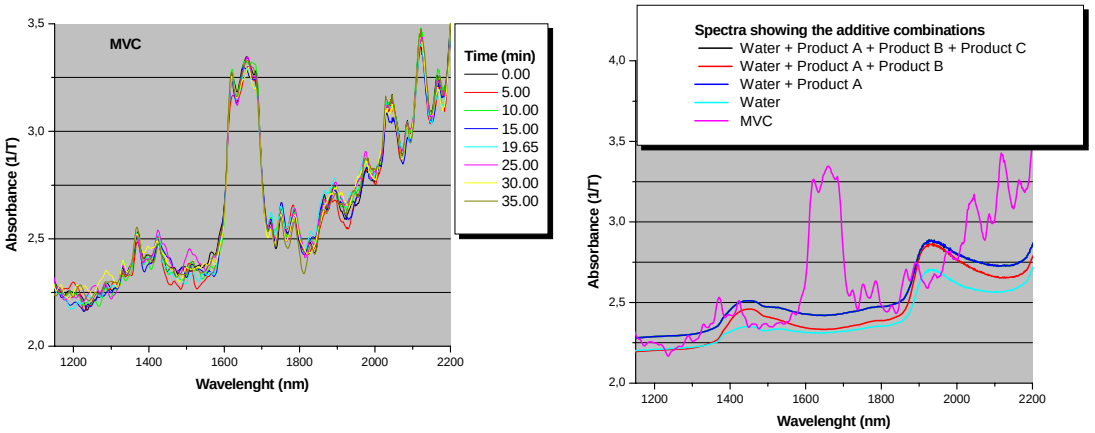

Figure 2 - Spectra of VCM and Additives used in the polymerization.

As one can see in Figure 2, the spectral absorbance presents a strong peak in the 1600 nm region, showing that this region can be useful for quantitative analyses. Based on the observations of the spectra obtained from different experimental conditions, it can be said that spectral variations are different in the whole experimental region, showing that NIRS is sensitive to the variations of the proposed experimental values. Assuming that the different experimental conditions could lead to PVC particles with different morphological characteristics, NIRS can be employed to monitor the morphological properties of PVC particles and could be used for control purposes at plant site.

2.2.1. Calibration Studies

Empirical calibration models were obtained based on the NIR spectra and PVC morphological properties obtained during actual runs. Polymer samples obtained at the end of the polymerization batches were used for determination of important resin

properties, such as BD, CPA and Dp. The standard PLS technique was used for model building. The calibration model for BD was built with eight factors, while models were built with ten factors for the others morphological parameters (CPA and Dp). Calibration was performed only with the final batch samples, because quality parameters BD, CPA and Dp can be measured only when the polymerization is finished. As shown in Figure 3, the calibration models reproduce very well the experimental data, which confirms the quality of predictions given by these models. (Models were validated with additional data, but results are not shown for lack of space.)

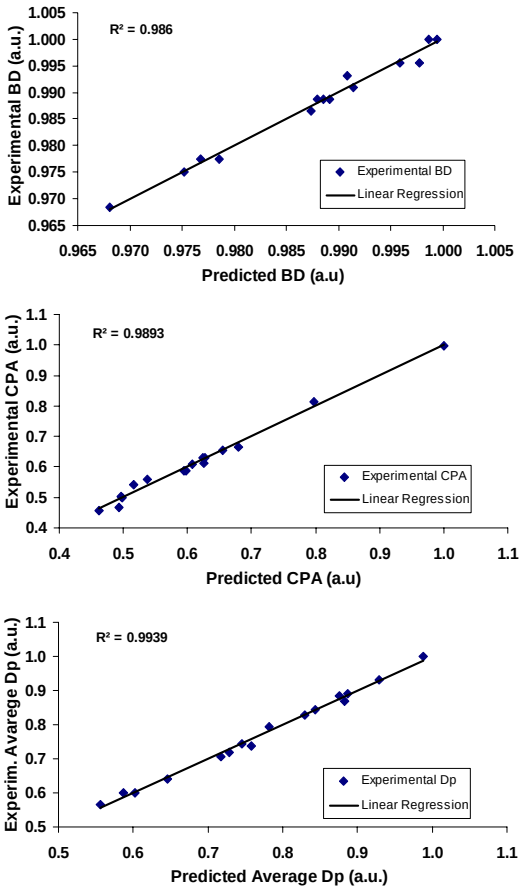

Figure 3 – Prediction of the PVC Morphological Properties. **(A)** Bulk Density; **(B)** Cold Plasticizer Absorption; **(C)** Average Particle Diameter.

The evolution of morphological properties of PVC along the batch is analyzed in the second part of this work (de Faria Jr. et al., 2009) and the reader should refer to this publication for more detailed information about dynamic trajectories. De Faria Jr. et al. (2009) showed that it is possible to follow the dynamic evolution of morphological properties (for example, bulk density and cold plasticizer absorption) in real time, in heterogeneous VCM processes, using NIR spectroscopy technique.

3. Conclusions

Several vinyl chloride polymerizations were performed in suspension mode to evaluate the NIR spectral response to different process variables. Obtained results show excellent

agreement between experimental data and predicted values given by the calibration models and indicate clearly that the NIRS technique can be used successfully to monitor properties related to PVC particle morphology. It is very important to emphasize that this is the first time in the open literature that NIR spectroscopy is used to predict morphological parameters of suspension PVC particles, such as BD, CPA and D_p. Calibration models reproduce available experimental data fairly well, showing that morphological parameters of PVC particle can be followed in-line during the polymerization process. Based on this, the in-line monitoring of these variables during the VCM polymerization with a NIR probe could be used as a fundamental piece during the implementation of advanced monitoring and control schemes, aiming at controlling the morphology of PVC resins.

Abstract

The present work focuses on the thermodynamic modeling of the Bunsen section of the Iodine-Sulfur thermochemical cycle for hydrogen production on the basis of a combination of UNIQUAC activity coefficient and solvation models. The complexity of the material system, two immiscible electrolyte aqueous phases (H_2SO_4 rich and HI rich), is managed by defining an equivalent material system able to capture the main physical phenomena. Only the key species involved and their mutual interactions are taken into account, reducing the number of parameters to be estimated from a hundred to only 15. Results show a good agreement with published experimental data, with a better description of the impurities in the HI_x phase than in the sulfuric acid phase.

Keywords: H_2 production, IS thermo-cycle, Bunsen section, liquid–liquid equilibria.

1. The Sulfur–Iodine Thermochemical cycle

Hydrogen is considered to be one of the best energy carriers for the future. It can be produced from water by thermo-chemical cycles. The Iodine–Sulfur (IS) thermo-chemical water splitting cycle is one of the most promising (O'Keefe *et al.*, 1982), chosen among one hundred other possible cycles and expected to become a major source of massive hydrogen production combined with nuclear energy.
This cycle, depicted in figure 1, is divided into three sections, namely:

1. The Bunsen section (I), where sulfur dioxide reacts with excess water and iodine to produce two immiscible electrolyte aqueous phases: the upper phase containing mainly water and sulfuric acid (H_2SO_4 rich phase) and the heavy phase with water, hydroiodic acid and iodine (HI_x phase).
2. The sulfuric acid concentration and decomposition section (II),
3. The hydroiodic acid concentration and decomposition section (III).

In the two last sections, intermediate acids break down upon heating to release oxygen and hydrogen respectively while water, iodine and sulfur dioxide are recycled in the system.
After modeling the phase equilibria of the HI_x section (Hadj-Kali *et al.*, 2009), we focus in this paper on the complex liquid – liquid equilibrium occurring in the Bunsen section.

2. The Bunsen reaction

The starting point of the IS cycle is the Bunsen reaction:

$$2\ H_2O + SO_2 + I_2 \leftrightarrow H_2SO_4 + 2\ HI \qquad \text{(R1)} \qquad [1]$$

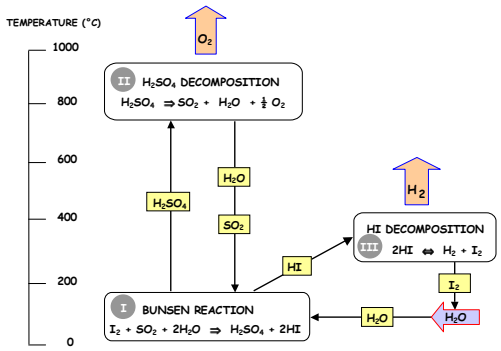

Figure 1. Sulfur – Iodine thermo-chemical cycle scheme.

This reaction is carried out at 120°C. With standard stoichiometry, its standard Gibbs free energy is positive: $\Delta G°(400\ K) = +82\ kJ.mol^{-1}$. In the late 1970s and early 1980s, General Atomics (GA, Normann *et al.*, 1981) found that the conversion is greatly improved by using excess iodine and water.

Excess iodine not only shifts equation [1] equilibrium towards the production of acids, but also causes the two acids to spontaneously separate into two aqueous solutions: hydroiodic rich (HI_x) heavy phase and sulfuric acid (SA) rich light phase. However, when this excess is too large, the compositions of the two phases stop changing because the iodine saturation point is reached.

Like iodine, the excess of water causes the equilibrium to be shifted forward but it also causes a substantial change in the reaction Gibbs free energy due to acids dilution. The sulfuric acid complexes with water and hydroiodic acid complexes with water and iodine, according to the following equations (Elder et al., 2005):

$$H_2SO_4 + 4H_2O \leftrightarrow (H_2SO_4 + 4H_2O)_{aq} \qquad \Delta G^{\circ,400\ K} = -66\ kJ.mole^{-1} \qquad (R2) \quad [2]$$

$$2HI + 8I_2 + 10H_2O \leftrightarrow (2HI + 10H_2O + 8I_2)_{aq} \quad \Delta G^{\circ,400\ K} = -104\ kJ.mole^{-1} \quad (R3) \quad [3]$$

Combining the three reactions (R1), (R2) and (R3) leads to a modified Bunsen reaction proposed by GA which has a negative Gibbs free energy: $\Delta G°(400\ K) = -88\ kJ.mol^{-1}$:

$$9\ I_2 + SO_2 + 16\ H_2O \leftrightarrow (2\ HI + 10\ H_2O + 8\ I_2)_{aq} + (H_2SO_4 + 4\ H_2O)_{aq} \qquad (R4) \quad [4]$$

3. Bunsen section thermodynamic modeling

3.1. Liquid – liquid equilibrium calculation basis

The liquid – liquid equilibrium between phases involves activities equality of each component *i* present in both phases, expressed in terms of activity coefficients γ_i by:

Equilibrium equations: $$\gamma_i(T, \mathbf{x}) \cdot x_i - \gamma_i(T, \mathbf{x}') \cdot x'_i = 0 \qquad i = 1, Nc \qquad [5]$$

At given temperature, pressure and global compositions **z**, the compositions of each phase at equilibrium (**x** and **x'**) and the split ratio τ are calculated by solving an isothermal liquid-liquid equilibrium flash model which includes equations [5-7]:

Partial mass balances: $$z_i - (1-\tau) \cdot x_i - \tau \cdot x'_i = 0 \qquad i = 1, Nc \qquad [6]$$

Summation equation: $$\sum_i x_i - \sum_i x'_i = 0 \qquad [7]$$

An excess Gibbs free energy model is then needed to calculate the activity coefficients.

3.2. The new model versus previous models

In order to compute activity coefficients, a symmetric convention is adopted that combines the UNIQUAC model (Abrams and Prausnitz, 1975) with Engel's electrolytic solvation model (Engels, 1990): the first model accounts for short range interactions by means of two terms (combinatorial and residual) and the second model accounts for complexes formation.

Until this work, all published models for this system were derived from a classical electrolyte approach. First, Davis and Conger (1980) proposed to apply the Pitzer-Debye-Hückel model (Pitzer, 1980). Later Mathias (2002) has used the electrolyte-NRTL model developed by Chen and Evans, (1986) that combines the Pitzer-Debye-Hückel model for long-range ion-ion electrostatic interactions with the NRTL theory (Renon and Prausnitz, 1968) for short-range energetic interactions. Recently, O'Connell (2008) proposed an improvement of Mathias' model.

3.3. Model description

The proposed model considers three solvation reactions:

1. Solvation of HI by H_2O:

$$m_1H_2O + HI \leftrightarrow 2C_1 \qquad \text{(RS1)} \quad [8]$$

with $\{2C_1\} \equiv \{[H_3O^+,(m_1\text{-}1)H_2O]; I^-\}$

2. Solvation of H_2SO_4 by H_2O:

$$m_2H_2O + H_2SO_4 \leftrightarrow 2C_2 \qquad \text{(RS2)} \quad [9]$$

with $\{2C_2\} \equiv \{[H_3O^+,(m_2\text{-}1)H_2O]; HSO_4^-\}$

3. Solvation of HI by I_2 in the presence of water:

$$m_1H_2O + m_3I_2 + HI \leftrightarrow 2C_3 \qquad \text{(RS3)} \quad [10]$$

with $\{2C_3\} \equiv \{[H_3O^+,(m_1\text{-}1)H_2O]; [I_3^-,(m_3\text{-}1)\,I_2]\}$

where C_i are the resulting complexes, as defined by Engels (1990), and m_i the solvation numbers. The corresponding solvation constants K_i are function of the temperature:

$$K_i = exp\left(A_{K_i} + B_{K\,i}/T\right) \qquad [11]$$

Each solvation equilibrium introduces a new species, the complex C_i, and requests 3 parameters to be estimated: m_i, A_{Ki} and B_{Ki}. Therefore, the whole system with N_C=7 species (I_2, HI, H_2O, H_2SO_4, C_1, C_2, C_3), has 93 parameters to be estimated from experimental data: 84 parameters to estimate n×(n-1) UNIQUAC binary interaction parameters with their temperature dependence and 9 parameters for the three solvation equilibria. This number is too high in view of available experimental data.

3.4. Model assumptions

On the basis of the operating conditions of Bunsen reaction (water and iodine in large excess (O'Keefe *et al.*, 1982)), the very large immiscibility gap between these two species (Kracek, 1931) and the presence of I_3^- ions in the solution (Palmer and Lietzke, 1982), a first series of hypotheses can be formulated:

a. Total dissociation of both acids (HI and H_2SO_4) in the presence of an excess of water; the second acidity of H_2SO_4 being neglected.
b. Solvation of all H^+ ions by three H_2O molecules, independently whether they come from HI or H_2SO_4 totally dissociated.

The hypotheses a and b enable to substitute the measured species HI and H_2SO_4 by two apparent species, that we write $[HI,3H_2O]$ and $[H_2SO_4,3H_2O]$. They correspond to the complexes $\{[H_3O^+,(m_1\text{-}1)H_2O]; I^-\}$ and $\{[H_3O^+,(m_2\text{-}1)H_2O]; HSO_4^-\}$ of solvation reactions (RS1) and (RS2) with $m_1 = m_2 = 3$.

c. Solvation of each hydrated complex [HI,3H_2O] by one mole of I_2 (m_3=1) following the reaction (RS3). The resulting complex is noted {[HI,3H_2O]; I_2} and corresponds to {[H_3O^+,(m_1-1)H_2O]; [I_3^-,(m_3 – 1) I_2]} with m_1=3 and m_3=1.

As a result, the number of species drops from 7 to 5 whereas the number of parameters to identify drops from 84 to 40, with only 2 solvation parameters. It is still too much regarding the number of available experimental data. Thus, a second series of hypotheses is formulated about binary interactions:

d. The [H_2SO_4,3H_2O] hydrated complex interacts like water with other species. Engels' results (1990) on H_2O–H_2SO_4 vapor-liquid equilibria modeling showed that the interaction between water and the solvation complex of H_2SO_4 by H_2O is negligible.
e. The complex {[HI,3H_2O]; I_2]} interacts like iodine with other species.

Note that the hypotheses d and e imply that the chemical theory alone allows to partially represent the non ideal behavior of the solution.

Finally, the number of parameters of the reduced model drops to 14 (including temperature dependency of UNIQUAC A_{ij} binary interaction parameters and 2 solvation parameters) and the binary interaction parameters matrix becomes:

Table 1. Binary interaction parameters matrix.

	I_2	{[HI,3H_2O]; I_2}	H_2O	[H_2SO_4,3H_2O]	[HI,3H_2O]
I_2	0		A_{12}		A_{13}
{[HI,3H_2O]; I_2}					
H_2O	A_{21}		0		A_{23}
[H_2SO_4,3H_2O]					
[HI,3H_2O]	A_{31}		A_{32}		0

The new species [HI,3H_2O], [H_2SO_4,3H_2O] and {[HI,3H_2O]; I_2} are created in the data base of Simulis® Thermodynamics properties server and their UNIQUAC parameters r_i and q_i are estimated according to Bondi's group contribution method (Bondi, 1964).

4. Available experimental data

Nowadays, available experimental data were published by Sakurai *et al.*, 1999, 2000; Giaconia *et al.*, 2007; Lee *et al.*, 2008. The influence of HI (k), I_2 (m) and H_2O (n) mole numbers for one sulfuric acid mole on liquid-liquid equilibria is studied. The data points are noted 1/k/m/n. General Atomic typical stoichiometry of reaction (R4) corresponds to a 1/2/8/14 data point. Most of those data are compiled in Lee et al. (2008). Covering the largest temperature range from 25°C to 120°C, they are used in this work.

5. Results and discussion

The reduced model reproduces demixtion for all experimental data. Table 2 reports the mean and median relative differences between experimental and calculated molar fractions at each temperature. The results highlight that the relative errors are smaller for the main species (H_2O, HI, I_2 in HI_x phase and H_2O, H_2SO_4 in SA phase) than for impurities (HI, I_2 in SA phase and H_2SO_4 in HI_x phase) in both phases. That is because impurities experimental absolute values are small and lead automatically to larger relative errors and they likely bear larger uncertainties. Otherwise, there are no significant differences between the various temperature sets, hinting at a reasonable temperature dependency of the parameters.

Table 2. Mean and median relative differences between experimental and calculated molar fractions upon the data of Lee et al. (2008)

T (°C)	All species		Impurities		Main species	
	mean	Median	mean	Median	Mean	median
25	13.5%	3.4%	30.5%	30.6%	3.3%	1.9%
40	17.1%	6.6%	32.7%	18.2%	7.7%	3.1%
60	20.0%	9.9%	41.9%	30.2%	6.9%	3.7%
80	16.0%	7.3%	31.8%	27.1%	6.5%	3.3%
100	20.5%	7.6%	45.6%	37.8%	5.5%	1.6%
120	15.9%	4.2%	33.2%	27.9%	5.6%	1.5%

Figure 2 present results by comparing the calculated and experimental molar fractions for HI_x phase at 80°C. The histograms below detail the variation of errors with variables 'm' and 'n' for a given composition ($HI/H_2SO_4/I_2/H_2O$) = (1/2/m/n).

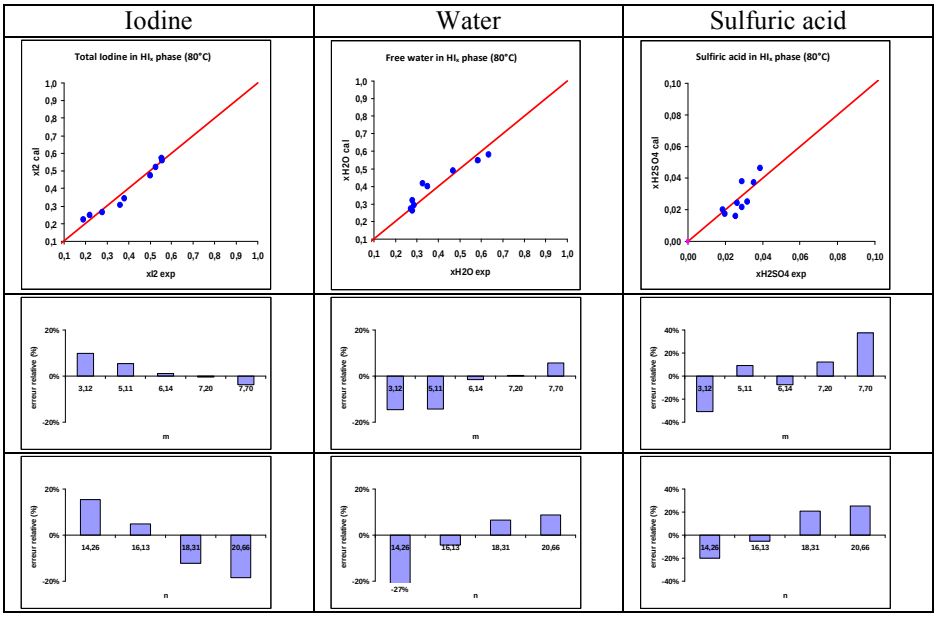

Figure 2. Calculated compositions versus experimental data for the HI_x phase at 80°C: main species are represented by water and iodine and impurities by sulfuric acid.

6. Conclusion

To our knowledge, for the first time a thermodynamic model representing the liquid-liquid equilibria of the Bunsen section of the Sulfur – Iodine thermochemical cycle over a large temperature range is proposed. This model is based on UNIQUAC's activity coefficient model combined with solvation equilibria.

Due to the high level of complexity of the system and the lack of experimental data, a fine description of all species and phenomena cannot be obtained. The formulation of

sound hypotheses, concerning the species present and their interactions, allows to reduce significantly the number of parameters and enables their estimation. The reduced model reproduces demixtion for all data points with an acceptable mean relative error: below 6% for the main species (water and sulfuric acid in the H_2SO_4 rich phase; water, iodine and hydrogen iodide in the HI_x rich phase) and below 30% for the impurities (iodine and hydrogen iodide in the H_2SO_4 rich phase; sulfuric acid in the HI rich phase).

Abstract

The simulation of crude oil distillation units, necessary for the optimization and the on-line performance assessment is very sensitive to the characterization of the feed. The conventional on line characterization technique is based on considering that the crude oil feed is the combination of known crude oils present in a database combined by volume average. Alternatively, a technique based on near-infrared spectroscopy that is able to characterize the petroleum on-line was implemented in order to characterize the crude oil. Prediction models for the main physico-chemical properties have been developed using chemometrics. For Real Time Optimization (RTO) a reference model must be frequently adjusted to fresh operation data. The adaptation of the model is necessary in order to ensure that it represents the system even if there are changes in its constitutive parameters. This feature also ensures that the mathematical optimization problem to be solved in order to obtain the set points of a new operating mode for the process does represent an optimal solution, or at least is close to it. Both the characterization techniques were applied to petroleum samples available for a very long interval of operation (a year) and their result are introduced into the detailed model that is adjusted to the operating data available for this same time range. The accuracy of the predictions shows that the new on-line technique would drive the system to better operating modes.

Keywords: Petroleum; Near Infrared Spectroscopy; Real Time Optimization.

1. Introduction

Real-time characterization of crude petroleum is an important objective for the petroleum industry because it has been pointed as the main factor for the increase in productivity (Dhaval et al., 2003). The crude distillation unit (CDU) is at the heart of any petroleum refinery and is one of the most complicated operations in the field of separation processes. The products from CDU are basically mixtures of a great variety of hydrocarbons that it is almost impossible to characterize in terms of individual components. Moreover, it is sufficient to characterize these products in terms of a certain number of properties, usually measured off line, in laboratory, at intervals of 8 - 24 h. (Dhaval *et al.*, 2003).

The simulation of a CDU separation processes involves many complex nonlinear relations between independent and dependent variables of the system, although there are no chemical reactions. The independent variables are usually crude oil properties and the manipulated variables of the CDU, such as energy inputs, reflux ratios, and product flow rates; the dependent variables are the oil product qualities, the system operating performance and the plant profit (Chau-kuang *et al*. 2004).
Techniques based on near-infrared (NIR) spectroscopy have been used to characterize and classify Brazilian crude oil samples. Based on the spectroscopic data, prediction models of Simulated Distillation (SimDis), density (API degree) and viscosity were developed, using chemometrics and neural network techniques. The application of chemometrics to spectroscopic data in order to develop mathematical models allows the extraction of information in order to predict physical properties.

2. NIR spectroscopy

NIR is probably the spectroscopic technique with the most applications in industry in general and in the petroleum industry in particular (Hidajat *et al.* 2000; Hannisdal *et al.* 2005; Falla *et al.* 2006; Abbas *et al.* 2006). NIR region extends from 14000 – 4000 cm-1 (800-2500 nm). Absorption bands in the NIR region are related to the overtone and combination bands of the vibrations of functional groups (–CH, -NH and –OH). Highly overlapping absorption peaks make spectra too complex to be interpreted qualitatively and low sensitivity limits quantitative analysis. However, with advances in instrumentation and chemometrics, NIR spectroscopy has emerged as a valuable analytical tool. Mathematical algorithms extract useful chemical information from NIR spectral features. Analysis in the NIR region is particularly advantageous because it permits the usage of fiber-optic technology for remote sensing because various optical fibers are available as NIR radiation guides (Chung *et al*. 2007).

3. Crude distillation unit simulator

A good CDU simulator usually encompasses an analytical model for multi-component distillation based on equilibrium stage concept. However, perfect equilibrium is seldom achieved because of poor mixing, insufficient time of contact, etc., and hence, stage efficiencies must be incorporated in the equilibrium relations. Since there is yet no reasonable method to calculate these efficiencies accurately, these are actually treated as tuning parameters, which will allow the model predictions to match the plant performance. Efficiencies are functions of composition in both phases and other operating conditions and hence, can be expected to change with time (Dhaval *et al.*,2003).

4. Experimental

The SimDis curve (accumulated weight percent vaporized at a given temperature), the density and the viscosity were correlated to the NIR spectra. These correlations were obtained in a combination of chemometrics pretreatment techniques with artificial neural network models.

4.1. Samples

The crude oil samples came from storage tanks of a Brazilian refinery. The samples were sealed and stored below 5ºC in order to reduce the loss of light components and the natural degradation processes. API density and viscosity analysis were performed

following ASTM norms. Viscosity of the samples ranges between 5.1 cp and 36.1 cp and API from 23.3 and 33.0. More than a half of the samples have their API degree concentrated between 25 and 28. For viscosity the distribution is approximately uniform between 5 and 24 cp. There is an outlier with viscosity 36.1 cp.

4.2. NIR apparatus and software

The oil samples were analyzed in a NIR spectrometer, model FTLA2000 – 160 (ABB Bomem), 4000 – 14000 cm^{-1} region, with DTGS detector and Tg source. A type of fiber optics was used, model 041.202 – NIR fiber of length 6m (off-line tests). The transmittance NIR sensor, model 661.760-NIR, had a 1 mm path length. The fiber optics and the transmittance NIR sensor were from Hellma. NIR spectra (bi-dimensional data) were recorded over the wavelength range 5600 – 6100 cm^{-1} at 1.93 nm intervals, which corresponds to the first overtones region of C-H stretching vibrations.

4.3. Simulated Distillation

Simulated Distillation analyses (ASTM 7169) were performed on an Agilent Technologies 7890A gas chromatograph (GC), equipped with cold-on column (COC) inlet, flame ionization detector (FID) and a cryogenic column oven system. An oxygen trap (Agilent Technologies) was used in the carrier gas line (helium) to remove traces of oxygen. The detector signal was recorded as area slices (time intervals) for consecutive increasing retention times. Agilent Chemstation B.03.01 software was used for data acquisition and simulated distillation software (Wasson) was used processing data as well as boiling point distribution of the samples. Prior to injection, the samples were diluted in carbon disulfide with low benzene content (Vetec) to about 2 wt%. High purity CS_2 was used as a solvent because of its miscibility with residues, low boiling point and low response factor in the FID. The injection volumes were 0.2 µL. The distribution of boiling points for carbon number standards from C5 to C120 (Analytical Controls) were obtained using a megabore capillary column MXT-500Sim Dist 6.0 m length, 0.53 mm ID, 0.15 µm film thickness (Restek). The GC oven was programmed from -20 to 425 ºC at a rate of 15ºC /min. External standard reference gas oil (Wasson) that resembles the samples of crude oil was used, diluted in carbon disulfide to about 2 wt %. A baseline compensation analysis, or baseline blank, was performed exactly as for a conventional analysis, except that no injection was done. The blank analysis was necessary due to the usual occurrence of chromatographic baseline instability, due to the extreme temperature conditions that make the column subject to bleed. The blank analysis must be performed periodically between sample measurements because the baseline varies slightly from sample to sample.

4.4. Prediction models

Models for prediction of the Simulated Distillation (SimDis) density (API degree) and viscosity were developed, using chemometrics and neural network techniques. The methodology developed is according to “Characterization of crude petroleum by NIR” of F.S. Falla et al. 2006.

In figure 1 parity plots for the prediction of 20% and 80% are presented.

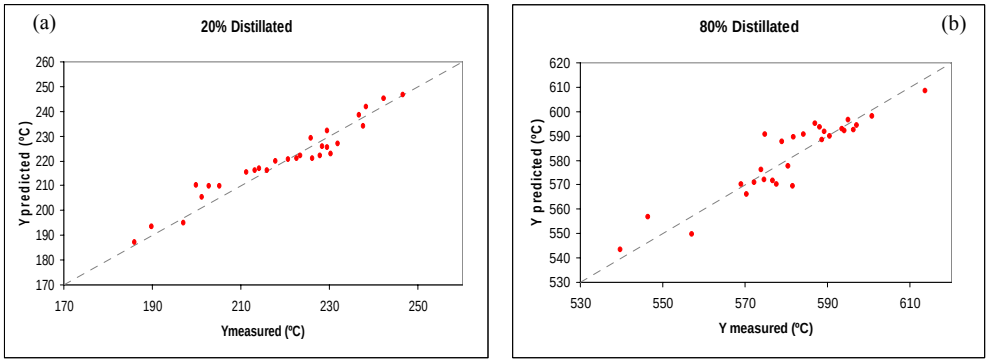

Figure 1- Parity plots for the prediction of (a) 20% and (b) 80% Distillated.

5. Methodology

A simulation model of five distillation columns from Henrique Lage (REVAP) refinery was built in Aspen HYSYS® simulation software in steady state mode. The objective is to monitor the results of the NIR analysis on the accuracy of predictions obtained through the process simulator.

In the simulation model oil characterization must be introduced. The idea is to introduce both characterization results, from the data base and obtained from NIR analysis and to assess the prediction of the models, by comparing the predictions with the data contained in the operation data base.

The procedure for the simulation is:

- The characterization of the petroleum is introduced in the simulation;
- The degrees of freedom of the system are set based on the data available on the process data base which is analyzed in order to select steady-state operating conditions (Carrillo Le Roux et al. 2008);
- As measurements are subject to errors a reconciliation step is performed.

To reconcile the variables, the optimizer tool in Aspen HYSYS® was used. Some values are corrected, interfering in other parameters, in order to minimize an error function of difference between refinery data (target) and calculated values.

The loss function for the first tower is given by:

$$L = \sum_i w_i . \left(\frac{F_i - F_i^{meas}}{F_i^{meas}} \right)^2 + \sum_j \left(\frac{T_j - T_j^{meas}}{T_j^{meas}} \right)^2$$

where F_i are the flows (Volumetric flow in m^3/h) and T_j are the temperatures (given in Kelvin). The weights w_i are related to the importance given to each measurement.

The SimDis distillation curve, the density and viscosity of some petroleum samples used at the refinery in the year 2007 were available. The first column is a preflash tower which has 15 stages. There are 14 measured variables related to this column available

from the refinery, where 5 of them are used as independent variables as this simulation unit has 5 degrees of freedom and 9 dependent variables.

The stabilizer tower is fed by naphta product from the preflash. Its model has 35 trays, a condenser, a reboiler, one inlet stream, one bottom outlet and three condenser draws. There are 15 variables measured at the refinery, where 4 of them are used as independent variables.

The bottom stream from the preflash column is fed to the third column, an atmospheric tower. Its model has 45 trays, a condenser, a reboiler, three pump-arounds, one side stripper, three inlet streams (including two vapor feeds) and seven outlets. There are 35 measured variables connected to this column available from the refinery, where 8 of them are considered independent.

The vacuum tower and the side vacuum column are not still considered in the model. Redundancy in process data is present for all the columns, because the number of variables is much bigger than the number of degrees of freedom.

6. Results

In the simulation of the preflash tower, 4 different sets of independent variables were assumed. Set 1 considers as independent the reflux flow, the gas flow (from the condenser), the naphtha flow, the subcooling temperature and the bottom reflux temperature. Set 2 considers as independent: reflux flow, gas flow, naphtha flow, bottom reflux flow and subcooling temperature. Set 3 considers: reflux flow, gas flow, bottom reflux flow, subcooling temperature and bottom reflux temperature. Set 4 includes: reflux flow, gas flow, bottom reflux flow, subcooling temperature and bottom temperature.

In order to minimize the loss function, all the flows considered in the calculation of each method were varied. Table 1 shows the value of the loss for different operation steady states of the refinery (and corresponding petroleum) and different methods.

Table 1. Value of the loss function for different input sets and operating points.

	P 1	P 2	P 3	P 4	P 5
Set 1	10,5	52,9	54,4	24,8	115,4
Set 2	4,5	24,8	16,5	11,6	23,9
Set 3	10,4	39,4	41,8	24,9	56,4
Set 4	12,3	40,5	44,1	27,7	57,4

According to table 1, at condition P1 the lowest loss is obtained while at condition P5 the biggest is reached. Set 2, that is the only one using 4 flows as input, had the best reconciliation.

A table 2 compares calculated and target parameters for the case that had minimum error that is set 2 and condition of operation P1.

Table 2. Calculated and measured variables for the case that presented minimum error.

Parameter	Calculated	Measured	Unit
Reflux volume flow	210,2	220,5	m3/h
Bottom reflux volume flow	667,1	645,8	m3/h
Bottom volume flow	1489,5	1418	m3/h
Naphtha volume flow	185,8	214,5	m3/h
Gas flow at standard conditions	1693,8	1700	Nm3/h
Top temperature	157,9	146	^{o}C
Bottom reflux temperature	433,8	375,8	^{o}C
Bottom temperature	313,2	288,4	^{o}C

7. Conclusion

The methodology is promising, because the simulation permits not only to compare the predictions but also to obtain the reconciliation of the measured variables. The real time characterization of the crude oil feed will allow the optimization problem to reach more realistic solutions.

A method of representation of petroleum by a real components substitute mixture

Franklin D.R. Cuellar [a] Galo A.C.Le Roux [a],

[a]*LSCP/CESQ - Department of Chemical Engineering, Polytechnic School - University of São Paulo. Av. Prof. Luciano Gualberto, n. 380, trav. 3, CEP 05508-900, São Paulo - SP, Brazil. E-mail address: galoroux@usp.br,*

Abstract

In the refining of petroleum it is important to predict the distribution of the products and their quality. Conventionally, petroleum is characterized by methods based on distillation analysis, like the True Boiling Point (TBP) and ASTM D86, which are the most usual analytical methods. In order to predict the distribution of the products and its relation to the operating conditions, steady-state simulation is extremely important. Conventionally, tens of pseudocomponents are generated in order to represent the petroleum. Pseudocomponents have individual properties that do not necessarily correspond to any real component and are obtained by semi-empirical methods. More recently, the approximation of the petroleum by a reduced set of real components has been proposed. In order to design the substitute mixtures, dynamic models representing the standard tests for TBP and ASTM-D86 were developed as differential algebraic equations (DAE). Results for the simulation of these properties, experimental results and properties obtained from some commercial programs are compared, showing that the models developed here are reliable.

Keywords: TBP, ASTM D86, Dynamic simulation .

1. Introduction

In the refining of petroleum it is important to predict the distribution of the products and their quality. Conventionally, petroleum is characterized by methods based on distillation analysis, like the True Boiling Point (TBP) and ASTM D86, which are the most usual analytical methods. The ASTM D86 determines the boiling range of the petroleum product by performing a simple batch distillation. The distillation is performed in a laboratory batch distillation unit at ambient pressure under conditions that are designed to provide approximately one theoretical plate fractionation. The TBP test method employs a fractionating column that has an efficiency of 14 to 18 theoretical plates operated at a reflux ratio of 5.

In order to predict the distribution of the products and its relation to the operating conditions, steady-state simulation based on first-principles, in terms of mass and energy balances and equilibrium relations, is extremely important. As the number of components is very high, the mixture composition cannot be directly used. Conventionally, tens of pseudocomponents are generated in order to represent the petroleum. Pseucomponents have individual properties that do not necessarily correspond to any real component and are obtained by semi-empirical methods. The appropriate parameters of characterization for use in thermodynamic models, such as critical temperature, critical pressure, critical volume, acentric factor and molecular weight is possible with the use of equations and empirical correlations.

More recently, the approximation of the petroleum by a reduced set of real components has been proposed (Eckert, 2005). The advantage of this approach is that the substitute mixture can be used in processes where chemical reactions take place. As the ability of modern computers to perform calculations is enormous, using a large number of real components is feasible and is no more necessary to use a reduced number of pseudocomponents. For real components, precise estimation of the critical properties is not an issue, because these are set *a priori* by the nature of the components. However the main challenge of this new method is determining the components and their quantity that are chosen to represent the original mixture. An important aspect to consider is the quality of data available, as for heavy oil very few information is available in the literature.

An important task is to fit the experimental information from the original mixture with the representation methods. Conventional analyses are standardized by the American Society for Testing and Materials (ASTM). The different standards that can be used to determine the characteristics of volatility in the mixture are the ASTM D2892, ASTM D86 and ASTM D1160.

The objective of this work is to generate the ASTM characterization curves D2892 and D86 by simulation from real components mixture. The ASTM standards were implemented in a batch distillation simulator. This step will make possible to compare the results obtained by simulation with the analysis obtained experimentally data. This will integrate a methodology for real components selection.

2. Method of real components

The method of representation of petroleum by a substitute mixture of real components avoids the use of empirical equations for determining the critical properties such as critical pressure, critical temperature, among others, essential for working with pseudocomponentes. For the ASTM D2892 (True Boiling Point curve) there are different analyses that can be applied to perform the selection of the substitute mixture:

a. Distribution of the Bubble Point (ASTM D2892).
b. Distribution of density.
c. Distribution of viscosity.
d. Distribution of Molecular Weight.

These characterization curves are dependent of the mass or volume fraction distilled. The curves (density, viscosity and molecular weight) should be related to the bubble temperature. The bubble point distribution is essential for an initial representation of the multicomponent mixture.

The temperature range of the bubble point (Initial Point-End Point), denoted as ST should be subdivide entirely in continuous intervals without overlapping,. The technical division of the intervals can be diverse. For example equidistant points can be considered, as a starting point, For the selection of the representative components the next steps are recommended:

• The curve (a) is at least necessary;
• One component is selected for each of subinterval of the curve (a).
• If some or all of the curves (b, c, d) are available, each of the properties available should be weighted to optimize the selection of representative components in accordance the following metrics:

$$\sum_{j=a}^{b,c,d} w_j \left(\frac{\zeta_{r,j,z} - \zeta_{m,j,z}}{\zeta_{m,j,z}} \right) \rightarrow \min_z \qquad (1)$$

Where j corresponds to the available properties (a, b, c e d) of components from the database respectively and the index m is attached to the measured values. The expression is calculated for the candidate component, z = 1 ,.... Zk. and the component with the lowest value of the expression above is selected to represent the range.
When the selection of real components is complete, the quantity of each component can be specified by analogy to the pseudocomponents to establish the mass or volume of fraction of distillate (Eckert et al., 2003). As defined in equation 2.

$$x_j = \left(\varphi_j^R - \varphi_j^L\right)\left(1 - \varphi_{LEj}^R\right) / \left(\sum_{i=LE+1}^{I} \left(\varphi_i^R - \varphi_i^L\right) \right) \qquad (2)$$

$$j = LE + 1, ..., I$$

where I is the total number of components, LE, is the number of light-end components, R, the right limit of the range, L, the left limit of the rang, and φ the volume (mass) fraction distilled

3. Results

This section presents the simulation results for the ASTM D86 and ASTM D2892 built in BatchSep (AspenTech 2006). The method of representation of petroleum by a real components substitute mixture was applied as the method for the approximation of the characterization. Aspen BatchSep is a tool for the simulation of distillation in batch mode that allows the generation of models with a friendly interface for the user.

3.1. Example 1

Greenfield and Lavole (1998) presented the results of the experimental curve ASTM D86 for a mixture of 7 hydrocarbons with known composition. These results are presented in figure 2. In this case, the comparison was drawn with another commercial simulator: Aspen HYSYS. The procedure used by the commercial simulator is not explicitly stated in the software manual.
Figure 1 shows that results are close but there are some differences: the D86 curves have different IP and EP for both commercial simulators. In the case of BatchSep the beginning of the curve presents a mild difference when compared to the experimental curve. This can be explained by the fact that a possible experimental loss of light components can introduce some error to the experimental results. Otherwise, the rest of the simulated curve fits well the experimental one.

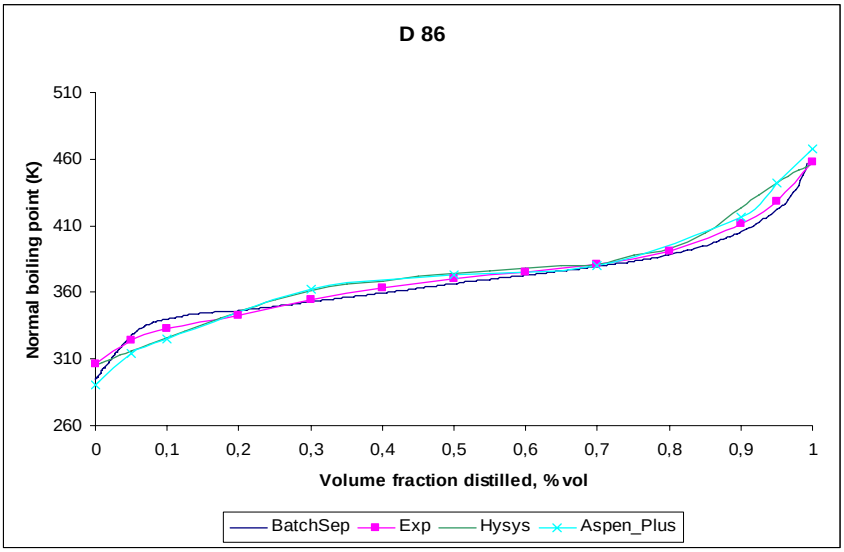

Figure 1. Prediction of the ASTM D86 with commercials simulation and the comparison with the experiment for a mixture of 7 real components.

3.2. Example 2

The experimental information presented by Miquel and Castells (1994) ASTM D 2892 data were used in order to obtain the substitute mixture of real components by the methodology proposed by Eckert (2005). The selected components and their proportion are summarized in Table 1.

Table 1. Components select into the Substitute Mixture

Name	CAS No.	Molar fraction
2,3,3,4-TETRAMETHYLPENTANE	16747-38-9	0.091711
2,4-DIMETHYLOCTANE	4032-94-4	0.114961
ISOBUTYLCYCLOHEXANE	1678-98-4	0.12756
2-ETHYL-P-XYLENE	1578-88-9	0.134563
METHYLCYCLOPENTADIENE-DIMER	26472-00-4	0.110087
1,3,5-TRIETHYLBENZENE	102-25-0	0.121606
PENTAMETHYLBENZENE	700-12-9	0.121845
N-HEPTYLBENZENE	1078-71-3	0.101989
1-ETHYLNAPHTHALENE	1127-76-0	0.075676

The curve generated with the substitute mixture in the simulator BatchSep is presented in figure 2.

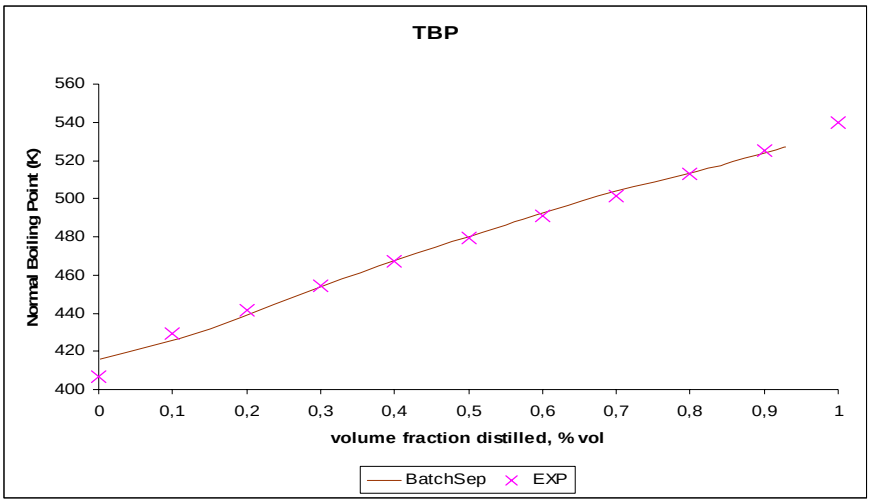

Figure 2. Prediction of the ASTM D2892 with Batchsep.

3.3. Example 3

The experimental information presented by Lojkásek and Ruzicka (1992) was used. The ASTM D 2892 and density data were used in order to obtain the real components substitute mixture by the methodology proposed by Eckert (2005). The selected components and their proportion are not summarized in this paper, but the final mixture contains 18 hydrocarbons obtained with weights $w_T = 1$ and $w_\rho = 1/100$ in equation (1).

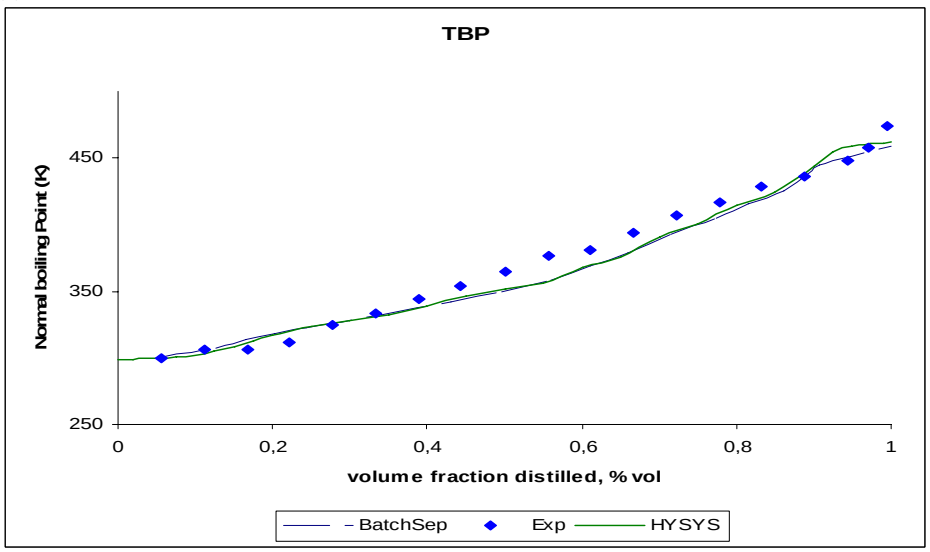

Figure 3. Prediction of the ASTM D2892 with BatchSep and HYSYS.

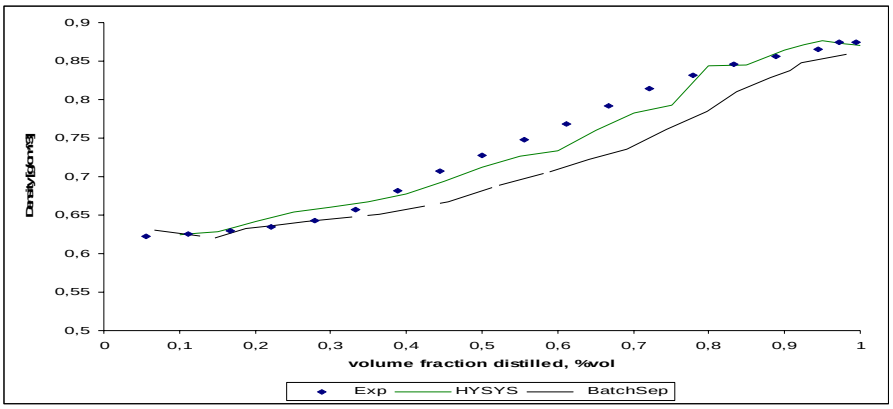

Figure 4. Prediction of the density with BatchSep and HYSYS.

The comparison of the experimental curves with the real components substitute mixture selected (BatchSep) and HYSYS (pseudocomponents) is presented in Figs 3 and 4. It can be observed that the match is fairly good, but the discrepancy is due to the availability of components in the thermodynamic data base.

4. Conclusions

The results presented in this paper show that the method of representation of petroleum by real components substitute mixture can be used in the simulation of complex mixtures and can replace the traditional method of pseudocomponentes. The algorithm suggested for the selection of the mixture needs to be replaced in order to have enough components across the range of temperature considered. This is the next step to be implemented that will generate mixed integer nonlinear problems. The real components substitute mixture must be compared also in the simulation of crude distillation units. This was already done but could not be presented here (Cuellar, 2009).

Abstract

Real-Time Optimization (RTO) applications consist of a paramount tool for the Refining and the Chemical Process Industries. It evaluates the chemical process operational conditions, calculates optimum operating conditions and sends setpoints to the plant in order to maximize the overall profit. The purpose of this paper is to report the sustain activities with respect to the RTO models for Olefins plants in a partnership formed by Aspen Technology, the world's leading supplier of process simulation software, and Braskem S.A., the Brazilian leading petrochemical company. Reliability on the RTO results leads the operators to consistently implement the suggested setpoints to the plants. In addition, operational results showed the RTO models were able to increase the ethylene production and reduce high valued chemicals losses, thus improving plant profit. The results also include drastic reductions in steam import rates.

Keywords: RTO, Olefins Plants, Sustain.

1. Introduction

Real-Time Optimization (RTO) applications are very powerful tools used to improve profitability of Refining and Chemical Process Industries. They consist mainly of a rigorous simulation model of the process coupled with managing applications, links to the plant control system and information databases. The integrated application is able to collect data from the plant and other sources, check their consistency, input them to the simulation model and determine after running an optimization cycle of parameterization and optimization cases, the optimal operating conditions that lead to maximize the plant profit. In 2005 Braskem decided to implement Advanced Process Controls (APC) and RTO in its two olefins plants located at Camacari Petrochemical Complex, Northeast of Brazil. Aspen Technology, the world's leading supplier of software for the refining and chemical industries was chosen for the project development, implementation and support.

The two Braskem RTO models started running in closed loop in 2007. Increase in high valued chemicals production along with reduction of product losses and utilities consumptions has already proven its value generated by project implementation. Due to its plant wide action and rather complex nature, APC and RTO require dedicated support by a team of engineers responsible to sustain the economical results that they return to the company. Training and commitment of operators to RTO are of

fundamental importance for the success of the project as they must be able to analyze and accept or reject the setpoints calculated by the optimizers. Care with information input to the models shall be taken on a daily basis, especially in a naphtha steam cracking unit, where feed composition changes may affect dramatically operating conditions and yields. Model setpoint calculations must also take production scheduling and planning into account. This work describes the activities required to sustain the value produced by the Braskem's Real-Time Optimizers.

2. RTO Aspen Technology Solution for Olefins Plants

AspenONE™ is the market-leading application suite that enables process manufacturers to implement best practices for optimizing engineering, manufacturing, and supply chain operations.

The RTO, Aspen Tech Solution for Olefins Plants is composed by main two modules. The first one is the plant model that is built in Aspen Plus™, which is a market-leading process modeling tool for conceptual design, optimization, and performance monitoring for the chemicals, polymer, specialty chemicals, metals and minerals, and coal power industries. The model is based on steady-state fundamental Engineering principles.

For Real-Time applications and large scope plant models, Aspen Plus™ offers the Equation Oriented mode, in which the plant steady-state models can be solved in Parameter Estimation, Data Reconciliation, Simulation and Optimization modes. In addition, Aspen Plus™ brings the DMO™ solver that solves the non linear chemical process model equations using the SQP algorithm. Moreover, Aspen Plus™ includes links to Technip's SPYRO ethylene cracker models.

The second module is Aspen OnLine™. It enables the execution of an Aspen Plus equation-oriented model for continuous online and closed-loop implementation. The tool contains a steady-state detection module and it also integrates the optimizer with Advanced Process Control (APC) tools. Figure 1 shows the online closed loop cycle for the Aspen Technology RTO application.

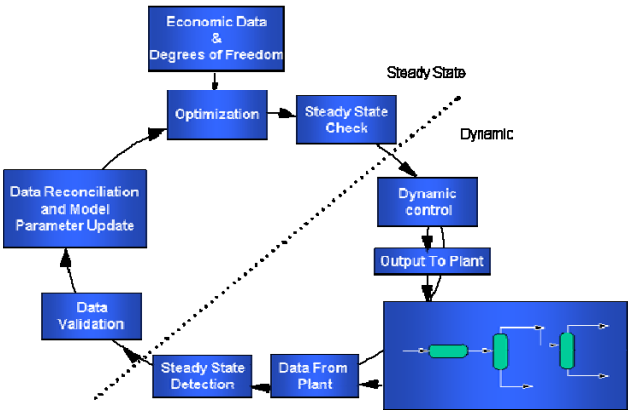

Figure 1 – Aspen Technology RTO Closed Loop Mechanism

3. Literature Review

Olefins plant remains as one of the most challenging chemical process in terms of operational and modeling perspectives. Companies seek for increasing the throughput to maximize production of ethylene and propylene and at the same time reducing the energy consumption.

The true understating of the pyrolysis reactions that take place in the furnace coils are the core component for a reliable operation and also for development of robust models. Van Goethem et al. (2008) developed new options for thermal cracking of ethane and similar light hydrocarbons. The authors validated their model in two applications that ethylene production is maximized at maximum temperature and minimal pressure reaction conditions. Guangying et al. (2008) modeled a quench oil system of an ethylene plant using real components instead of pseudo-components. Mercangöz and Doyle III (2006) developed a RTO model integrated with the control system for the pulp and mill industry. The authors report significant annual savings by the tool. Biegler and Zavala (2009) address the integration of process control models with scheduling and planning models. The authors emphasize the real-time optimization strategies that can be used to merge and replace the steady-state tasks and linear predictive control models. Gubitoso and Pinto (2007) address the operational planning of a real-world ethylene plant.

4. Sustain Activities

Sustain activities can be defined as a set of tasks that aims to maximize the benefits that a tool can deliver inside a plant or a complex. Tools related to chemical process technology, such as APC, Real-Time Optimization, Scheduling and Planning applications are heavily affected by Sustain Activities. It is crucial that companies apply a consistent set of activities that sustain these tools in order to keep the maximum possible benefits. Figure 2 shows the typical benefits from tools related to chemical process technology versus time.

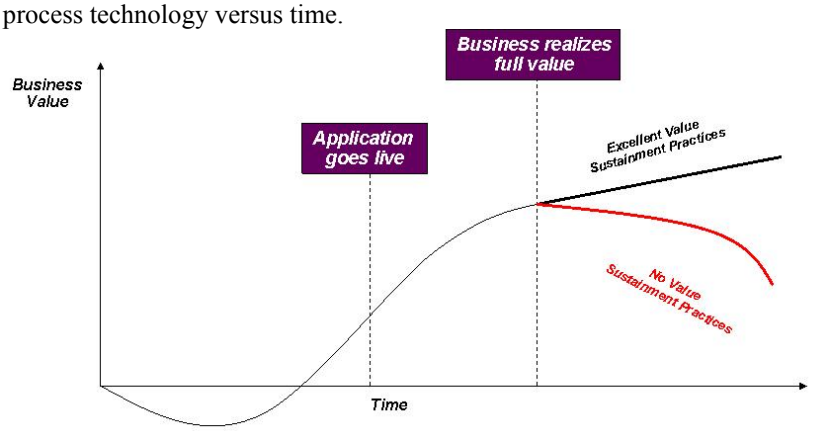

Figure 2 – Typical Benefits versus Time of Chemical Process Tools

The companies get a considerable return rate in all operation levels right after its commissioning. However, as time passes, several challenges take place, thus reducing the tools benefits. If no action is taken, the companies do not get the maximum benefits and some even abandon them. In here, the actions taken in the Aspen Tech – Braskem Sustain Program are described in order to maximize the RTO applications benefits.

4.1. Operator Training

Engineers should carry out an intensive training with operators. They must explain the RTO closed loop mechanism and emphasize the following points:

- RTO system maximizes the plant profits: The system drives the plant to its limits as the operators accept the setpoints. Any questions should be directed to the Engineers. They are able to explain why the RTO suggests the moves on the optimized variables

based on plant status, active constraints and products, raw materials and utilities prices. Also, RTO is safe. Engineers should state that the RTO respect the operational variable bounds and do not cause high disturbances to the plant;

- RTO suggested setpoints should be as clear as possible for operators to review. They should spend a minor time reviewing the setpoints. This can be critical for furnaces operators. Olefins plants typically have 10 to 18 furnaces. The RTO system regularly sends 3 setpoints for each furnace (Total HydroCarbon Feed, Dilution Steam to HydroCarbon Ratio and Severity). Therefore, the operators need to review up to 54 setpoints, which is a considerable amount of information;
- With increasing operator's confidence on the RTO results, the system can be turned to "Auto-Accept" mode, that is, if the operator does not reject the results in the review time, the setpoints are sent to the APC system. Braskem currently operates both RTO systems in Auto-Accept mode.

4.2. Furnace Feed Composition

The furnace liquid feed composition is a crucial component that has to be properly updated to enhance the model precision when calculating the furnace effluent composition. Typically, an Olefins plant can be fed by a wide range of naphthas, such as Full Range, Light, Heavy Naphthas or condensates. The naphtha composition drastically affects the furnace effluent composition. The Aspen Tech APC and RTO system relies on SPYRO^{TM} from Technip. In the beginning of the Sustain Project, the system relied on the online PIONA analyzers to characterize the naphthas that feed the furnaces. This approach presented large offsets between the model predictions and the plant production rates for several products. To eliminate these, a manual laboratory analysis was implemented, where a naphtha sample is collected from the field and a full and open component chromatographic analysis is performed. Although somewhat manual, it was able to enhance the model performance in predicting the plant yields.

4.3. RTO & Scheduling and Planning Integration

Scheduling and planning models consider plant resources, capacities and availability, task sequence and their respective duration. Main decisions for planning/scheduling models consist of discrete and continuous variables, such as the available raw materials to purchase, how much of each product should be produced in a monthly/weekly basis. These models can be applied to a chain of factories or to a single plant and are applied in a monthly or weekly basis.

The common information that Planning, Scheduling and RTO models share are key product target production rates. Therefore, the integration is performed by including the production target rates in the RTO models. The maximized profit of the original model shown in (1) is a linear equation that takes into account the difference of all product revenues by the sum of the raw material and utilities costs.

$$Profit = \sum product_i \;\; C_i - \sum feed_j \;\; C_j - \sum utility_u \;\; C_u \tag{1}$$

The new objective function is shown by equation (2).

$$Profit = \sum product_i \;\; C_i - \sum feed_j \;\; C_j - \sum utility_u \;\; C_u - C_p . \left[\overline{F_p^{TARGET}} \right] \tag{2}$$

The penalty term reduces the profit when the plant production rate is under the production target rates. This is accomplished by adding two constraints in the RTO model, shown by (3) and (4). Constraint (3) states that variable $\overline{F_p^{TARGET}}$ must be greater

than or equal to zero, whereas (4) imposes $\overline{F_p^{TARGET}}$ should be greater than or equal to the difference of the production target $\left(F_p^{TARGET}\right)$ and the plant rates for each product p $\left(F_p^{PLANT}\right)$.

$$\overline{F_p^{TARGET}} \geq 0 \qquad \forall p \qquad (3)$$

$$\overline{F_p^{TARGET}} \geq \left[F_p^{TARGET} - F_p^{PLANT}\right] \qquad \forall p \qquad (4)$$

Two possible scenarios arise for these constraints. The first is when the plant rates are already above the production target. Then, constraint (3) is activated, while (4) is relaxed. Note that in this scenario, the penalty is equal to zero. The second scenario is characterized when the plant rate is under the production target rates. Then, constraint (4) is activated, whereas (3) is relaxed. Therefore, the overall plant profit is penalized.

5. Results

The Sustain Project performed at the Olefins plants at Braskem showed significant results. Due to a confidentiality policy, only relative process results are shown by the following pictures. Figure 3 shows a drastic reduction in the High Pressure steam make-up to total furnace feed and to the ethylene production ratios when the operators accepted the suggested RTO setpoints. In this particular case, Braskem was able to save US$100,000 in High-Pressure steam import in eight days. In addition, operators started accepting RTO setpoint more frequently after the intensive training, Engineers support and after getting acquainted with the setpoint review procedure.

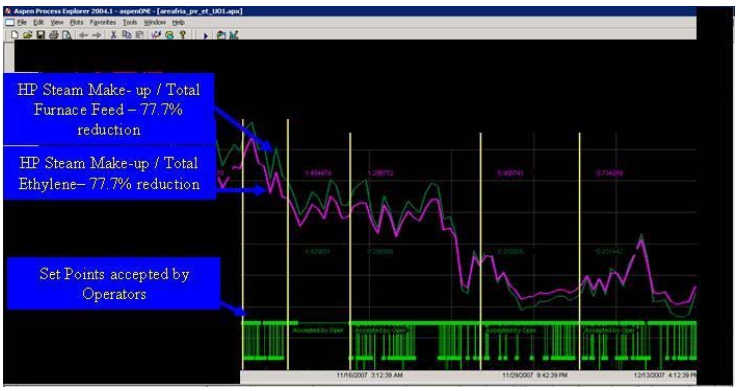

Figure 3 – Reduction in High Pressure Steam Make-up to Olefins Plant

Figure 4(a) shows the ethylene production at the cold side at one of the plants and the ethylene flow rate predicted by the model at the furnaces header. Before the laboratory implementation, the model presented a large offset since there are ethylene losses along the plant. The laboratory analysis procedure implemented eliminated the large offsets. Figure 4(b) shows the RTO system was able to maintain the ethylene production rate at the production target and to increase the pyrolysis gasoline production flow rate.

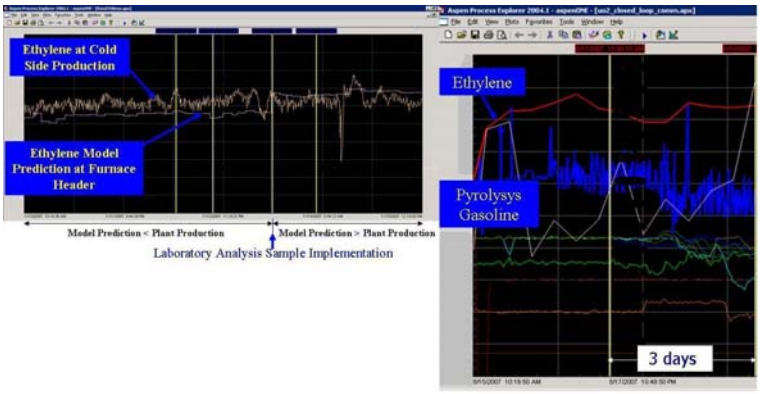

Figure 4 – Laboratory analysis scheme(a) and ethylene production target rates(b)

Figure 5 shows reduction of ethylene and methane losses in the demethanizer column. In this particular case, the RTO and the APC systems were able to reduce the methane losses by 43% and ethylene losses by 59%.

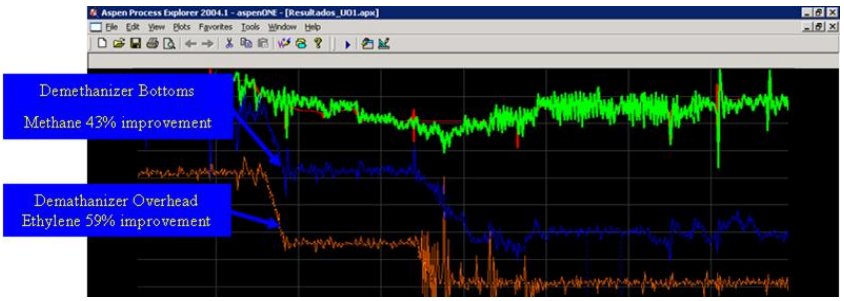

Figure 5 – Demethanizer losses improvements

6. Conclusions

Results proves that the Sustain Activities applied to the RTO systems at Braskem Olefins plants brought several operational improvements in the plants and also helped in sustaining the value generated by the optimizer.

Stochastic dynamic predictions using kriging for nanoparticle synthesis

Andres F. Hernandez,[a] Martha A. Grover[a]

[a] School of Chemical & Biomolecular Engineering, Georgia Institute of Technology. Atlanta, GA. 30332-0100. E-mail: martha.grover@chbe.gatech.edu

Abstract

Kriging is an empirical modeling approach that has been widely applied in engineering for the approximation of deterministic functions, due its flexibility and ability to interpolate observed data. Despite its statistical properties, kriging has not been developed to approximate stochastic functions or to describe the dynamics of systems with multiple outputs. Our paper proposes a methodology to construct approximate models for multivariate stochastic dynamic simulations using kriging, by combining ideas from design of experiments and dynamic systems modeling. We then apply the methodology in the prediction of a dynamic size distribution during the synthesis of nanoparticles.

Keywords: Kriging, Dynamic Systems Modeling, Stochastic, Nanoparticle

1. Introduction

One of the most challenging problems in nanoparticle synthesis is the controlled generation of a monodisperse size distribution while sustaining a high yield. Because of the small size scale, molecular simulations are needed for modeling the manufacturing process. Unfortunately, the computational time of these simulations is usually too high for tasks like process control, requiring the creation of approximated models.

Kriging (also known as Gaussian process regression model) has recently been applied in the field of dynamic systems modeling [1, 2]. It is possible to approximate the state variable dynamics by implementing a recursive state-space formulation of a kriging model. The construction of this recursive function requires enough information to map from one discrete time to the next discrete time. For complex dynamic systems, obtaining the information to describe this dynamic function usually is time consuming, which requires minimizing the number of simulations while the system information is maximized over the state space. This problem can be viewed as a sequential selection of simulated data [3].

2. Methodology

2.1. Kriging

Kriging is a modeling approach for generalized linear regression models which accounts for the correlation in the residuals between the regression model and the observations [4, 5]. Kriging formulates a local correlation between the residuals of the linear regression model as a function of the location of the model inputs. Assume there is a set S of input/output pairs $\left\{\left(\mathbf{x}^i, \mathrm{y}^i\right)\right\}$, where $\mathbf{x}^i \in \mathbb{R}^d$, $y^i \in \mathbb{R}$, i = 1… n. A usual

covariance function to model the correlation at short distances between samples in the set is [1]:

$$\mathrm{V}_{ij}\left(\mathbf{x}_i,\mathbf{x}_j\right)=\sigma_c^2\cdot\exp\left[\sum_{k=1}^{d}\frac{\left(\left|\mathrm{x}_{i,k}\text{ - }\mathrm{x}_{j,k}\right|\right)^2}{\theta_k^2}\right]+\sigma_u^2\cdot\delta_{ij} \tag{1}$$

where δ_{ij} is the Kronecker delta and σ_c^2, $\theta_1^2\ldots\theta_d^2$, σ_u^2 are the kriging parameters that control the features of the correlation. In particular, σ_u^2 is included to model the random noise component of the function to be fitted. By using this covariance function, a kriging prediction for a new input $\mathbf{x}_o$ is [6]:

$$\hat{\mathrm{y}}\left(\mathbf{x}_o,S\right)=\mathrm{h}\left(\mathbf{x}_o\right)^T\hat{\boldsymbol{\beta}}+\mathrm{V}^T\left(\mathbf{x}_o,S\right)\cdot\mathrm{V}^{-1}\left(S,S\right)\cdot\left(\mathbf{y}\text{ - }\mathrm{H}\left(S\right)\hat{\boldsymbol{\beta}}\right) \tag{2}$$

where h, H represent a set of *p* regression functions evaluated at the unknown input and the inputs in *S*, $\hat{\boldsymbol{\beta}}$ is the generalized least-squares estimator of the regression coefficients and $\mathbf{y}=\left[\mathrm{y}^1,\ldots,\mathrm{y}^n\right]^T$. The corresponding variance of the prediction is:

$$\sigma_{\hat{\mathrm{y}}}^2\left(\mathbf{x}_o\right)=\mathrm{V}\left(\mathbf{x}_o,\mathbf{x}_o\right)\text{ - }\left[\mathrm{h}\left(\mathbf{x}_o\right)^T\ \mathrm{V}^T\left(\mathbf{x}_o,S\right)\right]\begin{bmatrix}0 & \mathrm{H}^T\left(S\right)\\ \mathrm{H}\left(S\right) & \mathrm{V}\left(S,S\right)\end{bmatrix}^{-1}\begin{bmatrix}\mathrm{h}\left(\mathbf{x}_o\right)\\ \mathrm{V}\left(\mathbf{x}_o,S\right)\end{bmatrix} \tag{3}$$

Frequently, the kriging parameters are obtained by maximizing the likelihood prediction over the multivariate normal distribution of the outputs in the set *S*.

2.2. Application of kriging in dynamic systems modeling

An approximated model for dynamic systems can be written based on the kriging structure presented in the previous section. A kriging model can be used as an autoregressive model where inputs and outputs are fed back and employed as regressors to predict a current output [7]. A recursive state-space formulation for the state variables $\mathbf{w}\in\mathbb{R}^m$ and control inputs **u** can be written as [2]:

$$\begin{gathered}\mathbf{w}\left(k+1\right)=\hat{\mathrm{f}}\left[\mathbf{x}_o\left(k\right),\ S\right]\qquad \mathrm{k}=0,\ 1,\ 2,\ \ldots\\ \mathbf{x}_o\left(k\right)=\left[\mathbf{w}\left(k\right),\ \mathbf{u}\left(k\right)\right]\\ t=k\cdot\Delta t\\ S=\left\{\left(\mathbf{x}^i,\ \mathrm{y}^i\right)\right\},\ \mathrm{y}^i=\mathbf{w}^i\left(k+1\right)=\mathrm{f}\left[\mathbf{x}^i\left(k\right)\right]\end{gathered} \tag{4}$$

where $\hat{\mathrm{f}}$ is represented by the kriging model in Eq. (2). Our approximated model employs the concept of storage and retrieval of information [8], in which pre-computed function evaluations are stored and then used to drive an equation-free prediction of the system dynamics [9]. From the stored data, a subset of information is extracted in the set *S* to approximate the dynamics at a new value of **w** and **u** in a one-step-ahead

prediction. Notice that $\mathbf{x}$ belongs to a higher dimension than the state-space $\mathbf{w}$, ($\mathbf{x} \in \mathbb{R}^d$, $\mathbf{w} \in \mathbb{R}^m$ and $d \geq m$) because the variables in the kriging model should also contain control inputs. By taking the approximated value from the previous step, our model uses the set S to approximate the dynamic behavior. Due to the recursive nature of Eq. (4), error will propagate from one step to the next. However, it is possible to formulate a correction in the prediction using a truncated Taylor-Series expansion [10] that combines error estimation in the kriging parameters using the Fisher Information Matrix of the likelihood function, along with error estimates from the previous kriging prediction via Eq. (3).

2.3. Sequential Design and Analysis of Computer Experiments (Sequential DACE)

A sequential DACE design was used to improve the construction of the reference vectors in our methodology. This sequential DACE was implemented based on the variance of the kriging prediction, Eq. (3), as an indicator of regions where our approximated model is more uncertain [11].

To create an approximated model with multiple inputs and outputs, one kriging model is built for the prediction of each output variable using maximum likelihood estimation to define kriging parameters. Since the multivariate model is built with several kriging models, the uncertainty in all models should be considered to define new simulations. It is proposed as a measure of uncertainty in the model, the sum of the kriging variance over the normalized state variables. The algorithm continues until a satisfactory level of prediction variance is reached. Figure 1 shows a schematic of our algorithm.

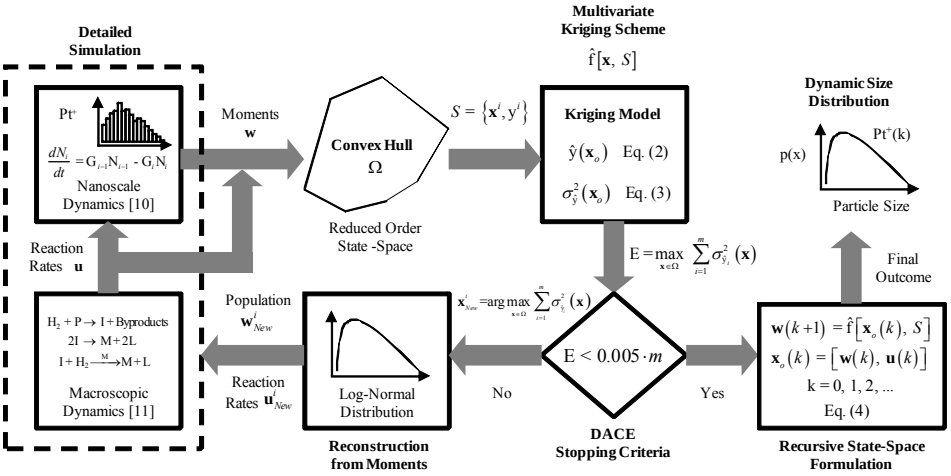

Figure 1. Sequential DACE design to approximate nanoparticle size distribution using a multivariate kriging scheme.

In this paper, we describe our detailed simulations as an ODE system that describes single adatom processes [12] for platinum deposition on porous alumina under supercritical CO_2 conditions [13]. The ODE system models the macroscopic dynamics of the hydrogen and precursor concentrations as well as the nanoscale dynamics of the nanoparticle distribution, which has a white noise term to generate stochastic behaviour. Our methodology creates a reduced state using the first three moments of the nanoparticle distribution, along with the nucleation and growth rates of the macroscopic

model to make the kriging model practical. Detailed simulations are collected for several macroscopic process settings of initial concentrations over a predetermined time period. The convex hull of these simulations defines the reduced state space.

From the convex hull, a set S of sampled information is selected to build the multivariate kriging scheme, and the uncertainty prediction is evaluated. Then, the sequential design of the stochastic simulations is applied over the convex hull closing the loop with the detailed simulations, assuming that the nanoparticle distribution is approximated by a log-normal distribution with corresponding raw moments calculated from the approximated model. The new sample point is collected at the point $\mathbf{x}$ of maximum uncertainty E. Our multivariate approximated model is rebuilt incorporating the new information in the set S, guiding the sequential design procedure. After the set S has been built, dynamic size distributions are obtained using the final approximated model for different macroscopic process settings.

3. Results and Discussion

Figure 2 presents the reconstructed nanoparticle size distributions from the prediction of the first three moments assuming that the nanoparticle distribution is log-normal. The sequential DACE procedure improves the prediction of the nanoparticle distribution by selecting additional sample points usually located close to the boundaries of the sampling space. The final kriging model uses a total of 23 sample points that creates a good approximation of the location of the peak and the width of the distribution. Our improved kriging model also shows a satisfactory result in the prediction of the long-term behavior of the nanoparticle distribution.

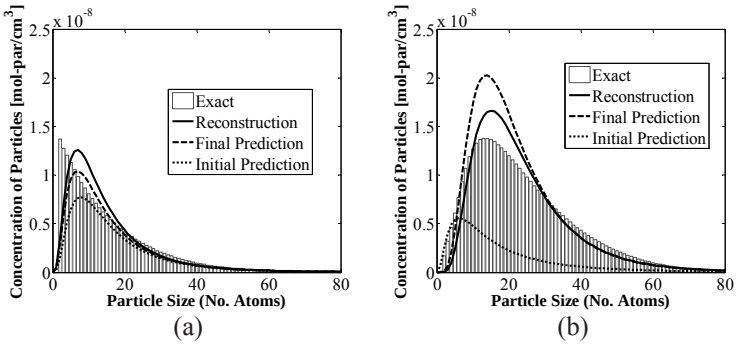

Figure 2. Reconstructed nanoparticle size distributions using the first three moments predicted by the kriging model. (a) Distributions at $t = 3$ *sec*. (b) Distributions at $t = 60$ *sec*. Initial Concentrations: $H_2 = 5 \times 10^{-5}$ *mol/cm*^{3}, *Precursor* $= 1 \times 10^{-5}$ *mol/cm*^{3}.

Comparing the nanoparticle distribution prediction made at $t = 3$ *sec* and $t = 60$ *sec*, the final kriging model exhibits a more accurate prediction over time than the initial kriging model. The effect of the error propagation and the uncertainty in the prediction can be seen in Figure 3, where the dynamics of the first three moments are shown. The addition of new sample points improves the prediction of all moments in the entire time frame of interest, showing the robustness of the approximated model. Some ideas to improve the performance of our model include the selection of different covariance and regression functions in the kriging expression or a better selection of the reduced state variables of

the system (increasing the number of moments extracted from the distribution or adding some macroscopic variables like concentration profiles).

The implemented sequential DACE design uses the prediction uncertainty of the model as a measurement in the selection of new sample points. Since the kriging model predicts exactly the information of the actual sample points, the prediction variance is equal to zero at those points. This situation creates several local maxima, most of them located at the boundaries of the reduced state space. We improve the chance to find the global maximum by randomizing the initial value of the optimization problem. 25 random points in the reduced state space are used to evaluate the objective function prior the optimization and the initial value is selected by the maximum value of the function. The results of the optimization procedure of the sequential DACE design are shown in Figures 4 and 5.

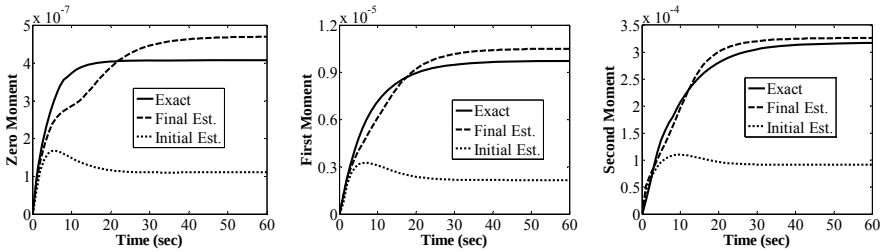

Figure 3. Dynamic approximation of the first three moments of the nanoparticle size distribution before and after use sequential DACE design on the approximated model. Initial Concentrations: $H_2 = 5 \times 10^{-5}$ *mol/cm*^{3}, *Precursor* $= 1 \times 10^{-5}$ *mol/cm*^{3}.

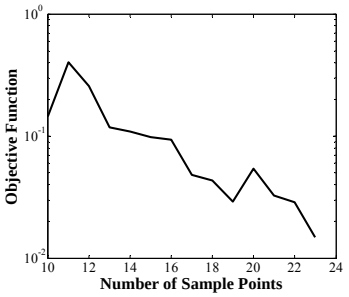

Figure 4. Improvement using sequential DACE design, as a function of the number of sample points used in the kriging models.

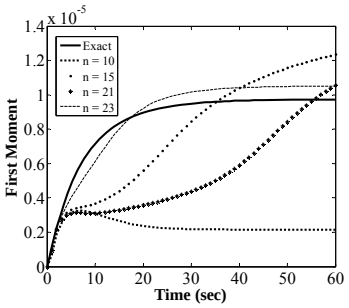

Figure 5. Improvement in the dynamic approximation of the first moment by using the sequential DACE design. Initial Concentrations: $H_2 = 5 \times 10^{-5}$ *mol/cm*^{3}, *Precursor* $= 1 \times 10^{-5}$ *mol/cm*^{3}.

The addition of the new 13 sample points decreases the value of the normalized kriging variance as well as the dynamic prediction of the first moment. The relevance of this fact is that the model can select by automatically where new and relevant information is needed from a full simulation in order to improve the approximation.

A global dynamic analysis was perform from 40 different macroscopic process settings, using 30 different multivariate kriging schemes and using the Euclidean distance

between the exact and the predicted trajectories at each time as an error measurement. After our sequential DACE design was implemented, the overall dynamic error in the trajectories decreases by 37%. A completely different sampling strategy must be developed when we are interested in a single nominal trajectory.

4. Conclusions and Future Work

This paper demonstrates the application of sequential DACE techniques to improve the accuracy of an approximate model from a stochastic simulation. By using a detailed simulation for nanoparticle synthesis, our model develops approximates of the nanoparticle size distribution obtained from the full simulations. The sequential DACE design based on the prediction uncertainty of the model shows a good performance in the selection of additional sample points to improve its accuracy.

One aspect that has not been investigated yet is the approximation of stiff systems. In our methodology, one of the keys to an accurate prediction is an appropriate selection of a time step that captures the dynamics of the system. A preliminary idea of how to approximate these systems will involve mixing information generated at different time steps that can be correlated at smaller time steps.

Since our approximate model requires recorded information to define the boundaries of the reduced state space for future sampling, the creation and management of databases is relevant. Ideas coming from data mining can be implemented in the construction of the preliminary reference vectors for our kriging model. By including these ideas, we expect to improve the construction of the convex hull.

Estimating the Normal Boiling Point of Organic Compounds Based on Elements and Chemical Bonds

Xia Li, Xiang Shu-Guang and Jia Xiao-Ping

The Hi-Tech Institute for Petroleum and Chemical Industry，Qingdao University of Science and Technology，Qingdao，266042，Shandong，China

Abstract

Based on elements and chemical bonds, a new method for estimating the normal boiling point of pure organic compounds from chemical structure was proposed. This method considers the contributions of interactions between elements and chemical bonds in the molecule. On the basis of 4,060 kinds of credible experimental data, 7 correlation equations are obtained by regression analysis. A mean absolute average deviation of 15.16K, less much than mostly used group contribution methods for alkyne, chloride derivative, iodine derivative, especially for alkane, bromide derivative, aromatic hydrocarbon, alicyclic hydrocarbon and sulphide organic compounds. Compared with the other group contributions methods, the proposed method in this paper showed significant improvements in accuracy and the ability to distinguish among isomers.

Keywords: the normal boiling point, elements, chemical bonds, group-contribution techniques

1. Introduction

The boiling point of organic compounds is of importance in the design of new organic compounds and in some industrial processes since they are the factors that primarily control solubility and vapour pressure [1-3].

Despite the enormous amount of available boiling point data, there are very few useful general means for quantitatively relating the boiling points of a compound to its chemical structure [4]. Most of the work in the prediction of the phase transition temperature of compounds has been focused mainly on boiling point estimation. Recently simple group contribution methods were proposed to predict the boiling points. It was found that the boiling temperature can be estimated simply by using molecular fragment values. Most of the methods were developed mainly from small data sets and can be used to predict only certain classes of organic compounds [5].

From the experience gained with the development of the previous group contribution methods, based on elements and chemical bonds, a new method for estimating the normal boiling point of pure organic compounds from chemical structure was proposed.

2. Physical Property Data Set

A data base containing boiling points, molecular weight, molecular descriptors, etc. was developed in Yaws' Handbook of Thermodynamic and Physical Properties of Chemical Compounds [6]. The data set for the normal boiling points (measured at 1 atm) consists of 4,060 compounds. The normal boiling points were credible experimental data. The compounds considered in this study were substituted aromatic including heterocyclic

compounds. The substituents used were the non-hydrogen bonding and single hydrogen bonding groups. These were methyl(CH_3), methylene (CH_2), cyano (CN), oxygen (O), hydroxyl(OH), halogens, nitro(NO_2), aldehyde (CHO),made(CONH2), keto (CO), carboxyl(COOH), Sulfur(S), sulfoxide(SO), mercapto (SH), thiocyanate (SCN), and isothiocyanate (NCS) groups.

3. Development of the new method

3.1 Molecular Descriptors

The elements and chemical bonds were regarded as basic contribution units in this method. Elements were divided into C, H, O, F, Cl, Br, I, N and S. Chemical bonds were divided into cyclic and non-cyclic. According to the different atoms, the chemical bonds were divided into C-C, C-H, C-O, cyclical C-C, cyclical C-O, and so on. Because the chemical bond in benzene was different from C-C and C=C, it was regarded as a special one. The list of structural groups for the new method (9 elements, 29 chemical bonds and 32 adjacent chemical bonds) were given in table 2.

3.2 Statistical Analysis

The Statistical Analysis of the data was performed using Matlab 7.0. The correlation coefficient and standard error were used as a measure of correlation for the equations developed. However, in selecting the best model emphasis was placed upon reducing the standard error.

3.3 Regression algorithm

From the experience gained with the development of the previous method, six linear regression of equation were employed.

$$T_b^k = m + \sum_j n_j \Delta T_{bj} \tag{1}$$

$$T_b = m + \frac{\sum_j n_j \Delta T_{bj}}{M^k} \tag{2}$$

$$T_b = m + \frac{\sum_j n_j \Delta T_{bj}}{M^k + l} \tag{3}$$

$$T_b = m + \frac{l + \sum_j n_j \Delta T_{bj}}{M^k} \tag{4}$$

$$T_b = m + k * (\sum_j n_j \Delta T_{bj})^l \tag{5}$$

$$T_b^l = m + \frac{\sum_j n_j \Delta T_{bj}}{M^k} \tag{6}$$

3.4 Correlation coefficient and group contributions

The correlation coefficients were found in Table 1. The contributions of elements, chemical bonds and the adjacent chemical bonds interaction were showed in Table 2, Table 3 and Table 4.

3.5 Results and discussion

We will compare the above results with those from Joback and Reid (JR) [7], Devotta and Pendyala (DP) [8], Constantinuou and Gani (CG) [9], Marrero-Moreion and Pardillo (MP) [10]. All methods have in common the fact that they only require the knowledge about the molecular structure and therefore are comparable. The probability of a prediction failure (extreme deviation between experimental and estimated value) was chosen as the most important criterion for the reliability of a model.

The first correlation proposed here gives a mean absolute average deviation of 15.88K for 4060 compounds (second correlation: 15.89K (4060), third correlation: 15.16K (4060), fourth correlation: 15.34K (4060), fifth correlation: 15.78K (4060), sixth correlation: 16.47K (4060), JR: 33.45K (4060), DP: 33.37K (4060), CG: 16.43K (3893), MP: 17.02K (3549)). This means that it combines the lowest deviation with the broadest range of applicability.

In order to test the predictive capability of the method, experimental normal boiling temperatures for 10 components, not in the database used for regression, were compared with the predicted values. The results showed that the method proposed in this paper had significant improvements in accuracy.

To test the predictive capability of the method to differentiate the same kind of isomers, a detailed procedure for the estimation of T_b is given in Table 6 for heptane

isomers. The results showed that the method proposed in this paper had the ability to distinguish among isomers.

Table 5 Comparison of the method proposed for compounds, not used for regression

4. Conclusions

Based on elements and chemical bonds, a new method for estimating the normal boiling point of pure organic compounds was developed. The predictions are based exclusively on the molecular structure of the compound. The first correlation proposed in paper gives a mean absolute average deviation of 2.78K (second correlation: 1.91K, third correlation: 1.74K, fourth correlation: 1.84K, fifth correlation: 2.74K, sixth correlation: 1.77K, JR: 5.83K, DP: 5.90K, CG: 3.96K, MP: 3.17K) for 10 components, not in the database used for regression. The results of the new method were in most cases far more accurate than previous methods and had the ability to distinguish among isomers.

List of symbols

AAE	a mean absolute average deviation (K)
AAPE	a mean relative average deviation (%)
m , k, l	correlation coefficient
M	molecular weight
N	number of compounds
n_i	number of group i in compounds
n_j	number of group j in compounds
T_b	the normal boiling point of compounds (K)
$T_b^{\exp}$	the experimental normal boiling temperature (K)
T_b^{cal}	the predicted normal boiling temperature (K)
ΔT_b	the contribution of elements or chemical bonds (K)
ΔT_{bj}	he contribution of group j in compounds (K)

Abstract

Finding optimal operating conditions fast with a scarce budget of experimental runs is a key problem to speed up the development and scaling up of innovative bioprocesses. A methodology for model-based design of dynamic experiments in modeling for optimization is proposed and successfully applied to the optimization of a fed-batch bioreactor related to the production of r-interleukin-11 whose DNA has been cloned in an *E. coli* strain. A library of tendency models is used to increasingly bias bioreactor operating conditions towards an optimum. Parametric uncertainty of tendency models is iteratively reduced using Global Sensitivity Analysis (GSA). At each iteration, the 'most informative' tendency model is used for designining the next dynamic experiment. Model selection is based on minimizing an error measure which separates parametric uncertainty from structural errors to trade-off exploration with exploitation.

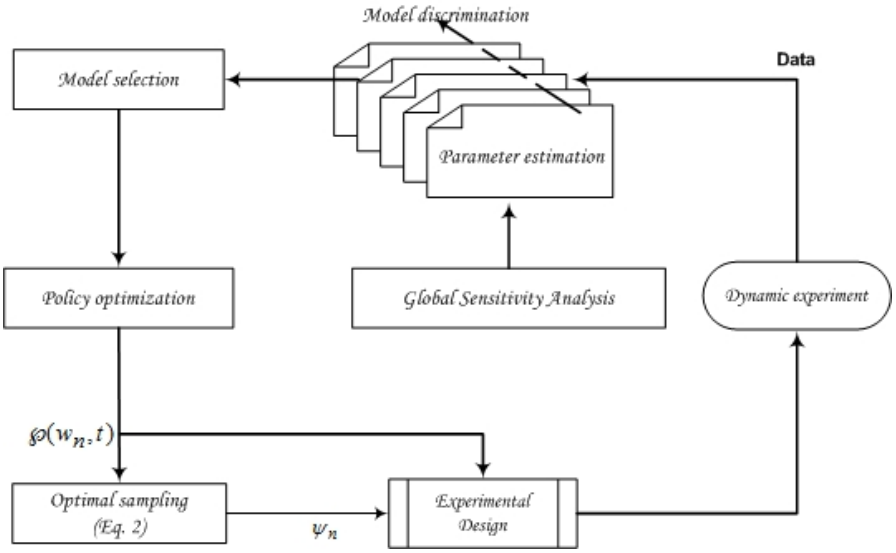
Keywords: Modeling, optimization, experimental design, dynamic experiments.

1. Introduction

Findings in the 1950s that DNA is the molecule that encodes proteins, which in turn controls all the cellular processes including metabolic pathways, have provided the impetus for the biotechnology era (Walsh, 2007) in the development of high valued-added pharmaceuticals such as insulin, humanized antibodies, interferons or interleukins along with biofuels (Fischer *et al*., 2008) and new materials (e.g. biodegradable polymers). The recombinant microorganism is typically grown in a fed-batch bioreactor to high cell concentration and then expression of the heterologous protein is triggered so as to obtain considerable quantities of the target product (Cooney, 1983). In a fed-batch culture, the feed rate of the carbon source, usually glucose, must be manipulated in order to restrict overflow metabolism and glucose repression. To this aim, model-based optimization of a bioreactor operating condition seems to be the safe and economic approach to resort with. Application of Pontryagin's maximum principle for fed-batch bioreactor optimization has been studied by several researchers (Mahadevan and Doyle III, 2003). However, most of these optimization methodologies for bioprocess scaling up and productivity inprovement have not been widely adopted for industrial use since the perfect model assumption is far from realistic and bioreactor behavior is quite often deviant from model predictions. Also, relevant measurement are sparse and delayed. Considering the large uncertainty and poor reproducibility in novel bioprocesses along with metabolic regulation, the development of an accurate mathematical model of bioreactor dynamics is a costly and very difficult undertaking. A better approach in innovative bioprocesses is to improve the operating policy by resorting to tendency models (Visser *et al.*, 2000) for designing optimally informative experiments which iteratively reduce the performance prediction uncertainty (Martínez and Wilson, 2003).

2. Modeling for optimization

At each iteration, the core idea of "modeling for optimization" is to select from a library of tendency models the one which allows computing inputs that increasingly improve the operating policy and bias data gathering accordingly. To this aim, a dynamic experiment is designed around the current policy, and optimal sampling times are calculated so as to maximize information content regarding performance improvement. The experiment is carried out and new data are collected. Based on incoming data the sub-set of model parameters for each tendency model are re-estimated which selectively reduces its parametric uncertainty. Based on total modeling errors a tendency model is selected for policy re-optimization. With the new input policy, a new iteration begins. The identification-optimization cycle is continued until no performance improvement is obtained and the input policy converges. Fig. 1 provides an overall picture of the proposed methodology.



Fig, 1. Modeling for optimization using designed dynamic experiments

2.1. Problem statement

In what follows let's assume that the dynamic behavior of the bioreactor under study may be modeled alternatively by a library of ℓ tendency models

$$\frac{dx_i}{dt} = f(x_i(t), \wp(w,t), \theta, t) \;\; 0 \le t \le t_f, \quad x_i(0): \text{given}, i = 1,2,...,\ell \qquad (1)$$

and the optimization objective to be maximized iteratively via experimental runs is

$$J(w) = h(x(t_f)) + \int_0^{t_f} g(x(t), \wp(w,t), \theta, t)dt \qquad (2)$$

where $x(t)$ is an n_s-dimensional vector of time dependent state variables, w is an m-dimensional vector of parameters for the input policy $\wp$, θ is a p-dimensional vector of model parameters and t_f is the final time of a batch run. The function g is the instantaneous reward function along the state trajectory $x(t)$ defined by a given policy parameterization whereas the function h is the specific reward for the final state of the batch run when using the input policy $\wp(w,t)$.

2.2. Model selection

Model selection is based on distinguishing between parametric uncertainty and structural errors in performance prediction using tendency models (see Fig. 2 for details). For a given tendency model and a plausible realization of its parameters, the corresponding simulated trajectory of the process performance index $\tilde{J}_i, i = 1,2,..., n_{sp}$. At the *ith* sampling point, a sample average $\bar{J}_i$ of n different model parameterizations can be used to characterize the *parametric uncertainty* for the tendency model as follows (Asprey and Machietto, 2002; Chen and Asprey, 2003):

$$\varepsilon_{J_i \to \bar{J}_i} == \frac{1}{n_{sp}\, n} tr\left[\left(\tilde{J}_{ij} - \bar{J}_i\right) W_{ij} \left(\tilde{J}_{ij} - \bar{J}_i\right)^T \right]; i = 1,2,..., n_{sp};\ j = 1,2,..., n \qquad (3)$$

As a measure of *structural errors* inherent to a given tendency model, the average performance trajectory $\bar{J}_i$ is compared to the actual (observed) trajectory J_i

$$\varepsilon_{\bar{J} \to J} = \frac{1}{n_{sp}} tr\left[\left(\bar{J}_i - J_i\right)^T W_{ii} \left(\bar{J}_i - J_i\right) \right]; i = 1,2,..., n_{sp}; W_{ii} :\ \textit{weighting matrix} \qquad (4)$$

where n_{sp} is the number of sampling points. The total error of a model is expressed as the sum of parametric uncertainty in Eq. (3) plus its structural error defined as it is shown in Eq. (4). For policy optimization, model selection in each iteration is based on choosing the tendency model from the model library whose total error is the lowest. More elaborated strategies for model selection can also be developed. For example, initially model selection may emphasize reducing parametric uncertainty and as more data are gathered model selection is more based on structural errors.

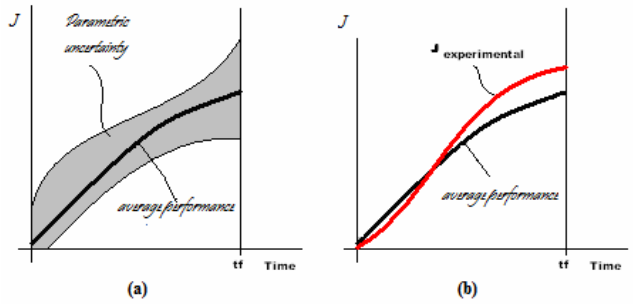


Fig. 2. Model selection based on total error: (a) Parametric uncertainty; (b) structural errors.

2.3. Optimal sampling

For a given policy in the current policy iteration of Fig. 1 optimal sampling times ψ^{opt} along a batch run must be calculated so as to bring new information to selectively reduce parametric uncertainty which affect the most the value estimation of the performance index J trajectory. Assuming model parameters are set to $\hat{\theta}$ and the

current version of the optimal policy is $\wp(w,t)$, the issue of optimal sampling is related to calculating at which sampling times $\psi^{opt} \in \Psi$ in a dynamic experiment the values of measured process variables are most informative in modeling for optimization assuming that the policy evaluation step should narrow down the uncertainty about the optimal input. To this end, the following optimization problem is solved:

$$\psi^{opt} = \max_{\psi \in \Psi} \det\left|M(\hat{\theta}, \wp(w_n,t), \psi)\right| , \; M = Q^T Q , \; Q = \begin{pmatrix} Si_{11} & \cdots & Si_{1n} \\ \vdots & \ddots & \vdots \\ Si_{m1} & \cdots & Si_{mn} \end{pmatrix} \qquad (5)$$

where each entry of the matrix Q , Si_{ij}, measures the sensitivity of the performance index $J(w)$ at the *i-th* sampling time with respect to *j-th* parameter of the operating policy. To calculate Si_{ij}, Global Sensitivity Analysis (GSA) is proposed (Saltelli et al., 2006). GSA is a variance-based technique that decomposes model outputs variability as a combination of uncertainty intervals for each independent input factor and its interactions with other factors using Monte Carlo sampling techniques.

3. Case study

To illustrate the proposed methodology results obtained in the optimization of fed-batch fermentation process for the recombinant protein **rIL-11** using a genetically modified *E. coli* strain are presented. Production of recombinant proteins in *E. coli* has been widely applied in both laboratory research and bioproduct manufacturing since this microorganism is considered a reliable source of proteins. This method may achieve profitable mass productivity due to high density cell growth and fast product formation. A structured kinetic model proposed by Tang *et al.* (2007) which describes state variables trajectories such as: biomass (X), substrate (S), intracellular recombinant protein concentration (P) will be used as an *in silico* bioreactor to generate the required data in the modeling for optimization approach. Four unstructured (tendency) models which differ in their biomass growth kinetics are used as guidelines for policy optimization so that the mismatch between the "real" bioprocess and alternative models of the fed-batch bioreactor is accounted for by increasingly biasing data gathering. Also, the operation policy has been defined based on the substrate feeding rate and induction time t_{ind} as the main components subject to optimization, including the initial culture condition. The performance index $J(t)$ is related to the amount of recombinant protein obtained at the final time of production runs. Tendency model equations and their alternative biomass growth kinetics are:

$$\frac{dX}{dt} = \mu X; \qquad \frac{dS}{dt} = -\frac{\mu}{Y_{xs}} X - f(X,t) \; ; \; \frac{dP}{dt} = r_P - \mu P \qquad (6)$$

$$r_P = \begin{cases} 0, & t < t_{ind} \\ K_P^{\max}\left(\frac{S}{K_S + S}\right)\left[\frac{1}{1+\left(\frac{P}{KI_P}\right)^5}\right], & t \geq t_{ind} \end{cases}$$

$$\begin{aligned} &\textit{First order} : \mu = \mu_{\max} S, \; f(X,t) = 0 \\ &\textit{Monod} : \mu = \mu_{\max} \frac{S}{K_s + S}, \; f(X,t) = 0 \\ &\textit{Contois} : \mu = \mu_{\max} \frac{S}{K_X X + S}, \; f(X,t) = 0 \\ &\textit{Monod} : \mu = \mu_{\max} \frac{S}{K_s + S}, \; f(X,t) = m.X \end{aligned}$$

Based on experimental data provided by Tang et al. (2007), a rather rough estimation of each tendency model parameters was made and referred to as "initial values" in Table 1.

Due to the significant level of parametric uncertainty a ±50% confidence interval around these initial values for each parameter is assumed in the first policy optimization iteration. A uniform distribution over its confidence interval is assumed initially for each model parameter. Experimental data have been conveniently pre-treated to reduce significantly the signal-to-noise ratio and outliers are not present.

Table 1. Initial parameterizations of tendency models based on experimental data

Parameter	Unit	Model			
		1st Order	Monod	Contois	Maintenance
$\mu_{\max}$	h^{-1}	0.2000	0.6301	0.5607	0.5261
K_s	$g\ L^{-1}$	2.0184	1.4956	-	0.7190
Y_{xs}	$g_{biomass}\ g_{substrate}^{-1}$	0.3982	0.4506	0.4826	0.4464
$K_P^{\max}$	$g\ L^{-1}$	0.0759	0.0629	0.0557	0.0536
KI_p	$g\ (L\ h)^{-1}$	0.0877	0.0609	0.0627	0.0600
K_x	$g_{substrate}\ g_{biomass}^{-1}$	-	-	1.7291	-
m	h^{-1}	-	-	-	0.0100

At any time *t*, the input policy is defined by a vector *w* of parameters corresponding to two different degrees of freedom for process optimization. A subset of the policy parameters corresponds to inputs that can be modified only from run-to-run but are time-invariant in a given run such as the substrate feeding concentration, run duration or induction time. The remaining entries are parameters which are used here for describing the profile of time-varying controls such as the feeding rate. In the latter case, a key issue is the mathematical description to be used so as to provide ample room for different variability patterns within economic and safety constraints with a minimum number of independent parameters. Even though other profile functions (high-order polymonials, Gaussian Processes, etc.) can be used for shape flexibility with a small number of parameters, the following quadratic inverse polynomial is used hereafter:

Table 2. Sequential optimization of a E. coli culture for rIL-11

Parameter	Units	Initial Condition	1st iter	2nd iter	3rd iter	4th iter	5th iter	6th iter
Z	$L\ h^{-1}$	1	-	-	-	-	-	-

S_0	$g\ L^{-1}$	6	3.93	7	7	7	7	7
$J.V_f$	g	**1.60**	**6.06**	**3.75**	**7.15**	**6.40**	**7.22**	**7.22**

$$F_{in} = \begin{Bmatrix} 0 & t < t_0 \\ \dfrac{At}{1 + Bt + Ct^2} & t \geq t_0 \end{Bmatrix} \quad (7)$$

As it is shown in Table 2, despite the rough approximation of tendency models, they provide a very valuable guideline for fast optimization with a handfull of experiments. Based on their total errors, *Monod* and *Contois* kinetics are the most infomative for re-calculating the input policy for dynamic experiments (see Table 3 and Table 4 below).

Table 3. Total error in 1st iter.

Model	$E_{\hat{j}_i \to \langle j \rangle}$	$E_{\langle j \rangle \to J}$	E_{total}
1st Order	0.0044	0.0209	0.0254

$1.65\ 10^{-5}$	$9.85\ 10^{-4}$	**0.0010**
$2.01\ 10^{-4}$	0.0045	0.0047

4. Final remarks

A systematic procedure is proposed for sequential design of dynamic experiments in modeling for optimization using a library of tendency models for safe exploration of alternative parameterizations of the input policy to improve operating conditions. At each iteration, model selection is based on the total model error which accounts separately for parametric uncertainty and structural errors. Since tendency models are initially plagued with uncertainty model selection using poorly estimated total errors makes possible to trade off exploitation with exploration which is instrumental for model-based optimization with imperfect models. Global sensitivity analysis has been used to formulate the optimal sampling in each experiment as an optimization problem.

Abstract

Technological learning has been treated as an exogenous variable in most energy system models despite the possibility of conditions produced by model variables having significant effects on the development of technologies. When technological learning has been endogenously treated within energy system models, it has often been accomplished through the use of learning curves. By assigning all technological change to a single variables such as cumulative sales, or even including research spending in a two-factor learning curve, the ability to examine the effects of directed policy are severely limited.

Technology pipelines represent the potentials and limitations of each successive generation of a technology individually while using the aggregated improvements learning curves represent to progress through each development stage of the particular technology generation. While multiple generations of a technology may be under concurrent development, by treating each generation individually the true capabilities and limitations may be exposed. With the possibilities for a technology known, development stage dependent policies may be implemented for each generation, instead of a blanket program for the entire technology. The use of the technology pipelines can help to bring energy system models more accurate means of simulating the policies necessary for selecting and nurturing energy technologies until they reach commercial availability. A case study on solar photovoltaic technologies is provided as an example of the technology pipeline framework.

Keywords: Technological learning, Energy systems modeling, Learning curves

1. Introduction

Technological change will play a large role in the trajectory of future energy systems. Current technologies will evolve at different rates and new technologies will gain a foothold. These innovations will help determine the structure of future energy systems and, because they are path dependent, it is critical that they are represented within energy system models. This endogenous technological learning is the key to producing not only realistic future scenarios but also the path by which they may take to their future state.

Technological change, that is an increase in economic output without a corresponding increase in the economic inputs, has historically been treated as a constant or near constant progression in combined energy-economy models. This exogenous

representation is able to show the effects of change on the system, but does not account for how the change occurs. Implicit in this representation is the assumption that economic policies have no effect on research and development or on the adoption of new technologies. While this assumption may be quickly dismissed as simplistic, the economic description of technological change is much more difficult to formulate. The first step in this process is to realize that research and development must be treated as a fixed cost instead of as a raw material input into a product (Romer, 1990).

The basic idea of learning curves, that the cost of production for one unit of a product decreases as the total number of units produced increases, was first formulated more than 70 years ago (Wright, 1936). Though this idea of learning-by-doing has been successfully applied to many disparate industries (Yelle, 1979), it neglects to consider the effects of research and development explicitly, instead effectively attributing all improvements to economies of scale. Learning rates for a number of energy technologies have been calculated (McDonald and Schrattenholzer, 2001). The expansion of the learning curve idea to include a learning-by-searching variable (Kouvaritakis *et al.*, 2000) created the two factor learning curve and allows an explicit representation of the role research and development plays in technological change.

Integrating endogenous technical learning into energy system models has only become a subject of research attention comparatively recently. One of the first attempts at incorporating technological learning into an energy model was made by using investments made by the model as the only source of technical advancement (Messner, 1997) within the mixed integer programming MESSAGE III model. Concurrently the linear programming GENIE model was adapted to incorporate single factor learning curves as a measure for technological change for the study of electrical technology adoption (Mattsson and Wene, 1997). Similarly, single factor learning curves were used to endogenize technological learning in versions of the MARKAL (Loulou *et al.*, 2004) and ERIS (EC-TEEM, 2000) models that were used to study the effects of implementation of the Kyoto protocols on the electricity industry (Barreto, 2001). The variable elasticities used in two-factor learning curves have been formulated for a number of technologies and applied within the POLES (Criqui and Kouvaritakis, 2000) energy model. Additional two factor progress ratios for mature, evolving and emerging electricity technologies have also been calculated (Jamasb, 2007).

2. Research Pipelines

In order to more accurately represent the way new energy technologies are nurtured and developed a new formalism for their representation has been developed. Since one of the goals of long-term energy policy must be the selection and maturation of new technologies the problem can be likened to the management of a portfolio of new products candidates in the pharmaceutical industry (Blau *et al.*, 2004), a task that has already received significant research effort (Ding and Eliashberg, 2002), (Kavadias and Loch, 2004), (Rogers *et al.*, 2002).

As is common in the evolution of products in the pharmaceutical industry we will classify the progress of technologies into three stages. During the research stage a new means for accomplishing the goals specified for the technology are discovered and refined. It is during this first stage where the initial cost of the unit is defined and the initial capabilities of the technology are established. Production of the technology

during the research stage is limited to the laboratory scale. During the development stage work continues on advancing the capabilities of the technology but work also begins on improving the process by which the technology may be built. The economic realities of the technology often become more apparent during this second stage and technologies that have severe limitations that may hinder their ability to become economically competitive with existing technologies often fail at this stage. Production of the technology progresses during the development phase from the laboratory scale to the pilot plant scale. The final stage in the progress of the technology is the manufacturing stage. Here the production processes that were previously developed are refined further and new fabrication procedures may also be implemented.

In the widely-used punctuated equilibrium model of technological change learning occurs in two stages: short bursts of innovation followed by incremental progress. These revolutionary changes beget new technologies that create new markets and render previous technologies obsolete. While viewing technological change from this high level perspective is good for providing histories of technologies, it misses the significant changes that may occur within a technology by only representing the change that occurs within established technologies incrementally. The use of technological generations is necessary to differentiate between particular instances within a technology that have the same general capabilities but possess fundamental underlying differences in structure, material or design. Technological generations are meant to represent significant advances in performance within a technology regime (Lawless and Anderson, 1996). Therefore in the technology pipeline model of learning multiple generations of a technology may exist concurrently, each following the three evolutionary stages previously mentioned.

3. Example: Photovoltaic Solar Cell Technologies

Solar photovoltaics are an ideal choice to illustrate the concept of technology pipelines due to their well documented history and status as an emerging player in main stream electricity applications. Additionally, the specific generations of solar photovoltaics are much more well-defined than for many other energy technologies.

First generation photovoltaic technology is based on single junction cells made from crystalline silicon wafers. While modules based on these cells currently make up the bulk of the commercial market, their relatively low theoretical efficiency limit and the high cost of the composite materials and costly processing steps have combined to spur research on subsequent generations of photovoltaic technology that may have a lower floor cost. Thin film, or second generation, photovoltaic cells were conceived as a means of limiting the use of expensive raw materials in cell fabrication. A variety of exotic, and costly, materials are used in their production but the small amounts of material needed, as well as more economical processing methods, help to limit costs. Unfortunately the cheaper processing methods used for cadmium telluride, copper indium gallium selenide and amorphous silicon cells also produce more defects that limit cell efficiency, which ultimately raises the cost. Second generation technologies have already advanced to the production stages though they currently account for only one-tenth of solar cell production. Third generation cells attempt to retain the low cost approach of second generation cells but also increase efficiency through the use of tandem cells, multiple electron-hole pairs, hot carriers, multiband cells and thermophotonic devices (Green, 2002). Third generation technologies have only been

produced in limited quantities for specialty applications and are thus classified as at the beginning of the development phase within the technology pipeline framework.

In order to demonstrate the potential benefits of using the technology pipeline approach to examine policy level decisions a pair of scenarios for the worldwide solar photovoltaic industry was developed. Each generation of solar photovoltaic technology is assigned a two-factor learning curve that is used to calculate the cost of this particular instance of the technology. The detailed price data need for determining the individual learning by doing and learning by searching rates for second and third generation technologies is not yet public because they are still in early stages of commercialization. Therefore uniform learning rates were assumed for all three generations of the technology based on the longer history of the first generation technology. While this may over or under estimate the potential of the second and third generation technologies it allows the effects of the allowing generation specific policies to be examined in a more general manner. The learning by doing rate used is 18.4% and the learning by searching rate is 14.3% (Kobos *et al.*, 2006). Because the exact learning rates can have a major impact on determining the potential cost reductions for a technology it is important that the most accurate known values are used; those chosen are a good compromise of the varying values found in the literature. It is also important to note that the costs for the modules are based upon the reported market price, not the production costs.

In both the base case scenario and the generational policy scenario the photovoltaic industry's production capacity is assumed to grow at a rate of 15% per year for a period of ten years. While this may seem optimistic it is actually less than the actual rate of growth of 18% from 1993 to 1997 (Shah *et al.*, 1999) and that of 50% production growth rate of the industry in the USA from 2005 to 2007 (EIA, 2008). In both scenarios expansions in production capacity are split between the three generations based upon the current cost of the technology, with the lowest priced technology generation receiving a significantly larger share. Worldwide research and development spending is kept constant throughout the ten year period at $500 million per year, a figure that includes both industrial and governmental expenditures. The allocation of this research budget between the three generations of photovoltaic electricity generation technologies is what differentiates the two scenarios. In the base case scenario all funding is tied to the expansions in capacity; that is it follows the lead of the industry. In contrast, the generational policy scenario allocates the governmental portion of the funding based on the highest cost technology while the industrial portion of the funding follows the same rules as expansions in production capacity. This highest cost approach is predicated upon the assumption that those generations with the highest cost also have the most room for improvement.

The results of a discrete event simulation that models each of the two scenarios indicate that the implementation of generational specific policies can play a large role in the reducing the industry wide cost of a technology. The model is implemented as three states representing the stages of the technology generation. Any additions to research spending or production trigger a recalculation of the generational cost and a check on whether the generation should proceed to the next stage in development or remain in its current state. As may be seen in Figure 1, the allocation of additional research funding to the third generation produces a significant decrease in the module cost of the technology when compared to the base case. This result can also be inferred from the

structure of the learning curve formulation. Since the initial amount of research spending on the third generation technology is much smaller a doubling of the cumulative research spending, and hence significant cost reduction, requires less spending than an equivalent reduction for either of the more mature technology generations. This model assumes that the policy shift in research funding occurred before the start of the simulation time frame, as research spending does not translate into immediate discoveries. A typical time lag between research spending and its effect on the technology's learning curves is 2-3 years.

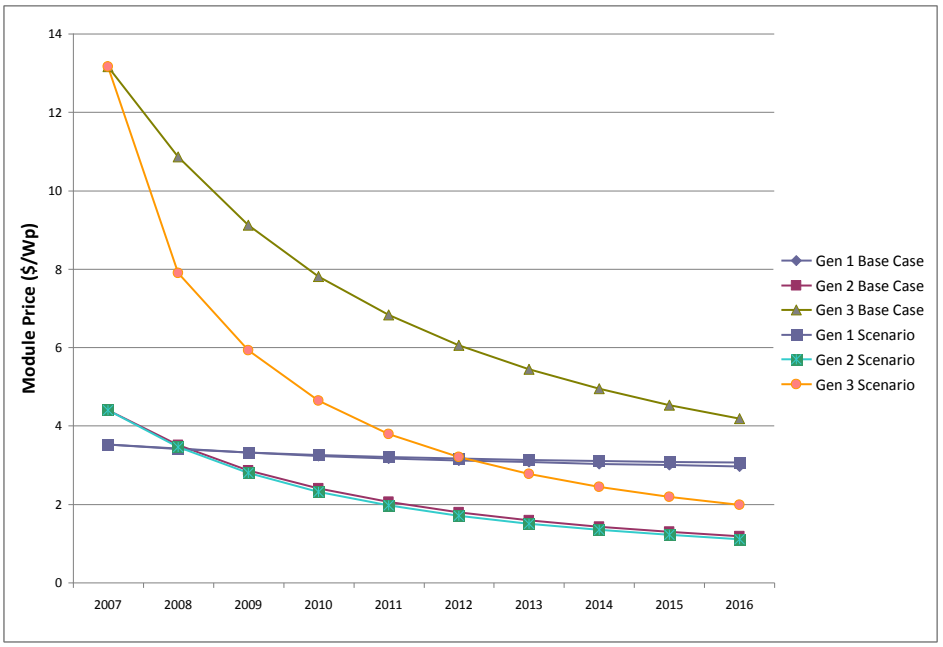

Figure 1: Solar photovoltaic module prices for the three technology generations in the base case and policy specific scenarios

Through the use of the research pipeline concept we have been able to examine how governmental and industrial policies that are focused on a particular segment of a technology may elucidate more information on the potentials of individual technology generations. Following the common single technology single learning curve model any changes in policy could only reproduce the potentials and limitations of the first generation photovoltaics that still dominate the industry. As second generation technologies have started to reach and surpass the cost levels of the first generation, a closer examination of the succeeding generations is necessary to illuminate the future path of the photovoltaic industry.

4. Conclusions

Energy system models have often treated technological learning as an exogenous variable. Government and industrial policies may play a large role in technological learning and thus models that aim to analysis these policies should treat technological learning endogenously. When endogenous technological learning has been considered, it has been in the form of industry-wide learning curves that prohibit the investigation of policy choices that focus on particular breeds of a technology. The technology pipeline

framework presented represents a decomposition of the learning curve concept often used to represent endogenous technological chance. An example from the field of solar photovoltaic electricity production has been used to illustrate how this decomposition may lead to the simulation of more detailed technology fostering policies.

Discrete Element Modeling for Multiscale Simulation of Aggregation Processes

Alexander Reinhold and Heiko Briesen

Max Planck Institute for Dynamics ofComplex Technical Systems, Sandtorstraße 1, 39106 Magdeburg, Germany.
Present Adress: Chair for Process Systems Engineering, Center of Life and Food Sciences Weihenstephan, TU München, 85350 Freising

Abstract

First steps of combining the favorable predictive capability of the discrete element method and the computational efficiency of the population balance approach are presented. Aggregation due to gravitational settling and shear induced aggregation are implemented and discussed as case studies. Results of the multiscale simulation show excellent results for 99 % of the total particle number.

Keywords: multiscale simulation, discrete element method, shear induced aggregation

1. Introduction

Population balance modeling is a commonly used tool to describe aggregation processes on a macroscopic level. Analytical aggregation rate kernels and suitable numerical discretization have to be used to obtain meaningful solutions of actual population balance models. However, a predictive simulation of aggregation is still not possible today due to the lack of predictive models for the aggregation rates.

The physics of aggregation are governed by many effects: particle mass fraction, particle shape, particle size distribution, spatial distribution of particles and the leading aggregation mechanism. For the derivation of well known aggregation rate kernels (e.g. the classical shear induced or Brownian aggregation rate kernel by Smouluchowski (1917)) very coarse assumptions have to be made in order to obtain an analytical solution: low particle mass fraction, ideal spherical particles, no dependency on particle size distribution, well mixed compartment and a single type of mechanism. With discrete element simulations, the Brownian aggregation rate kernel is reproduced for mass fractions lower than 0.1% (Trzeciak (2006), Heine and Pratsinis (2007)). However, it was also shown that Brownian aggregation rate kernels depend on the particle mass fraction and even depend on the specific particle size distribution.

Discrete element modeling of aggregation is capable of avoiding many modeling assumptions and provides more accurate and predictive models. However, discrete approaches are computationally expensive and therefore not immediately suited for a large population of particles. Equation-free multiscale modeling (Kevrekidis (2004)) provides a framework to combine the favorable predictive capability of discrete element simulation and the computational efficiency of population balances.

This paper discusses basic principles of the multiscale simulation of aggregation and focuses on two specific case studies: Shear induced aggregation and aggregation due to gravitational settling. The mandatory modeling assumptions for these aggregation rate

kernels are reconstructed in the discrete model to validate their accuracy. Additionally, the first results of multiscale simulations are presented.

2. Method

2.1. Population Balance

The particle population comprises of ideal spherical particles in a well-mixed compartment. The volume v (or radius $\lambda(v)$) is used as the only internal coordinate. Pure aggregation phenomena can be modeled by the population balance equation:

$$\frac{\partial \tilde{n}(t,v)}{\partial t} = \int_0^v r(\tilde{n}, v', v-v')dv' - \int_0^\infty r(\tilde{n}, v, v')dv' \quad , \tag{1}$$

where $\tilde{n}$ is the number-based particle size distribution and r are the aggregation rates. The aggregation rate measures the frequency of effective collisions per time and volume between particles of the sizes v and v'. With the assumption of binary aggregation, the aggregation rate kernel $\beta(v,v')$ is usually separated:

$$r(\tilde{n}, v, v') = \beta(v,v')\tilde{n}(v)\tilde{n}(v') \quad . \tag{2}$$

Available theoretically motivated aggregation rate kernels require the assumption of ideal spherical and homogenously distributed particles (Ramkrishna (2000)). Hence, the assumptions for the population balance in Eq. (1) are mandatory if analytical aggregation rate kernels are used. In this paper two case studies on aggregation are analyzed. Each one depends on a different set of physical parameters beside the dependency on particle radii. The shear induced aggregation rate kernel $\tilde{\beta}_{shear}$ depends on the shear rate γ. The aggregation rate kernel for aggregation due to gravitational settling $\tilde{\beta}_{grav}$ depends on the gravitational acceleration g, dynamic viscosity η, mass density of particles ρ_{part} and mass density of fluid ρ_{fluid}. The aggregation rate kernels for these cases can e.g. be found in Hounslow et al. (2001) and Ramkrishna (2000), respectively:

$$\tilde{\beta}_{shear}(v,v') = \frac{4\gamma}{3}\left(\lambda(v)+\lambda(v')\right)^3 \quad , \tag{3}$$

$$\tilde{\beta}_{grav}(v,v') = \frac{2\pi}{9}\frac{g\left|\rho_{part}-\rho_{fluid}\right|}{\eta}\left(\lambda(v)+\lambda(v')\right)^2\left|\lambda(v)^2-\lambda(v')^2\right| \quad . \tag{4}$$

2.2. Multiscale Framework

What happens, if the mandatory assumptions of spherical and homogeneously distributed particles are insufficient? Or assuming a dense particle population, the assumption of binary collisions becomes invalid. Analytical aggregation rate kernels and consequently analytical aggregation rates are no longer available.

Adopting the equation free multiscale framework (Kevrekidis et al. (2004)), this problem can be avoided. Instead of a closed analytical formulation of the problem, missing analytical equations are replaced by discrete element simulations. As discrete element simulations are very time consuming, the multiscale framework can profit from the time efficiency of the population balance equation plus the detail of modeling assumptions of the discrete element model.

The framework is based on the numerical solution of the population balance equation. Generally, any discretization method can be used to transform Eq. (1) into a set of ordinary differential equations. For this case study the fixed pivot technique presented by Kumar and Ramkrishna (1996) is used. The continuous particle size distribution $\tilde{n}$ is discretized in intervals i with a number of particles n_i in each interval. Each interval has a representative particle volume v_i. The resulting ordinary differential equations are integrated stepwise. For each step of the time integrator, aggregation rate kernels $\beta(v_i, v_j)$ are required for all pairs of representative particle sizes.[1]

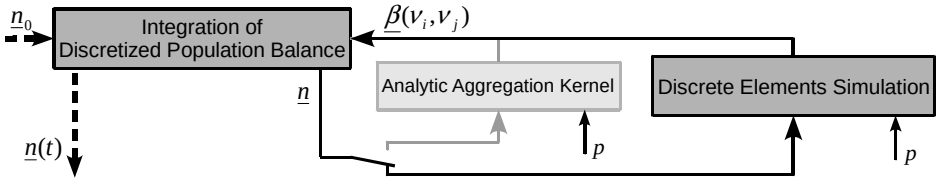

Figure 1: Scheme of multiscale framework

The basic scheme of the equation free multiscale framework adopted to aggregation processes is shown in Figure 1. Given the current state vector $\underline{n}$ and the required physical parameters p, the aggregation rate kernel can be calculated in two ways. If modeling assumptions allow usage of a given analytical aggregation rate kernel, the framework reduces to a closed analytic formulation on the macroscale level. If analytical expressions are leaking or invalid, statistical evaluation of discrete element simulations may be used instead.

2.3. Discrete Element Model

Using a discrete element model, the assumptions of ideal spherical particles and homogeneous spatial distribution are in principal not necessary. However, for the work presented here, these assumptions are exactly reconstructed to validate the framework with analytical aggregation rate kernels. The discrete element simulation is divided into three sections: initialization, simulation, statistical analysis.

2.3.1. Initialization

The discrete element simulation requires a number N of particles initialized with radii and position in the simulation volume of the size $V_{sim} = N / \sum_i n_i$. The position $\vec{x}_Q$ of each particle Q is equally distributed in the simulation volume. Trzeciak et. al (2006) and Heine and Pratsinis (2007) have shown that the aggregation rate kernel depends on the particle size distribution for Brownian aggregation. Hence, to construct a most flexible framework, the size distribution of the discrete particles must approximate the discretized particle distribution $\underline{n}$. The radius λ_Q for each particle Q is sampled from the probability distribution

$$P(\lambda_Q = \lambda(v_i)) = \frac{n_i}{\sum_i n_i} \tag{5}$$

to achieve this requirement.

[1] Note, that the actual choice of these representative particle sizes depend on the discretization of the inner coordinate.

2.3.2. Simulation

The derivation of the analytical aggregation rate kernels assumes constant particle velocities for shear and gravitational settling, respectively:

$$\vec{u}_{shear,Q} = \begin{pmatrix} 0 & \gamma & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} \vec{x}_Q \quad , \tag{6}$$

$$\vec{u}_{grav,Q} = \frac{2}{9} \frac{\lambda_Q{}^2 (\rho_{fluid} - \rho_{part})}{\eta} (0,1,0)^T \quad . \tag{7}$$

These velocities are integrated iteratively for small time steps τ. With each step, collisions between particles are checked. Each collision between two selected particles is counted once. If two particles collide again later, this collision is ignored. Collisions between two particles do not lead to an aggregation. Thus, the particle size distribution is conserved during the simulation.

2.3.3. Statistical Analysis

Given the number $C(\nu_i,\nu_j)$ of counted collisions between particle size classes i and j, the aggregation rate kernel can be calculated by :

$$\hat{\beta}(\nu_i,\nu_j) = C(\nu_i,\nu_j) \frac{V_{sim}{}^2}{T_{sim} V_{obsv}} \frac{1+\delta_{i,j}}{N_i (N_j - \delta_{i,j})} \frac{1}{1 - p_{init,(i,j)}} \quad , \tag{8}$$

where $\delta_{i,j}$ denotes the Kronecker delta and T_{sim} denotes the time span of the simulation. The observed volume V_{obsv} is slightly smaller than the simulation volume. The term $p_{init,(i,j)}$ is the probability of two particles fulfilling the collision condition just after initialization. A detailed description of these terms and the derivation of Eq. (8) is given by Reinhold (2008).

As the simulation is initialized randomly, the achieved aggregation rate kernel has a certain coefficient of variation. This coefficient of variation is approximated in Eq. (9) by assuming the number of counted collisions being normally distributed:

$$\theta_{\hat{\beta}(\nu_i,\nu_j)} = \frac{1}{\sqrt{\hat{\beta}(\nu_i,\nu_j)}} \sqrt{\frac{1+\delta_{i,j}}{T_{sim} N} \frac{\sum_k n_k}{n_i n_j}} \quad . \tag{9}$$

Eq. (9) can be used as a measure of quality for the estimates of the aggregation rate kernels. An increase of simulation time has the same effect on the coefficient of variation as the increase of the number of particles for the simulation. The accuracy of calculating small aggregation rate kernels becomes worse. Aggregation rate kernels for particles of the same size class have a coefficient of variation $\sqrt{2}$ times larger, than aggregation rate kernels for particles of different size classes. Additionally, the aggregation rate kernel for denser particle populations can be predicted more accurately.

3. Results

3.1. Discrete Element Model

To validate the implemented discrete element model for each case, a set of 10^5 stochastically independent simulations of $N = 6000$ particles and a time span of $T_{sim} = 0.5\,s$ were performed.

Particle sizes of $\lambda_1 = 4\,\mu m$ and $\lambda_2 = 8\,\mu m$ were initialized with particle densities of $n_1 = n_2 = 10^{13}\,m^{-3}$ for shear induced aggregation. The shear rate was $\gamma = 5\,s^{-1}$ and the time steps were limited to $\tau_{\max} = 2.5\,ms$. The mean aggregation rate kernel for two particles of size λ_1 was calculated and resulted in a relative error of 0.041% compared to the analytical aggregation rate kernel Eq. (3). The relative error of the aggregation rate kernels for the other aggregation pairs was significantly smaller.

Particle sizes of $\lambda_1 = 6\,\mu m$, $\lambda_2 = 8\,\mu m$ and $\lambda_3 = 10\,\mu m$ were used for aggregation due to gravitational settling. The particle densities were $n_1 = n_2 = n_3 = 10^{13}\,m^{-3}$. The physical parameters were set to the following values: $g = 9.81\,m\,s^{-2}$, $\eta = 10^{-3}\,kg\,m^{-1}\,s^{-1}$, $\rho_{part} = 900\,kg\,m^{-3}$ and $\rho_{fluid} = 10^3\,kg\,m^{-3}$. Time steps were limited to $\tau_{\max} = 21.5\,ms$. The mean aggregation rate kernel for particles of sizes λ_1 and λ_2 has a relative error of 0.046% compared to the analytical aggregation rate kernel Eq. (4). Again, the relative error of the aggregation rate kernels for the other aggregation pairs was significantly smaller.

3.2. Multiscale Simulations

For the case studies the following initial condition was used:

$$\tilde{n}(v, t_0) = \frac{n_0}{v_0} e^{-v/v_0} \quad , \tag{10}$$

with $n_0 = 10^{15}\,m^{-3}$ and $\lambda(v_0) = 1\,\mu m$. For the methodological comparison, a simple forward Euler algorithm was used to integrate the resulting ordinary differential equations with constant time steps of $\tau_{pop} = 0.4\,s$. The discrete element simulation was executed each time step simulating $N = 32000$ particles with a time span of $T_{sim} = 0.2\,s$. The results are shown in Fig. (2). Shear induced aggregation was simulated using a shear rate of $\gamma = 3.5\,s$. For aggregation due to gravitational settling the following parameters were used: $g = 9.81\,m\,s^{-2}$, $\eta = 10^{-3}\,kg\,m^{-1}\,s^{-1}$, $\rho_{part} = 1110\,kg\,m^{-3}$ and $\rho_{fluid} = 1000\,kg\,m^{-3}$.

The evolution of shear induced aggregation shows a more broadened particle size spectrum, whereas the aggregation due to gravitational settling is much steeper. The plots show an excellent agreement for particle size distribution values above $\tilde{n}(v) = 10^{25}\,m^{-4}$. The error in the remaining region represents not more than 1% of the total particle number. The reason for this deviation is connected to the initialization of the discrete element simulations. Just a discrete number of each particle size fraction can be initialized. If the expectation value of this number is of the order of 1 or below, no particles of this size category might be initialized. Hence, no aggregation rate kernel

can be calculated. These aggregation rate kernels are set to 0. The particle size distribution cannot propagate properly in regions, where aggregation partners would be necessary, which are unlikely to be initialized.

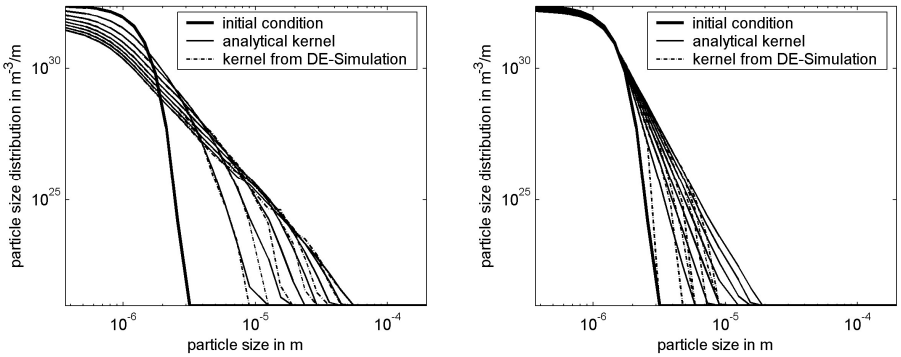

Figure 2: Evolution of particle size distribution for shear induced aggregation (left) and aggregation due to gravitational settling (right). The numerical solutions are depicted in 8 time steps of 42 seconds from 0 to 336 seconds.

3.3. Conclusions

Discrete element simulations are capable of covering a broad spectrum of modeling assumptions. Furthermore, if implemented carefully, they lead to results with no systematic error, as presented in section 3.1. The statistical accuracy of these simulations is solely limited by spent computational efforts. The first results of the multiscale framework already show an excellent agreement for the majority of the particle population. As this is only a validation study using known analytical kernels, it can only show the potential of this approach. Nevertheless, when reaching for predictive aggregation models, we conclude that the presented multiscale framework is capable of combining a high detail in modeling with efficient population balance models.

Optimal synthesis of heat exchanger networks using enthalpy-temperature functions to describe streams

Diego G. Oliva, Javier A. Francesconi, Miguel C. Mussati and Pio A. Aguirre

INGAR Instituto de Desarrollo y Diseño (CONICET-UTN), Avellaneda 3657, Santa Fe (3000), Argentina

Abstract

This work presents a mixed integer non linear programming (MINLP) model for heat exchanger network synthesis including a detailed description of the process streams resorting to a mathematical function that matches temperature with enthalpy. This allows the model to account for non linear behavior of streams by taking into consideration their composition. To achieve the objective, the energy balance equation proposed in the "synheat" model by Yee and Grossmann (1990) is modified but equations involving temperature are kept the same. A new equation is added to that model to describe the relationship between temperature and enthalpy by correlation. As the original model, this modified MINLP model provides the network structure that minimizes the total annual cost. The mathematical program has non-convex equations, and only locally optimal solutions can be guaranteed. The approach between cold and hot streams has more detailed information because describes the real behavior of streams, and avoids matches that a linear functionality or a classical model may allow. Correlations between temperature and enthalpy are a function of the components present in a particular stream. The required information can be collected from bibliography or public databases as those provided by NIST (National Institute of Standards and Technology). The proposed methodology is a useful tool when the minimum temperature approach between streams is small. Examples are presented and discussed to compare results when streams are described by linear and non linear functionality between temperature and enthalpy.

Keywords: Heat exchange network HEN, synthesis, MINLP models, synheat, temperature–enthalpy functionality.

1. Introduction

Two major methodologies have been proposed for the synthesis of heat exchanger network problems: sequential and simultaneous approaches. The pinch design method (Linnhoff and Hindmarsh, 1983) is one of the most-widely known, and is based in sequential approaches, in which targets are obtained sequentially using heuristic rules. On the other hand, methodologies based on mathematical programming techniques were developed. A complete review and classification of different methods were performed by Furman and Sahinidis (2002).

Yee and Grossmann (1990) developed a basic framework for heat exchanger network synthesis using a staged-superstructure formulated as a MINLP (Mixed Integer Non Linear Programming) model aiming at minimizing simultaneously the utility demands and the capital cost of the network. Several extensions of that framework were proposed addressing flexibility, incorporating detailed design aspects of the exchanger units, and focusing on global optimality issues.

Some modifications to the staged-superstructure models are here proposed to address process synthesis. When a process is to be synthesized is important to consider the composition of the streams involved because reactors behavior and structure of the entire process are function of these variables. Then, a modification to the classical stage-superstructure HEN models is made to take into account energy content and temperature approach between streams. These considerations provide a better description of streams in heat exchangers, and avoid infeasible streams matches.

2. Mathematical model

This derived model is inspired by the pioneering work of Yee and Grossmann (1990). Consequently, the superstructure proposed and the nomenclature used has some similarities with that work. Figure 1 shows the structure and variables involved. At the stage outlet, temperature and enthalpy are problem variables. It is possible to modify the original energy balances equations replacing temperature by enthalpy, maintaining streams feasibility equations with temperature, and adding a new equation to the original model that relates temperature and enthalpy. Non linear correlations for stream enthalpy as function of the stream molar composition and temperature are adopted.

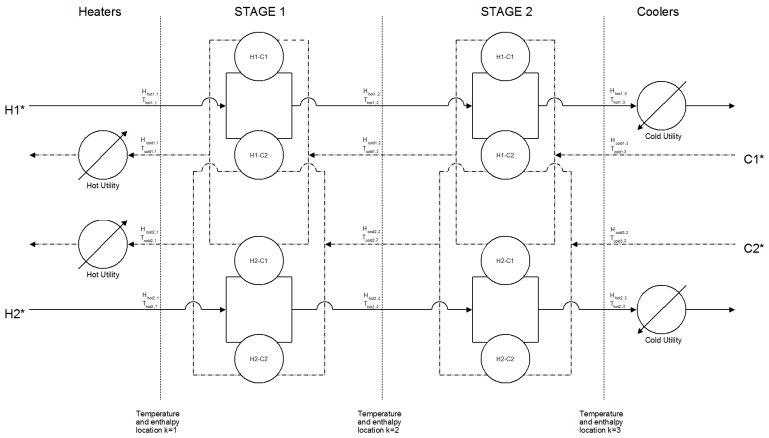

Figure 1. Superstructure with the new variables incorporated to the original model.

The new MINLP model can be written as follows (nomenclature is the same as in Yee and Grossmann, 1990):

2.1. Overall energy balance for each stream

The total heat balance for streams is given by:

$$(H_{IN_i} - H_{OUT_i}) = \sum_{k \in ST} \sum_{j \in CS} q_{i,j,k} + q_{CU,i} \quad \text{i} \in \text{HS} \qquad (1)$$

$$(H_{OUT_j} - H_{IN_j}) = \sum_{k \in ST} \sum_{i \in HS} q_{i,j,k} + q_{HU,j} \quad \text{j} \in \text{CS} \qquad (2)$$

2.2. Energy balance for each stage

The energy balance for each stage is a modified version of the Yee and Grossmann (1990) model.

$$(H_{i,k} - H_{i,k+1}) = \sum_{j \in CS} q_{i,j,k} \quad \text{i} \in \text{HS}, \text{k} \in \text{ST} \qquad (3)$$

$$(H_{j,k} - H_{j,k+1}) = \sum_{i \in CS} q_{i,j,k} \quad \text{j} \in C\text{S, k} \in \text{ST} \tag{4}$$

2.3. Inlet enthalpy assignment

These equations assign the inlet enthalpy to each stream.

$$H_{IN_j} = H_{j,k+1} \quad \text{j} \in \text{CS} \tag{5}$$

$$H_{IN_i} = H_{i,1} \quad \text{i} \in \text{HS} \tag{6}$$

2.4. Enthalpy feasibility

Here, the modified model replaces temperature by enthalpy to keep the order in each stage, and indirectly reaches temperature feasibility.

$$H_{\text{i,k}} \geq H_{i,k+1} \quad \text{i} \in \text{HS, k} \in \text{ST} \tag{7}$$

$$H_{\text{j,k}} \geq H_{j,k+1} \quad \text{j} \in \text{CS, k} \in \text{ST} \tag{8}$$

$$H_{OUT_i} \leq H_{i,k+1} \quad \text{i} \in \text{HS} \tag{9}$$

$$H_{OUT_j} \geq H_{j,1} \quad \text{j} \in \text{HS} \tag{10}$$

2.5. Heating and cooling duties

$$(H_{i,k+1} - H_{OUT_i}) = q_{CU,i} \quad \text{i} \in \text{HS} \tag{11}$$

$$(H_{OUT_j} - H_{j,1}) = q_{HU,j} \quad \text{j} \in \text{CS} \tag{12}$$

Equations (13) to (25) and (28) are the same as those proposed by Yee and Grossmann (1990). Equations (26) and (27) are added to correlate temperature and enthalpy. This allows the model to provide a better description of the streams.

2.6. Upper bound constraints

$$q_{i,j,k} - Q_{\max} y_{i,j,k} \leq 0 \quad \text{i} \in \text{HS, j} \in \text{CS, k} \in \text{ST} \tag{13}$$

$$q_{CU,i} - Q_{\max} y_{CU,i} \leq 0 \quad \text{i} \in \text{HS} \tag{14}$$

$$q_{HU,j} - Q_{\max} y_{HU,j} \leq 0 \quad \text{j} \in \text{CS} \tag{15}$$

2.7. Temperature differences

$$\Delta T_{i,j,k} \leq T_{i,k} - T_{j,k} + \Delta T^{\max}(1 - y_{i,j,k}) \tag{16}$$

$$\Delta T_{i,j,k+1} \leq T_{i,k+1} - T_{j,k+1} + \Delta T^{\max}(1 - y_{i,j,k}) \tag{17}$$

$$\Delta T_{CU,i} \leq T_{i,k+1} - T_{OUT,CU} + \Delta T^{\max}(1 - y_{CU,i}) \tag{18}$$

$$\Delta T_{HU,i} \le T_{OUT,HU} - T_{j,1} + \Delta T^{\max}(1 - y_{HU,j}) \tag{19}$$

2.8. Logarithmic mean temperature differences

$$LMTD_{i,j,k} - \left[\frac{1}{6}(\Delta T_{i,j,k} + \Delta T_{i,j,k+1}) + \frac{2}{3}\sqrt{\Delta T_{i,j,k}\Delta T_{i,j,k+1}}\right] \le 0 \tag{20}$$

$$LMTD_{CU,i} - \left[\frac{1}{6}(\Delta T_{CU,i} + T_{OUT_i} - T_{IN_{CU}}) + \frac{2}{3}\sqrt{\Delta T_{CU,i}(T_{OUT_i} - T_{IN_{CU}})}\right] \le 0 \tag{21}$$

$$LMTD_{HU,j} - \left[\frac{1}{6}(\Delta T_{HU,j} + T_{IN_{HU}} - T_{OUT_j}) + \frac{2}{3}\sqrt{\Delta T_{HU,j}(T_{IN_{HU}} - T_{OUT_j})}\right] \le 0 \tag{22}$$

2.9. Heat exchanger area requirement

$$area_{i,j,k} - \frac{q_{i,j,k}}{U_{i,j}\, LMTD_{i,j,k}} = 0 \tag{23}$$

$$area_{CU,i} - \frac{q_{CU,i}}{U_{CU,i}\, LMTD_{CU,i}} = 0 \tag{24}$$

$$area_{HU,j} - \frac{q_{HU,j}}{U_{HU,j}\, LMTD_{HU,j}} = 0 \tag{25}$$

2.10. Enthalpy-temperature function

By incorporating Equation (26) and (27) to the original model of Yee and Grossmann (1990), a better description of streams in a heat exchanger is possible. It should be noted that in equation (26) $T_{i,k}$ is a function of $H_{i,k}$, and that function is expressed in terms of constant values, i.e. A_i, B_i, C_i, D_i, E_i, F_i and H_i; and analogously for equation (27), except for the suffix j, where values of these constants are taken from the NIST database depending on the stream composition.

$$H_{i,k} = \frac{1000.F}{MW}\left[\begin{array}{l} A_i.\left(\frac{T_{i,k}}{1000}\right) + B_i.\frac{\left(\frac{T_{i,k}}{1000}\right)^2}{2} + C_i.\frac{\left(\frac{T_{i,k}}{1000}\right)^3}{3} + \\ D_i.\frac{\left(\frac{T_{i,k}}{1000}\right)^4}{4} - \frac{E_i}{\left(\frac{T_{i,k}}{1000}\right)} + F_i - H_i \end{array}\right] \qquad i \in HS \tag{26}$$

$$H_{j,k} = \frac{1000.F}{MW}\left[A_j.\left(\frac{T_{j,k}}{1000}\right) + B_j.\frac{\left(\frac{T_{j,k}}{1000}\right)^2}{2} + C_j.\frac{\left(\frac{T_{j,k}}{1000}\right)^3}{3} + D_j.\frac{\left(\frac{T_{j,k}}{1000}\right)^4}{4} - \frac{E_j}{\left(\frac{T_{j,k}}{1000}\right)} + F_j - H_j \right] \qquad j \in CS \qquad (27)$$

2.11. Total annual cost

The objective function to be minimized is the Total Annual Cost (TAC)

$$TAC = \sum_{i\in HS} CCU\, q_{CU,i} + \sum_{j\in CS} CHU\, q_{HU,j} + \\ + \sum_{i\in HS}\sum_{j\in CS}\sum_{k\in ST} CF_{i,j} y_{i,j,k} + \sum_{i\in HS} CF_{i,CU}\, y_{CU,i} + \sum_{j\in CS} CF_{j,HU}\, y_{HU,j} + \\ + \sum_{i\in HS}\sum_{j\in CS}\sum_{k\in ST} C_{i,j}\left(area_{i,j,k}\right)^{\beta} + \sum_{i\in HS} C_{i,CU}\left(area_{i,CU}\right)^{\beta_{CU}} + \sum_{j\in CS} C_{j,HU}\left(area_{j,HU}\right)^{\beta_{HU}} \qquad (28)$$

3. Example

Water streams with different temperature levels are used. Table 1 shows the streams specifications.

Table 1. Streams Data.

Stream	TIN (K)	TOUT (K)	F(kg seg-1)	Cp (kJ kg-1 K-1)	F.Cp (kW K-1)	h (kW m-2 K-1)
H1	370	290	10.00	4.19	41.87	1.80
H2	480	380	7.00	2.02	14.14	2.00
HU	627	627	-	-	-	2.50
C1	280	350	8.00	4.19	33.52	1.80
C2	400	600	5.00	2.02	10.10	2.00
CU	280	285	-	-	-	1.00

Note that original model uses Cp values from Table 1 while proposed model uses parameters depicted in Table 2.

Table 2. Water coefficients used in temperature-enthalpy correlation.

	Water	
Coefficient	Condensed phase	Gas phase
A	-203.606	30.092
B	1523.290	6.833
C	-3196.413	6.793
D	2474.455	-2.534
E	3.855	0.082
F	-256.548	-250.881
G	-488.716	223.397
H	-285.830	-241.826

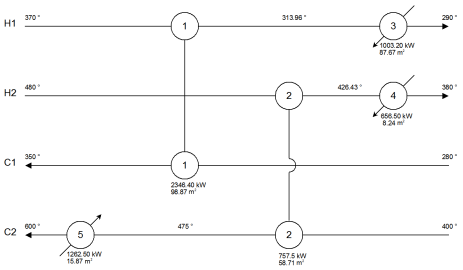

Figure 2. Network using the traditional model.

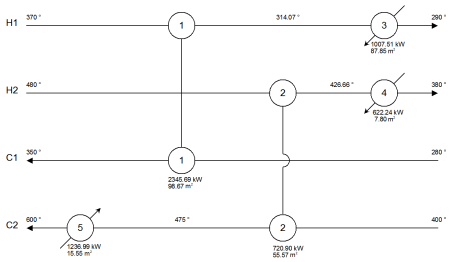

Figure 3. Network using the new model.

Table 3. Differences in the computed energy content according to the used model.

Stream	Energy Content Computed [kW]		Difference Between Models	%
	Traditional Model	New Proposed Model		
Hot 1	3349.60	3353.20	3.60	0.11
Hot 2	1413.50	1343.14	-70.36	-4.98
Cold 1	2346.40	2345.69	-0.71	-0.03
Cold 2	2020.00	1957.89	-62.11	-3.07

Differences between models are the energy computed in each stream (Table 3) and the temperature approach between streams. For example, the traditional model computes an energy content of 2020.00 kW for cold stream 2 while the proposed model with the temperature-enthalpy correlation computes 1957.89 kW. Figure 2 and Figure 3 show that the arrangements obtained with the traditional model and with the proposed model are similar. However, the proposed model provides a better solution than the original model regarding the TAC value, i.e. the original model computes $174,744.80 while the proposed model computes $171,622.91. Both models were implemented in GAMS (Brooke et al., 1997) and solved with the solver DICOPT solver (Duran and Grossmann, 1986).

4. Conclusion

A more rigorous description of process streams was proposed using a correlation. The temperature approach and the streams energy content are better described and computed using the temperature-enthalpy correlation as proposed in this model than the linear correlation frequently used. The proposed methodology is a useful tool when the minimum temperature approach between streams is small.

Abstract

The main goal this paper is related with the development of computational simulator for the artificial lift method based on Electrical Submersible Pump (ESP). This simulator will be able to represent the dynamic behavior, considering the source's model and electric energy transmission for the motor, the ESP model's electric motor (including the thermal calculation), flow simulations and three-dimensional animations for each ESP subsystem (motor, pump, seal, and so on). The simulator proposes an improvement in oil wells monitoring through a better knowledge of physical phenomena more relevant of the process. These information can prevent failures, facilitating decision-making in a smaller portion of time. Similarly, it allowing to control the increased oil production through adjustments of operating conditions (frequency, head well pressure, operations points, etc.).
Keywords: Electrical submersible pump, artificial lifting, modeling and optimization.

1. Introduction

For the oil production is necessary, first of all, discover the potential field producer through seismic and geological studies. Later, a well crossing one or more hydrocarbon bearing zones should be drilled. During the drilling is possible to confirm the presence of oil. In this case, the well should be coated and completed with a system of natural or artificial elevation that allows the lifting of fluids to the surface. The ESP is a method of artificial lift in which the power is transmitted by a cable to the electric motor that connects the centrifugal pump as illustrated in figure 1. The flow produced depends of reservoir characteristics, fluids properties, internal geometry of pump, rotation motor and suction and discharge pressures. It can change the flow produced, within certain limits, controlling the opening of control's valve (beam) or the rotation of centrifugal pump by adapting the motor's frequency. The cost is high in case of failure, because it needs of the drilling rig. There are cases in which all equipment must be replaced, further increasing costs. The time waiting for rig may be high, especially in offshore applications, generating losses due to delay in oil production.

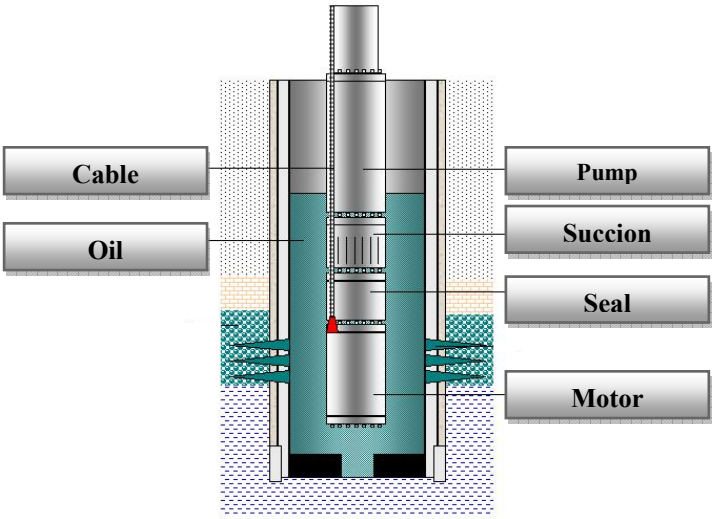

Fig.1. ESP system

1.1. Motivation

In the technical-economic view, it is expected that the flow will be as large as possible. This context leads to adjustment in beam on surface and inverter's frequency on electric motor. Another basic requirement is related with the failures time. It is expected that the failures average time will be as long as possible to decrease loss of profit and maintenance costs. Sometimes is necessary to stop motor because operation schedules or failures on electric system. In this case, it is strongly recommend hold the stop status for a time even motor's temperature decrease for a safe work level. Currently, this time is defined based on operator experience and reading of diverse operational variables. A simulator can be used to train the operators about the real conditions work through features fluids, reservoir scheme, well design and pump models. Currently, there is not a commercial simulator that provides the previous functionalities.

2. Description of Model

In the technique of computer simulation is established a model able to describe or represent the real problem to be submitted an "experimental" manipulation in a computer. Through simulations, it is possible to visualize the main stages of process. In this context, this paper proposes a simulator for the computational method of artificial lift, considering the characteristics of the reservoir, model of fluid flow inside a pump ESP, model of electric motor considering the heating effect and integration of Variable Speed Drives (VSD).

2.1. Motor

The electric motors used to boost the ESPs are induction phase, tubular geometry usually two poles which rotate around 3500 rpm for a frequency of 60Hz. The motors are designed to work in difficult conditions: immersed in fluids that being produced, high pressures and high temperatures. To support these conditions, the motors have a mineral oil to ensure electrical isolation, lubrication of bearings and cooling of motor.

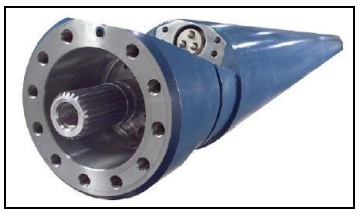

Fig.2. Induction motor

The model of dynamic behavior of electric motor was based in [1]. This model is based on linear processing called dq0 that allows the calculation of torque linking voltages, currents, flow dispersion and angular speed instantly. From these relations is estimated power factor, active power, efficiency and the heat generated in motor windings.

2.2. Pump

The pump used is a centrifugal with multiple stages, each stage consisting of an impelidor and diffuser. The impelidor creates a centrifugal field which is responsible for increasing the speed and pressure of the fluid. The flow through the diffuser the fluid will find a progressive increase in the flow that cause drop in speed and increase in pressure (Bernoulli's theorem). Each stage provides an increase of the pressure fluid. The pump's stages are based on requirements fluids productions. In figure 3 is represented a stage of the pump and the principle of operation for several stages.

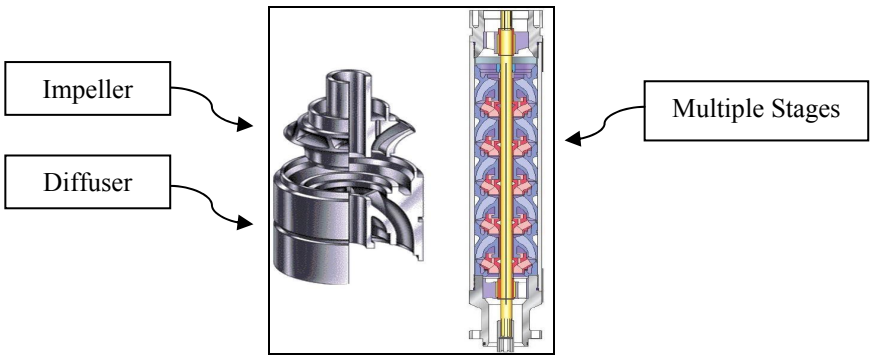

Fig.3. Representation of centrifugal pump

The shape and size of impelidor and diffuser determine the flow to be pumped, stages number and their ability to lift or head. The manufacturers publish a curve of each model of pump. These curves are given considering a single stage draining water should be corrected when applied to other values of fluid viscosity. If present biphasic flow inside the pump the effect of gas must be considered. The simulator will correct the curve of performance the pump when pumping viscous oils. There are several procedures in the literature to correct pump performance for viscous applications. The simulator is based on the Hydraulic Institute. In figure 4, there is the behavior of the curve of the pump for water and a viscosity of 40cp.

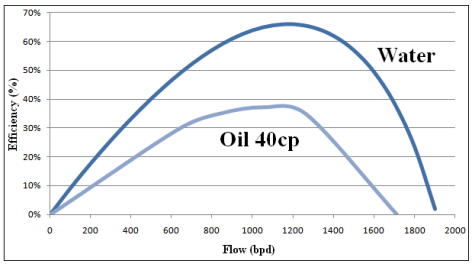

Fig.4. Effect of viscosity

The simulator will use motors with variable speed (VFD), so it is necessary to calculate the new performance curve for different frequencies of electric motor.
According to [2] changes following relations:

1. The flow (Q) changes directly proportional to rotation (N):

$$\frac{Q_2}{Q_1} = \frac{N_2}{N_1}$$

2. The head changes directly proportional with the square of the change in rotation:

$$\frac{Q_2}{Q_1} = \left(\frac{N_2}{N_1}\right)^2$$

3. The power changes directly proportional with the cube of the change in rotation:

$$\frac{Pot_2}{Pot_1} = \left(\frac{N_2}{N_1}\right)^3 \quad ie \quad \frac{Q_2}{Q_1} = \frac{N_2}{N_1} = \sqrt{\frac{H_2}{H_1}} = \sqrt[3]{\frac{Pot_2}{Pot_1}}$$

In figure 5, is an example of application of affinity laws illustrating the performance curve of pump for various frequencies.

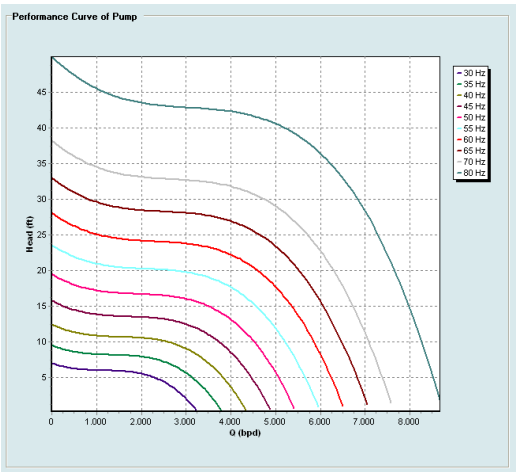

Fig.5. Application of affinity laws

2.3. Reservoir

For development a simulator of artificial lift is required detailed knowledge of the factors that determine the flow through the porous medium to the well. The pressure's curves available in a reservoir, called IPR curves (inflow Performance Relationship) [3]. They represent the relationship between the pressure flow at the bottom of the well and flow.

- IPR Vogel

$$\frac{q_o}{q_{\max}} = 1 - 0{,}2\frac{p_{wf}}{p_e} - 0{,}8\left(\frac{p_{wf}}{p_e}\right)^2$$

Such that

p_e :static pressure	$q_{\max}$:maximum flow	q_0 : flow	p_{wf} : pressure

2.4. Flow of fluids

The fluids that flow through an oil well are complex mixtures of water and hydrocarbons. This work is considering the flow of oil, water and gas.

This simulator used the calculation of multiphase flow in two sections of pipe: casing, between the perforation and pump, in the production tubing between the pump and the surface. The correlations adopted are widely used in the petroleum industry, as described by [4].

3. Results

3.1. Graphical User Interface.

The main screen of the simulator is shown in Figure 6, so that the three-dimensional animation shows the dynamic behavior of the whole process. Also will be able to make the animation of each component of the BCS system (pump, motor, separator, protector). On the right side of the screen, the simulator will show the curve of the pump, dynamic level, the engine torque curve, rotation of the engine, the current curves.

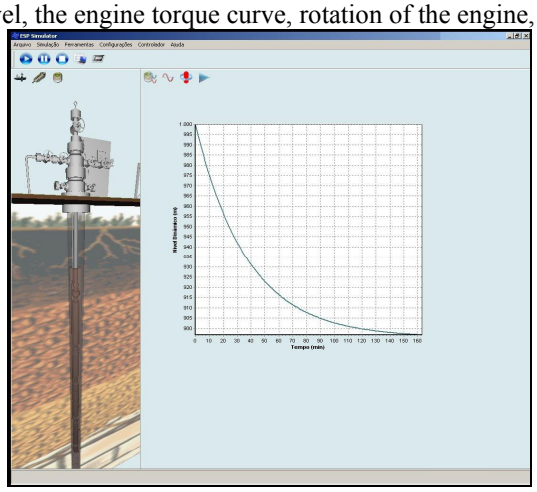

Fig.6. The main screen of the simulator

The setup screen of the simulator has been subdivided into properties of fluids, mechanical scheme, correlations of multiphase flow, reservoir and setting the pump.

3.2. Simulation of a case

In implementation of a case picked up the model of the pump, number of stages and a frequency of 60 Hz, as shown in Figure 7.

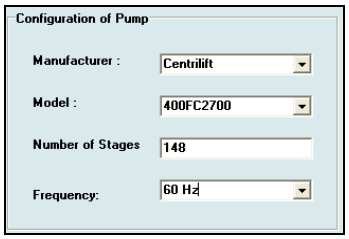

Fig. 7. Setting the pump.

The figure 8 illustrates the input data for the properties of fluids and reservoir.

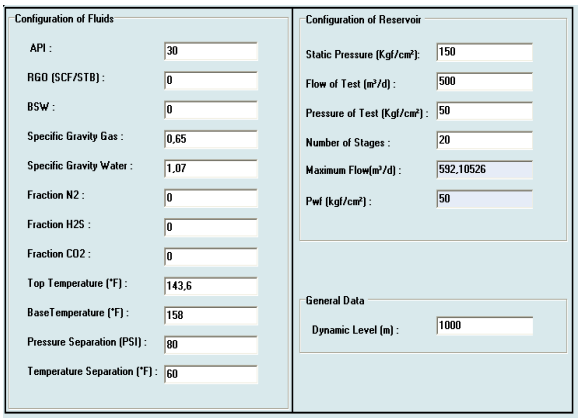

Fig.8. Setup screen of the properties of reservoir and fluids

The graph representing the dynamic level of the well (m), depending on the time (min) to the input data described, is shown in Figure 6. Until the system reaches the equilibrium (steady), recording the final dynamic level in the 905m with steady flow in the 491, 4 m³/d. The simulator allows the adjustment of the feeding frequency in the 70Hz which will be a flow of 564,2 m³/d and dynamic level 1240 m.

4. Conclusions

It is viable to develop a computer simulator for the transient BCS system, from the integration of models available in the literature for the behavior of the reservoir, the pump, the flow of fluids and the electric motor. The computer simulation presented in this paper allows the prediction of operational parameters of the BCS system. The operation of the system in a more rational may contribute to increased production of oil and the useful life of equipment, reducing costs of intervention and intermissive profit. The simulator will also be useful for training of operators, helping to increase the efficiency of the industry of oil production.

Abstract

The crossover region is a phenomenological observation which may be used to synthesize supercritical fluid extraction process (SCFEP) and is supported by a number of experimental studies. This phenomenon means that there may be regions of temperature and pressure in the near critical fluid state where the solute solubility decreases with an isobaric increase in temperature. Accurate calculation of solid solubility in supercritical fluid does not imply that crossover pressure calculation has also good accuracy. In this paper, a new method to predict crossover pressure based on cubic equations of state is developed and applied to systems containing supercritical CO_2 and bixin. Peng-Robinson-LCVM-UNIFAC equation of state is used in a predictive way and crossover pressure is determined for several conditions. The method described here can in principle be applied to any solid-fluid system used in supercritical fluid extraction process synthesis.

Keywords: Supercritical fluid, crossover pressure, process synthesis

1. Introduction

The crossover region is a phenomenological observation supported by a relevant number of experimental studies. This phenomenon means that there may be regions of temperature and pressure in the near critical fluid state where the solute solubility decreases with an isobaric increase in temperature (Kelley and Chimowitz, 1989). Despite many database available for the solubility of solids in supercritical fluids, most of models fits experimental data to binary parameters only for solubility calculation and much less attention is given to accurate determination of crossover pressure.

The aim of this work is to present and discuss the principal mathematical aspects and equation constraints for computation of crossover pressure. A modified Peng-Robinson equation of state is used to exemplify crossover pressure calculation for the binary system containing supercritical carbon dioxide with bixin at several conditions.

2. Crossover Pressure Approach Modeling

The crossover pressure is defined as the point where the slope of the solubility versus temperature curve changes sign and the opposite effects of solute vapor pressure and solvent density on solubility compensate each other. Mathematically, it is expressed as

$$\left(\frac{\partial \ln y_2}{\partial T}\right)_P = 0 \tag{1}$$

where y_2, T and P denote for solute solubility, temperature and pressure, respectively.

It is well known that when plotting solubility versus pressure, isothermal curves cross each other twice and these intersections are called lower crossover pressure (LCP) and upper crossover pressure (UCP) points. At pressures between LCP and UCP, the solubility decreases increasing temperature because the solvent density effect overcomes the vapor pressure effect. At pressures below LCP or above UCP, the solubility increases with temperature as a consequence of the rapid increase in vapor pressure compared to a less pronounced solvent density effect (Foster et al., 1991).

Considering in the calculation of solid-SCF equilibrium that: (i) SCF does not dissolve in the solid phase; (ii) the molar volume of the solid is independent of pressure; (iii) the fugacity coefficient of pure vapor at temperature T and vapor pressure is unity, then, the solubility of solute can be expressed as

$$\ln y_2 = \ln P_2^s + \frac{v_2^s\left(P - P_2^s\right)}{RT} - \ln \hat{\phi}_2 - \ln P \tag{2}$$

where P_2^s and v_2^s are vapor pressure and molar volume of solid solute, respectively, and $\hat{\phi}_2$ is the fugacity coefficient of solid solute in the fluid phase (Foster et al., 1991).

Calculation of crossover pressure could be done in principle using Eq. (2) because at this point solubility values are equal. However, it is mathematically very hard to find the root P of this equation at the crossover point (Vieira de Melo *et al.*, 2009). To avoid this kind of problem, it is recommended to combine Eqs. (1) and (2), and the following equation is obtained for calculating the crossover pressure:

$$\frac{d \ln P_2^s}{dT}\left(1 - \frac{v_2^s P_2^s}{RT}\right) - \frac{v_2^s}{RT^2}\left(P - P_2^s\right) - \left(\frac{\partial \ln \hat{\phi}_2}{\partial T}\right)_P = 0 \tag{3}$$

Solute vapor pressure is calculated by

$$\ln P_2^s = A - \frac{B}{T} \tag{4}$$

The Clapeyron equation gives the relation between solid vapor pressure and enthalpy of sublimation, as follows

$$\frac{dP_2^s}{dT} = \frac{\Delta H^{sub}}{T.\left(v_2^g - v_2^s\right)} \tag{5}$$

Deriving Eq. (4) related to temperature gives

$$\frac{d\left(\ln P_2^S\right)}{dT} = \frac{1}{P_2^s}\frac{dP_2^S}{dT} = \frac{B}{T^2} \tag{6}$$

Comparing (5) and (6) gives

$$P_2^s = \frac{\Delta H^{sub}.T}{B\left(v_2^g - v_2^s\right)} \tag{7}$$

Substituting the Eqs. (4) and (6) in the Eq. (3), since the vapor pressure is very low regarding to the pressure P, Eq. (3) is simplified to give

$$\mathrm{F(P)} = \frac{B}{T^2} - \frac{v_2^s P}{RT^2} - \left(\frac{\partial \ln \hat{\phi}_2}{\partial T}\right)_P = 0 \tag{8}$$

The root from Eq. (8) is a crossover pressure. Some general considerations are needed to determine the crossover pressure.

$$\text{Defining } FT(2) = \left(\frac{\partial \ln \hat{\phi}_2}{\partial T}\right)_P \tag{9}$$

and deriving the Eq. (8) related to *P* with constant temperature, and taking into account the Eq. (9), one can obtain:

$$\left(\frac{\partial F(P)}{\partial P}\right)\Bigg|_T = -\frac{v_2^s}{RT^2} - \frac{\partial FT(2)}{\partial P} \tag{10}$$

On the inflexion point of *F(P)*, one must have the descent part of *FT(2)* because,

$$\frac{\partial FT(2)}{\partial P} < 0 \tag{11}$$

On the other hand, the inflexion point of *FT(2)* corresponds the negative part of *F(P)* inclination, so

$$\left(\frac{\partial F(P)}{\partial P}\right)\Bigg|_T = -\frac{v_2^s}{RT^2} < 0 \tag{12}$$

As a consequence one can evaluate the general aspect of the *F(P)*. The two roots, which correspond to two crossover points, are obtained as: the inferior crossover correspond to inferior point of *FT(2)*, the superior crossover correspond to the negative inclusive of *FT(2)* curve. Thus, the inflexion point of *F(P)* corresponds to a negative inclination of *F(T)* curve. One can conclude that the two crossover pressures correspond to the negative inclination of *FT(2)* curve.

It is also important to analyze the influence of parameter B on crossover pressure. Vieira de Melo *et al.* (2009) show that as the parameter B diminishes at constant temperature, the crossover pressure increases. One can analyze the relative contribution related to the terms of the new equation for the determination of crossover pressure, that is, Eq. (8). Considering P higher to the inflexion point of Eq. (8), one has in this case

$$\left(\frac{\partial F(P)}{\partial P}\right) > 0 \tag{13}$$

Therefore, $(-\frac{v_2^s}{RT^2} - \frac{\partial FT(2)}{\partial P}) > 0$ (14)

As seen before, for this pressure *P*, $\frac{\partial FT(2)}{\partial P} < 0$, and one can say that

$$\left|\frac{\partial FT(2)}{\partial P}\right| > \frac{v_2^s}{RT^2} \tag{15}$$

Consequently, from the analyses of a pressure P lower to the inflexion point pressure,

$$\left(\frac{\partial F(P)}{\partial P}\right) < 0 \quad \text{and} \quad -\frac{v_2^s}{RT^2} - \frac{\partial FT(2)}{\partial P} < 0 \tag{16}$$

In relation to the Eq. (16), one has two evaluations to do:

(i) For $\frac{\partial FT(2)}{\partial P} > 0$, the Eq.(16) will be satisfied independently of the relation between the modules of the terms of the inequality;

(ii) To satisfy the inequality $\frac{\partial FT(2)}{\partial P} < 0$, one must has necessarily the following behaviour: $\left|\frac{\partial FT(2)}{\partial P}\right| < \frac{v_2^s}{RT^2}$

So, it can be concluded that for pressures above the upper crossover pressure and pressure below the lower crossover pressure, the values of function *F(P)* must have positives. Considering for the Eq. (8) that:

$$L = -\frac{v_2^s.P}{RT^2} - FT(2) \tag{17}$$

For pressures on this range, $F(P) > 0$ and as a consequence $(B/T^2) < L$. For pressures between the two crossover pressures, $F(P) < 0$ and therefore $(B/T^2) < L$. At both crossover pressures, the value of $F(P)$ is null and $(B/T^2) = L$. For a constant temperature T, the term B/T^2 is constant and the term $v_2^s.P/RT^2$ corresponds to a linear variation with the pressure. At constant temperature, for pressure between upper and lower crossover pressures, the value of is higher than B/T^2.

It can be theoretically shown (Vieira de Melo *et al.*, 2009) that depending on the value of B/T^2 in Eq. (11) the others terms of this equation may be less or more significant. If this first term decreases, the second term seems to affect more and the third one to affect less on the result, and as a consequence the crossover pressure increases. Calculation of upper crossover pressure depends on the sublimation pressure parameters A and B, whose initial input values are determined by two different group contribution procedures. In the first procedure, parameters A and B are initially determined from group contribution, using input information of critical temperature (T_c), critical pressure (P_c) and normal boiling point temperature (T_b), and subsequently internally adjusted. In the second procedure, parameters A and B are initially calculated using the enthalpy of sublimation (ΔH^{sub}) and the melting point temperature (T_f), and subsequently internally adjusted.

3. Results and Discussion

The results obtained in this paper consider only the upper crossover pressure (UCP) for the system CO_2-bixin. To calculate crossover pressure, only solubility experimental data and the molecular structure of the solute are given. The properties of the compounds of this system and the detailed calculation procedure can be found in Vieira de Melo *et al.* (2009). Table 1 presents the calculated values of crossover pressure (*Pco*), sublimation pressure parameter *B* and molar volume of solid solute (v_2^s) for the isotherms of 288, 308 and 328K. The influence of parameter B on the crossover pressure calculated for the system CO_2-bixin at 288, 308 and 328 K is shown in Fig. 1. Increasing B decreases the convergence crossover pressure for each temperature as theoretically can be demonstrated. Although the values of molar volume and sublimation pressure of solid solute are tuned during convergence procedure of crossover pressure calculation, it is important to remark that they are interdependent due to Equation (2). So, increasing sublimation pressure decreases the molar volume of solid. As one could expect, sublimation pressure values are very low.

Table 1. Calculated crossover pressure (*Pco*), sublimation pressure parameter *B* and molar volume of solid solute (v_2^s) for CO2-bixin at 288, 308 and 328K

		Pco (atm)

4. Conclusions

In this paper, a new method to predict crossover pressure based on cubic equations of state is developed and applied to systems containing supercritical CO_2, and bixin. Peng-Robinson-LCVM-UNIFAC equation of state (Boukouvalas *et al.*, 1994) is used in a predictive way and crossover pressure is determined for several conditions. Correlations among many important properties as molar volume and vapor pressure of solid solute are investigated and it is shown that sublimation pressure has particularly an important role on the accurate calculation of crossover pressure. Depending on the slope of sublimation pressure curve, the three terms in the equation for crossover pressure calculation can be less or more significant on the results. Despite the illustration of this method using Peng-Robinson-LCVM-UNIFAC equation of state for CO_2-bixin, it is important to say that the crossover pressure analysis presented in this paper is independent of the equation of state used to calculate the fugacity coefficient of solid solute in the fluid phase. So, this method can be applied to any solid-fluid system used in supercritical fluid extraction.

Abstract

Many computational problems occur during optimization of high-pressure phase equilibrium of polymer systems due to the existence of critical points and to the possibility of there being more than two equilibrium phases. In this work the main numerical aspects related to high-pressure flash simulation with the Soave-Redlich-Kwong (SRK) and the Sanchez and Lacombe (SL) equations of state are examined. A LDPE (low-density polyethylene) high pressure flash industrial separator is used to case study of 8 resins. The results show that Sanchez-Lacombe equation of state is more appropriate to overcome the numerical difficulties associated with the complexity of polymer systems.

Keywords: high pressure, phase equilibrium, polymer, optimization.

1. Introduction

Optimization of polymerization process which includes some separation steps depends critically on the accurate knowledge of polymer phase equilibrium. Modeling of thermodynamic properties of polymer mixtures demands considerable efforts due to the large difference in the molecular sizes of polymers and solvents, mainly at high pressures. Reliable simulators are essential to calculate rigorously industrial separator operational conditions. However, many computational problems occur in this kind of system associated with the existence of critical points and their mathematical singularity, and also due to the possibility of there being more than two equilibrium phases (Heidemann, 1983). Several attempts to use EOS to model polymer systems can be found in the literature, but they focus on low pressure ranges and laboratory experimental data (Wang, 2007; Kalospiros and Tassios, 1995). As a consequence, these systems contain low molecular weight polymer and are investigated very far from the typical operational conditions of industrial polymer separation processes. In this work some advances in the computation of high pressure phase equilibrium for polymer systems with equations of state are presented and several numerical aspects are discussed in detail. A high pressure flash separator for polyethylene is used as a case-study to explicit these features. Performances of Sanchez-Lacombe (SL) and Soave-

Redlich-Kwong (SRK) equations of state are compared using industrial experimental data. The SRK equation of state is employed with two different mixing rules: LCVM and Wong-Sandler. Bogdanic-Vidal activity coefficient model is coupled with SRK EOS through these mixing rules as recommended Costa *et al.* (2008). The main numerical aspects examined for each EOS employed are the influence of mass and mole composition in the phase equilibrium, the general optimization strategy for the estimation of the EOS interaction parameters, the algorithms of flash calculation, the influence of low and high polymer concentration, and the convergence criteria at each step calculation.

2. Thermodynamic Models

2.1. Soave-Redlich-Kwong (SRK) equation of state

The Soave-Redlich-Kwong (SRK) equation of state *(Soave, 1972)* is

$$P = \frac{RT}{v-b} - \frac{a(T)}{v(v+b)} \tag{1}$$

where parameters *a* and *b* can be given by Wong-Sandler mixing rules (Wong and Sandler, 1992):

$$a = b \cdot \left(\sum_i \frac{x_i \cdot a_i}{b_i} + \frac{G^E}{\delta} \right) \tag{2}$$

$$b = \frac{\sum_i \sum_j x_i \cdot x_j \cdot \frac{1}{2} \cdot \left[\left(b - a/R \cdot T\right)_i + \left(b - a/R \cdot T\right)_j \right] \left(1 - WS_{ij}\right)}{1 - \sum_i \left(a_i/b_i \cdot R \cdot T\right) - \left(G^E/\delta \cdot R \cdot T\right)} \tag{3}$$

δ is a numerical constant equal to *-ln2* for SRK EOS and WS_{ij} is the interaction parameter.

LCVM mixing rule is given by (Boukouvalas *et al*., 1994):

$$\alpha = \frac{a}{b \cdot R \cdot T} = \sum x_i \cdot \alpha_i + \left(\frac{\lambda}{A_v} + \frac{1-\lambda}{A_M} \right) \cdot \frac{G^E}{R \cdot T} + \frac{1-\lambda}{A_M} \cdot \sum x_i \cdot \ln\left(\frac{b}{b_i} \right) \tag{4}$$

with $A_V = \ln 2$ and $A_M = -0.53$ for SRK EOS and λ is 0.36. The classical linear mixing rule is used for parameter *b*.

LCVM and Wong-Sandler mixing rules need a G^E model and the recommended one is the BV model (Bogdanic and Vidal, 2000), whose segment activity coefficients are calculated through the UNIQUAC model and contains an interaction parameter UQ_{ij}.

2.2. Sanchez-Lacombe (SL) equation of state

The Sanchez and Lacombe EOS (Sanchez and Lacombe, 1976) is given by:

$$\tilde{\rho}^2 + \tilde{P} + \tilde{T} \cdot \left[\ln(1-\tilde{\rho}) + \left(1 - \frac{1}{r}\right) \cdot \tilde{\rho} \right] = 0 \tag{5}$$

$$\tilde{T} = \frac{T}{T^*} \qquad \tilde{P} = \frac{P}{P^*} \qquad \tilde{\rho} = \frac{\rho}{\rho^*} \tag{6}$$

$$T^* = \frac{\varepsilon^*}{k} \qquad P^* = \frac{\varepsilon^*}{v^*} \qquad \rho^* = \frac{MW}{r v^*} \tag{7}$$

where T is the absolute temperature, P is the pressure, ρ is the density, MW is the molecular weight, k is the Boltzmann constant, and r, ε^*, and v^* are pure component parameters related to the corresponding scale factors T^*, P^*, ρ^*, respectively. These scale factors are independent of the molecular size of the polymer. For mixtures, the model parameters are composition dependent. This dependence is expressed in terms of segment fraction of component i. The binary interaction parameters $SL1_{ij}$ and $SL2_{ij}$ are related to the cross parameters.

3. Equilibrium Calculation Methods

Equilibrium flash calculation is used to simulate the high pressure separator and to compare the results of two phase compositions x_i and y_i with industrial data. In flash calculations, the problem is to find β, the vapor phase equilibrium fraction of a mixture with initial composition z_i. This fraction is updated iteratively by first solving:

$$\sum (y_i - x_i) = \sum \left[(K_i - 1) \cdot z_i / (\beta \cdot K_i + 1 - \beta) \right] \tag{8}$$

for β, assuming that the K_i are constant. Then the phase mole fractions are evaluated from:

$$y_i = K_i \cdot x_i = \frac{K_i \cdot z_i}{\beta \cdot K_i + 1 - \beta} \tag{9}$$

The thermodynamic models for the two phases are then used to update the K_i values and the process is iteratively repeated as follows:

$$\ln K_i^{(n+1)} = \ln K_i^{(n)} + \ln \left(f_i^L / f_i^V \right)^{(n)} \tag{10}$$

An important point to highlight regarding the SL equation is the fact that usually the chemical potential is used instead of fugacity. Therefore, Eq. (10) is written as a function of chemical potential instead of fugacity and is expressed as:

$$\ln K_i^{(n+1)} = \ln K_i^{(n)} + \ln \left(\frac{\mu_i^L}{R \cdot T} - \frac{\mu_i^V}{R \cdot T} \right)^{(n)} \tag{11}$$

This equation can be solved for each iterative with a low computational effort. In successive substitution procedures, ratios of mole fractions (K factors) are used in an inner loop to find phase amounts and mole fractions using Eqs. (8) and (9). The K factors are updated in an outer loop until the values of the chemical potentials or fugacities in all coexisting phases are sufficiently close to each other. Sometimes the successive substitution algorithm itself can become oscillatory and divergent. The

analysis of Heidemann and Michelsen (1995) shows that this kind of instability of successive substitution can occur whenever any of the equilibrium phases shows strong negative departures from ideality. Heidemann and Michelsen (1995) suggested a simple "damping" procedure in the K factor updating algorithm that would result in a convergent process. With the strategy used in this work it is not necessary to employ this "damping" procedure regardless the equation of state used.

For polymer systems some numerical aspects are independent of the equations of state employed. One aspect to highlight is that composition must be always expressed as a function of weight fraction instead of mol fraction. Therefore, the mass fraction must be converted in mol fraction to calculate the component fugacity or chemical potential, but the returned composition must be expressed in mass fraction after equilibrium calculation. Different from what consider Koak and Heidemann (1996), we have kept the standard choice of volume fraction in SL equation as the composition variable. Another point regarding to solution of Eq. (8) is that the bisection method is used because it is known that the root β is encompassed by the interval (0, 1). The boundaries of this interval are the initial guess for root finding. Adjustable characteristic parameters of the various models are fitted to industrial operational data, and the Nelder-Mead simplex method (Nelder and Mead, 1964) is applied to minimize the following objective function:

$$OF = \sum_{i=1}^{nc} \left(w_{i,H}^{cal} - w_{i,H}^{\exp} \right)^2 + \sum_{i=1}^{nc} \left(w_{i,L}^{cal} - w_{i,L}^{\exp} \right)^2 \tag{12}$$

where w_i is the mass composition of component i, the subscripts H and L are related to the heavy and light phases, respectively, the superscripts *cal* and *exp* are related to the calculated and experimental values, respectively, and nc is the number of components. Usually, the convergence criterion of this estimation is 10^{-8} for the value of objective function. Some numerical features depend on the equation of state. Due to the high values assumed inside the algorithm of fugacity calculations for polymers at high pressure with SRK equation, an important contribution is regarding the calculation of constant equilibrium K_i. Once this property is monitored in update value by using Eq. (10), it is immaterial to divide both phase fugacities by pressure, and this numerical detail is crucial to solve this type of simulation problem. The constant equilibrium K_i is monitored and updated using Eq. (10), that can be expressed as a function of fugacity or fugacity coefficient. The advantage of using fugacity coefficient is that the pressure is the same for both phases. Therefore, dividing both fugacity coefficients by pressure in Eq. (10) is a simple but key numerical detail to overcome this kind of simulation convergence problem.

4. Results

Eight resins are investigated and their features are presented in Table 1, with the HPS operational conditions. The polymer is assumed to be monodisperse for all systems.

Table 1. LDPE molecular weight and HPS separator operational conditions

Resin	*MW* (g/mol)	T_{HPS} (°C)	P_{HPS} (bar)
LDPE-1	335000	280.29	250.06
LDPE-2	295200	278.80	251.90
LDPE-3	181000	230.29	249.88
LDPE-4	166000	253.03	250.55
LDPE-5	340000	237.68	249.87
LDPE-6	322000	277.17	249.54
LDPE-7	236600	247.92	254.00
LDPE-8	426300	265.33	253.28

Table 2 shows the binary interaction parameters between polymer and each other component: ethylene, ethane, propylene and propane. Due to similarity between molecular interactions the same value of binary interaction parameters is used for all pairs of components.

Table 2. Binary interaction parameters of EOS used for HPS simulation (LDPE resin)

Resin	$SL1_{ij}$	$SL2_{ij}$	UQ_{ij}^{*}	WS_{ij}	UQ_{ij}	λ
LDPE-1	1.5975	1.5075	0.0010	0.9440	0.0010	-0.3663
LDPE-2	1.5975	1.5075	0.0010	0.9296	0.0010	-0.2255
LDPE-3	2.0199	1.0099	0.0010	0.8237	0.0013	0.2235
LDPE-4	2.0199	1.0099	0.0010	0.9000	0.0011	-0.0703
LDPE-5	2.0199	1.0099	-0.0032	-0.4543	0.0028	3.6224
LDPE-6	1.5074	1.5033	0.0068	0.5873	0.0016	0.8922
LDPE-7	2.0000	0.9900	-0.0297	-2.6891	0.0025	3.0426
LDPE-8	1.5299	1.4850	0.0023	0.0560	0.0020	2.0432

Simulations of the HPS for the LDPE resins and comparison of the equation of state performances indicate that the Sanchez-Lacombe EOS is the best choice, as illustrated by Figure 1.

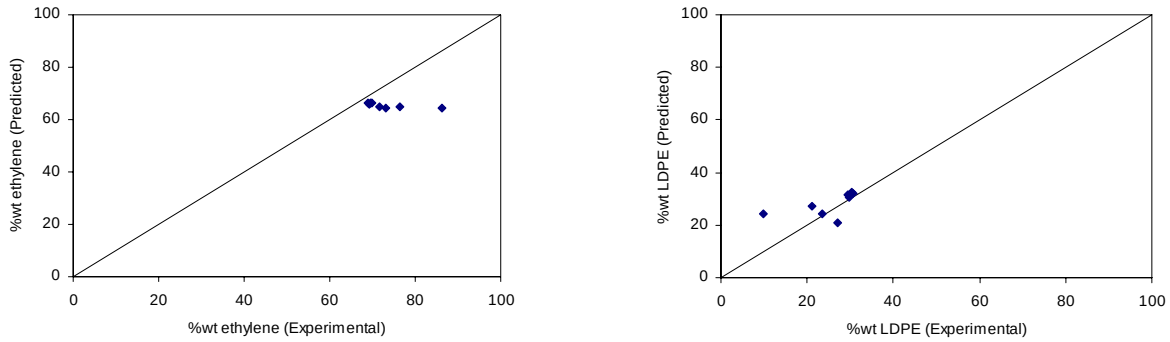

Figure 1. Predicted bottom composition of HPS separator versus experimental values for Sanchez-Lacombe EOS.

5. Conclusion

Simulation of high-pressure separators (HPS) in an industrial low density polyethylene (LDPE) process is used to evaluate Sanchez-Lacombe (SL) and Soave-Redlich-Kwong (SRK) models. Several numerical aspects were examined for each EOS. The results show that Sanchez-Lacombe equation of state is more appropriate to overcome the difficulties associated with the influence of mass and mole composition in the phase equilibrium, the general optimization strategy for the estimation of the EOS interaction parameters, the algorithms of flash calculation, the influence of low and high polymer concentration, and the convergence criteria at each step calculation. SRK-LCVM and SRK-WS are unable to describe the HPS overhead composition, since the results indicate only the presence of ethylene in this stream. Regarding the LDPE composition in the bottom stream, SRK-LCVM and SRK-WS give similar results but are not so accurate as SL.

Modeling the hydrodynamics and mass-transfer phenomena for sedimentary rocks used for Flue Gas Desulfurization. The effect of temperature.

Cataldo De Blasio, Jarl Ahlbeck and Tapio Westerlund

Åbo Akademi University , Technical faculty Process Design & Systems Engineering Biskopsgatan , 20500 ABO; E-mail address: cdeblasi@abo.fi

Abstract

Sedimentary rocks, such as limestone, are widely utilized in Flue Gas Desulfurization (FGD) processes. The study of the dissolution for solid particles involved in FGD is therefore significant for process design and plant operation. The rate of dissolution affects the cost of makeup and waste disposal. For this reason a method to test different qualities of raw materials can give us a better understanding of the desulfurization performance. One method to test the reactivity takes into account the utilization of diluted strong acids like hydrochloric acid [1]. In the present study the mass transport phenomena involved in batch stirred tank reactors (BSTRs) are modeled in presence of hydrochloric acid and the experiments were taken at different temperatures in order to demonstrate the reliability of the method. The Surface Renewal Time, also called Surface Time of Exposure (TOE), is a quantity describing the life-time of the separation surface between the solid and liquid faces. The method gives an estimation of the temperature effect over the solid particles dissolution in BSTR and can be used to evaluate the reactivity and the diffusivity values of different raw materials.

Keywords: Gas Desulfurization, Limestone Reactivity, Mathematical modeling, Transport Phenomena.

1. Objective

The present work takes into consideration a generalized form of the penetration theory first introduced by Higbie (1935). The present approach has been utilized for studying the absorption by simultaneous diffusion and chemical reaction for solid particles [5]. It was taken into account the modeling of the mass transport phenomena involved in BSTR systems. By evaluating the physical parameters involved, the ratio of convective to diffusive mass transport and the ratio of momentum and mass diffusivity, it was possible to relate the diffusivities and mass transfer coefficients at three different temperatures for raw materials in terms of a defined TOE. The generalization of the penetration theory for solid particles in BSTR gave us useful results; this encouraged us to utilize the same approach for evaluating the diffusion parameters at different temperatures. The objective of this study was to verify the method for evaluating the quality of solid particles used in flue gas desulfurization [8].

2. Theory

2.1. Main reactions involved

Previous studies [1] have considered the reactivity of calcium carbonate in presence of strong acids like hydrochloric acid. In the following table the main reactions involved are given:

Table 1. Main reactions involved in limestone-acid systems

Fenomena	Reactions
Dissolution of limestone	$CaCO_3(s) \rightarrow Ca^{2+} + CO_3^{2-}$
Carbonate ions react with the hydronium ions according to:	$H_3O^+ + CO_3^{2-} \rightarrow HCO_3^- + H_2O$
Carbonic ions react with hydronium ions	$HCO_3^- + H_3O^+ \rightarrow H_2CO_3 + H_2O$
Final products	$H_2CO_3 \rightarrow CO_2(g) + H_2O$

The system described above can be considered as one overall first order reaction [1]. We denote with C_{ai} the saturated concentration of the solute at the surface (Z = 0), C_a is the concentration of C_a^{2+} ions at a generic distance Z, t designates the time and k_r is the reaction rate constant. D_a represents the diffusivity of the considered dissolving element. The solute concentration into the bulk solution is described by the following differential equation:

$$\frac{\partial C_a}{\partial t} = D_a \frac{\partial^2 C_a}{\partial z^2} - k_r C_a \tag{1}$$

The boundary conditions are:

$$C_a = C_{ai}, z = 0, t > 0$$
$$C_a = 0, z > 0, t = 0$$
$$C_a = 0, z = \infty, t > 0$$

It can be proved, utilizing the Duhamel's theorem and by considering the analogy between heat and mass transfer for the same mixing conditions [2], that the final relation for the concentration of the diffusing component into the bulk solution is described by:

$$C_a = \frac{1}{2} \cdot C_{ai} \cdot \left[\exp\left(-z\sqrt{\frac{k_r}{D_a}} \right) + \exp\left(z\sqrt{\frac{k_r}{D_a}} \right) \right] \cdot \left[erfc\left(\frac{z}{2\sqrt{D_a \cdot t}} - \sqrt{k_r t} \right) \right] \tag{2}$$

The term *erfc[z, t]* in Eq.(2) gives the complementary Error Function of *erf[z, t]*. Considering the analogy between the heat and mass transfer and applying this theory to the present system, the dissolution of solid particles into the bulk solution can be described in terms of mass transfer per unit time as follows:

$$\dot{m} = \left(\pi \cdot d_p^2\right)\left(C_{ai} - C_\infty\right)\left(\frac{\langle k_c \rangle}{d_p}\right)\left[\frac{(3\cdot\pi)^{\frac{2}{3}}}{2^{\frac{7}{2}}\Gamma\left(\frac{4}{3}\right)}\right]\left(\mathrm{Re}\cdot Sc\right)^{1/3} \tag{3}$$

Where C_∞ is the solute concentration in the liquid region, d_p is the diameter corresponding to one particle having the total surface of reaction, k_c is the mass transfer coefficient, The term between the square brackets is considered to be a numerical value. [3], *Re* and *Sc* are respectively the Reynolds and the Schmidt number. In our case the Sherwood number is evaluated from:

$$\langle k_c \rangle = Sh\left(\frac{D_a}{d_p}\right) \tag{4}$$

From Eq.(3) it appear clear that the mass transfer per unit time is a function of the Sherwood number, this result is useful because Sherwood numbers have been evaluated for different kind of chemical reactors. More accurate values were obtained for diverse Schmidt numbers and for our system it is well described as follows [3]:

$$Sh = 2 + \left(0.4\cdot \mathrm{Re}^{0.5} + 0.06\cdot \mathrm{Re}^{2/3}\right)\cdot Sc^{0.4}\left(\frac{\mu_\infty}{\mu_w}\right)^{0.25} \tag{6}$$

The above formula is valid for $0.35 < Re < 8\cdot10^4$ and for $0.7 < Sc < 380$. The viscosity of the liquid medium is considered to be the same near the surface and at a reasonable distance, in this way the term $(\mu_\infty/\mu_w)\ \hat{}\ 0.25 = 1$. At this stage we consider again the general equation for mass transport related to the dissolving component and taking into account the reactor volume V we obtain:

$$V\frac{dC_a}{dt} = -V\cdot k_r\cdot C_a + \langle k_c \rangle\left(C_{ai} - C_a\right)\cdot S \tag{7}$$

Where the term S represents the surface of reaction. With $\tau = v/(kc\cdot S)$ and $k_r = 1/t_r$ for fast reactions, finally we get:

$$C_a = \frac{C_{ai}}{\tau}\left\{1 - \exp\left[-t\left(\frac{1}{t_r} + \frac{1}{\tau}\right)\right]\right\}\cdot\frac{1}{\frac{1}{t_r} + \frac{1}{\tau}} \tag{8}$$

2.2. The surface penetration theory.

It was assumed that the separation layer between two phases is considered to be a sum of differential volumes; in this case we consider that each of these volumes has a different age or life-time at the surface. At the solid liquid interface we consider a velocity profile to be linear, for this reason a particular velocity exists that belongs to a non-zero thickness. This layer has the same behavior of a solid if we consider the mass transport phenomena involved. The mass flux is described by the following formula [4]:

$$\langle N_i \rangle = \frac{1}{L}\int_0^L \sqrt{\frac{D_a \cdot v_i}{\pi \cdot x}}\Delta C \cdot dx \tag{9}$$

Where v_i is the solid-liquid velocity at the interface and L is the integration length along the x axis, ΔC is the already mentioned difference in concentration of the dissolving component. The mean coefficient of mass transfer is:

$$\langle k_c \rangle = 2\sqrt{\frac{D_a \cdot v_i}{\pi \cdot L}} \tag{10}$$

The quantity L/v_i represents a time θ over the integration length; this value can be obtained from experiments and is known as TOE or Surface Renewal Time [4].

3. Materials and methods

For particle size measurements the Malvern 2600 particle sizer system has been used. The equipment includes a batch stirred tank reactor and a laser-beam diffractometer where the sample particles were analyzed in order to get a particle size distribution. The model involved takes into account the variation of the particle size distribution derived from the distribution of the scattered light energy using the Fraunhofer diffraction theory and the spherical model, furthermore the procedure expected synchronized *pH* and particle size measurements. This theory is valid for opaque particles whose radius is large compared with the laser wavelength. For each size range, the limestone fraction in volume was given. In this way, it has been possible to evaluate the change in the sample volume as a function of time. The following table describes the sedimentary rocks used and their provenience, the sample tested showed the best quality in terms of TOE and mass transfer coefficient [8].

Table 2. Tested raw materials: general description

Sample	Description	Provenience
Ljj 01c	Paleoproterozoic magmatic limestone	Halpanen, Finland
Ljj 09c	Paleoproterozoic metamorphic limestone, marble	Parainen, Finland
Ljj-P	1900 million-year-old limestone metamorphosed to marble.	Parainen Finland

The sample indicated as Ljj-P is from the Parainen quarry in south west Finland. The carbonate rock is a 1900 million-year-old limestone metamorphosed to marble during the Svecofennian orogeny 1830 million years ago (metamorphosed limestone). Mineralogically it is almost pure calcite and texturally an even grained marble. The temperatures at which the experiments were conducted were: 25°, 38° and 42° Celsius.

4. Results and discussion

The concentration C_a is a function of: time, distance from the particle's surface, $z = 0$; it is also a function of the reaction rate constant (1/sec). Fig. 1 shows the concentration function for a determinate value of k_r Eq.(2), is this way the total amount dissolved is described by the surface integral over the time and the integration length. Eq.(8) is well described by Fig. 2 for assigned values of the diffusivity and surface of reaction. The mathematical treatment refers to a single shrinking particle.

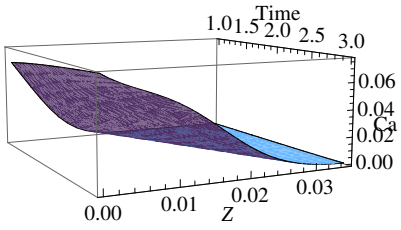

Fig. 1. Concentration in space and time at a determinate value of *kr* Eq.(2).

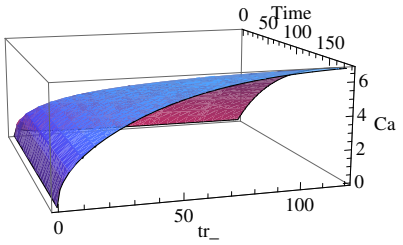

Fig. 2. Three dimensional representation of Eq.(8) C_a is expressed in micro-moles.

The following two dimensional figures are more suitable for the reporting of the Surface Time of Exposure (TOE) and the mass transfer coefficient as a parametric function of the temperature, experiments were conducted at three different temperatures: 25°, 38° and 42° Celsius, indicated respectively with the symbols: *, # and + in Fig. 3, 4, 5, 6. Experiments were conducted at equal time intervals. The mathematical fitting is shown by the dashed lines for each temperature. The results related to samples Ljj-09c and Ljj-P, Table 2, are reported as follows:

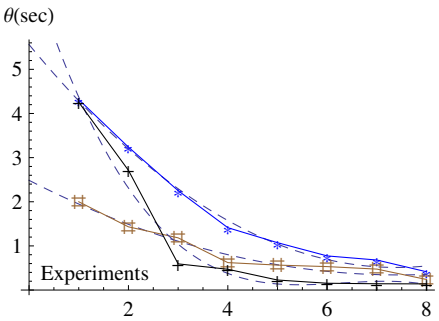

Fig. 3. TOE at 25°C, 38°C, 42°C. Sample: Ljj_P. Range: 150-250µm.

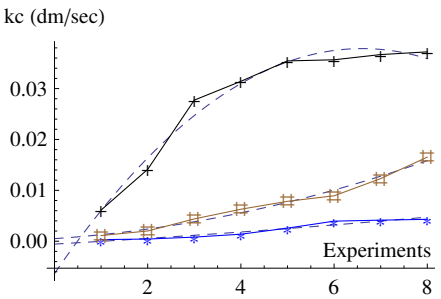

Fig. 4. K_c at 25°C, 38°C, 42°C. Sample: Ljj_P. Range: 150-250µm.

The experiments have been done immediately after the addition of hydrochloric acid to the system, the data reported also show the lag time needed in order to settle TOE and k_c to the minimum and maximum value respectively. Furthermore the derivatives of TOE and k_c at the first seconds indicate dependence from the temperature as well, the Surface Time of Exposure specify a punctual value while the derivative denotes an initial acceleration due to the diffusion phenomena. The following results are also in agreement with the above mentioned principles and in accordance with our expectations.

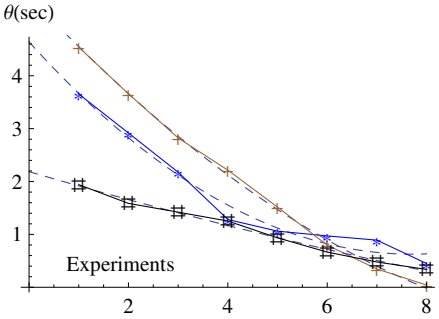

Fig. 5. TOE at 25°C, 38°C, 42°C. Sample:Ljj_09c. Range: 63-106µm

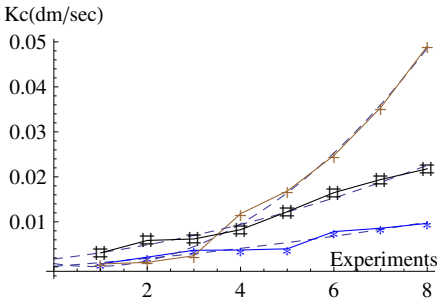

Fig. 6. K_c at 25°C, 38°C, 42°C. Sample: Ljj_09c. Range:63-106µm.

5. Conclusions

The experiments were conducted during a short period of time when the calcium carbonate is able to utilize all the hydronium ions in a fast way. When the concentration of carbonic acid (weak acid) is reasonably high, the second step of reaction shown in table one is less influent. See Fig.3. The hydronium concentration profile was in agreement with this mechanism. By evaluating the time of exposure and the mass transfer coefficient it has been demonstrated that the method is sensible to temperature variations; the experimental results are perfectly in accordance with the theory: at higher temperatures we have a more rapid decrease for the Surface Renewal Time and a greater increase for the mass transport coefficient, furthermore the above plots show also the non perfect mixing obtained among the initial experiments. The slope and the absolute values of TOE and mass transfer coefficient describe accurately the effect of temperature on the dissolution process.

Energy Optimization of a Kraft Pulp Mill

Araceli García, María González, Rodrigo Llano-Ponte, Jalel Labidi

Department of Chemical and Environmental Engineering – University of the Basque Country, Plaza Europa 1, San Sebastián 20018, Spain

Abstract

New regulations, economical and environmental requirements urge industrial companies to continuously improve the efficiency of their production technologies. The application of process integration tools for process retrofit is a must whenever energy or raw material intensive processes are considered. Since pulp and paper processes use a large amount of energy and water, the application of process integration techniques in this area is essential and can contribute to the protection of the environment to a great extent. CadSim Plus simulation software has been used to simulate several sections of a kraft pulp mill. Based on the process flow sheet and the developed simulation, pinch analysis was undertaken using the software Aspen HX-Net 2006. Potential of energy savings has been identified and the feasibility of the associated heat exchangers network (HEN) modification has been evaluated by the process simulation. The combination of both computer tools, has allowed to carry out the study of energy optimization of the process, maintaining the conditions of operation and evaluating the feasibility of the possible changes in the design of the heat exchangers network that allow minimizing the energy consumption.

Keywords: Process simulation, optimization, pinch analysis, heat exchange networks.

1. Introduction

Optimization and integration of industrial processes has become and important research topic, because it allows to analyze the factors that improve the production yield, as well as to study the mechanisms and possible changes that can minimize energy and water consumption and pollutant emissions (Nurmesniemi, 2007; Salama, 2008; Wang, 2009). For this purpose, the process simulation has turned out to be a very useful tool for the study and optimization of industrial processes, because it allows to analyze the behavior of the implied systems and to evaluate the feasibility of real conditions of operation with a previous knowledge of the process performance. Simulation software can be used to study the behavior of several process and equipments (Cardoso, 2009) and to analyze the general development of different processes, optimizing the operation conditions.

The paper industry is one of the most affected by the increasing need to reduce resources consumption since in most cases the production of pulp and paper generates an energy surplus that is often not conveniently used (Jönsson, 2008, Svensson, 2008b). In addition, this sector consumes a large amount of water and the feasibility of circuit closure, allowing optimal use of internal flows, and its influence on the process yield is becoming a subject widely studied. Usually the circuit closure and the use of water from the process imply an increase in the minimum temperature and the cooling requirement inside the plant, so that the processes of heat exchange in the mill are modified (Foo, 2008).

The highest energy consumption of the pulp mills is localized in the recovery zone. The evaporation process can consume up to 30% of the energy generated in the form of steam (Axelsson, 2008), and other equipment, such as paper machine which also requires large amounts of live steam (Sivill, 2005; Geldermann, 2006). The optimization of these processes is a key point to improving the overall process.

On the other hand, a way to optimize the use of energy is to redesign the Heat Exchange Networks (HEN), but also other equipment, such as the recovery boiler, where the optimization of the combustion process of black liquor results in a higher yield (Hektor, 2007). This case is very interesting because, although it is not a main part of the purpose of the pulp and paper production, the recovery process makes the mill self-sufficient of reagents and energy, making profitable the production. So, a by-product, like black liquor, results in an energy resource within the company as its combustion generates high-pressure steam.

Therefore, it is possible to convert a sector such as paper industry, usual consumer of energy and water resources, in a producer not just steam and electricity (Svensson, 2009), but also other high value-added products, such as tall oil and lignin of the black liquor (Svensson, 2008b).

Many authors have used simulation of pulp and paper processes (Castro, 2004; Turon, 2005) in conjunction with other tools to achieve the processes integration and energy optimization. Pinch analysis has been proved to be a powerful technique for this purpose, being employed for several analyses as heat exchanger networks studies, energy savings at different levels of the processes and minimizing water consumption of the mill (Wising, 2005; Nordmann, 2006).

In this work combination of process simulation and Pinch analysis has been used to achieve the energy optimization of kraft pulp mill.

2. Process Description

The studied pulp Kraft mill (Figure1) produces 400 Tones of pulp per day and uses a batch pulping process that comprises several stages. The mixture of wood chips and whit liquor are heated up to 170 ºC in heat exchanger using medium pressure steam (MPV, 15 bar). During the pulping process a part of the black liquor is recirculated and cooled from 144 ºC to approximately 90 ºC. For this purpose two heat exchangers are employed, using condensates and warm water from de water circuit. The obtained pulp from the digesters is then screened and washed with hot condensates (63 ºC aprox.) and a recirculated partial stream of washing liquor, since the other one is used in the digesters for pulp washing during one of the cooking stages.

Eight effects compose the evaporation plant, where the black liquor obtained from pulping process containing 17 % TDS (Total Dissolved Solids) is first preheated using low pressure steam (LPV, 5 bar) and then concentrated (up to 60 % TDS) before its combustion in the recovery boiler, where the resulting inorganic matter is used to reconstitute the white liquor employed in the pulping stage. The mill uses a second furnace burning the wood bark and producing high pressure steam (HPV, 55 bar) which used to produce electricity, MPV and LPV used within the pulp mill. The air required for the combustion is preheated by low and medium pressure steam.

The condensates generated in the evaporation plant and in all the heat exchangers that use live stream, as well as the water consumed in the surface condenser are classified according to their pollutant content (for the condensates: clean, dirty or very dirty) and temperature (warm, up to 45 ºC, or hot, up to 65 ºC) for internal reuse in the pulp mill. Clean condensates are heated by using LPV and used in the recovery boiler and to

adjust the stream extracted from the turbine; hot condensates and water are recirculated to several sections (causticizing, washing …). The water used to condensate the vapor of last evaporation stage is previously cooled in the cooling tower and mixed with a fresh water stream.

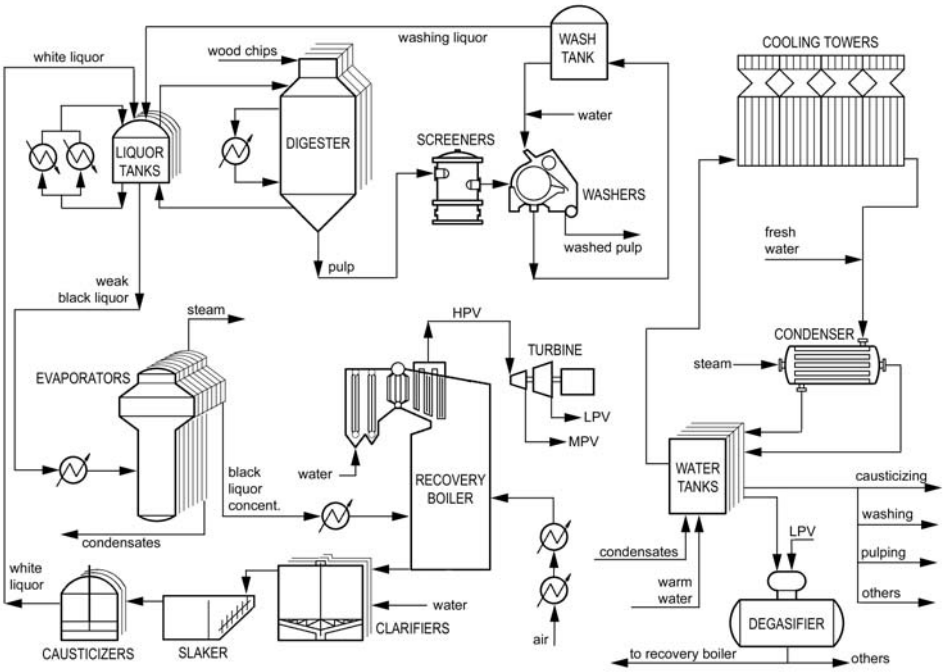

Figure 1. Diagram of the Pulp Mill sections studied

3. Kraft Process Simulation

The simulation of the process described has been developed by means of the software CadSim Plus (Aurel Systems), specifying main streams, equipment characteristics and process conditions. The simulation has been validated with several operation conditions. The results have been collected for a later energy study. The most important data are described in the Table1.

The recovery boiler generates HPV, which feed the turbine producing 28 T/h of MPV at 250 ºC, 62 T/h of LPV and around 7700 kW of electrical power. The live steam obtained is consumed in several sections of the mill (15.7 T/h MPV in pulping process, 14,5 T/h LPV for black liquor evaporation…).

4. Pinch Analysis

The Pinch Analysis has been carried out with the HX-Net software (AspenTech). The data extraction has been made using the process simulation and taking into account only streams with a minimum heat flow of 1 MW. The HEN has been analyzed taking into account the utilities consumption (steam and water), the characteristics of heat exchangers (area) and related costs (operation and investments).

The HEN of the Base Case consists of 9 heat exchangers and represents a total heat requirement of 18.17 MW. This configuration was compared to two case studies:

Table 1. Simulation results for the main sections of the Kraft Pulp Mill.

Pulping process		Recovery Furnace	
Chip load	62 T/h	Air consumption	128 T/h
Pulp production	160 T/h (90 % water)	HPV generation	61 T/h
White Liquor consumption	47 T/h (14 % TDS)	Water feeding	85 T/h
Black Liquor generation	144 T/h (17.8 % TDS)	Smelt production	7.8 T/h
Steam consumption	18.6 T/h	Steam consumption	8.8 T/h
Evaporation process		Causticizing process	
Concentrated Black Liquor	40 T/h (61 % TDS)	CaO consumption	3.1 T/h
Steam consumption	16.1 T/h	Turbine	
Cooling water to condenser	357 T/h (19 ºC)	Power generation	7721 kW

Scenario 1: new design of the HEN. In this case only utilities have been employed to satisfy the heat exchange requirements (live steam for heating and fresh water for cooling).

Scenario 2: resulting from the automatic optimization by means of HX-Net software, which implies a simple reorganization of the streams, changing the flow ratios in the branch designed.

The results of the analysis, energy consumptions (heating and cooling), and number of heat exchangers and related operating – investment costs, as well as the energy generated in the turbine (electricity) are reported in Table 2. The HEN initial configuration and two alternatives are represented in Figure 2.

Table 2. Energy savings and related operating and investments costs for the different scenarios.

	Base Case	Scenario 1		Scenario 2	
		value	% respect Base Case	value	% respect Base Case
Heating (MW)	18.17	18.17	-	18.17	-
Cooling (MW)	-	14.78	-	-	-
Area (m^2)	7327	3574	- 51	7148	-2.5
HE units	8	7	-12	8	-
Investments cost Index (cost)	$1.69 \cdot 10^7$	$7.77 \cdot 10^6$	-54	$1.63 \cdot 10^7$	-3
Operating cost Index (cost/year)	$1.82 \cdot 10^6$	$3.30 \cdot 10^6$	81	$1.82 \cdot 10^6$	-
Total Cost Index (cost/year)	$6.14 \cdot 10^6$	$5.28 \cdot 10^6$	-14	$5.99 \cdot 10^6$	-2

Base Case configuration takes advantages of most of the water generated in the process (condensates and warm water) for cooling some streams of the process. For Scenario 1 in which the water reusability has been removed, using only fresh water for cooling leading to an increase of energy requirement of 14.78 MW (49 %) compared with base case. however, the Scenario 1 represents the better economical option, since it implies a 14 % reduction of the total cost, but entails higher water consumption. The HEN configuration of Scenario 2 results in a minimizing of the total annual cost due the lower need of heat exchange area.

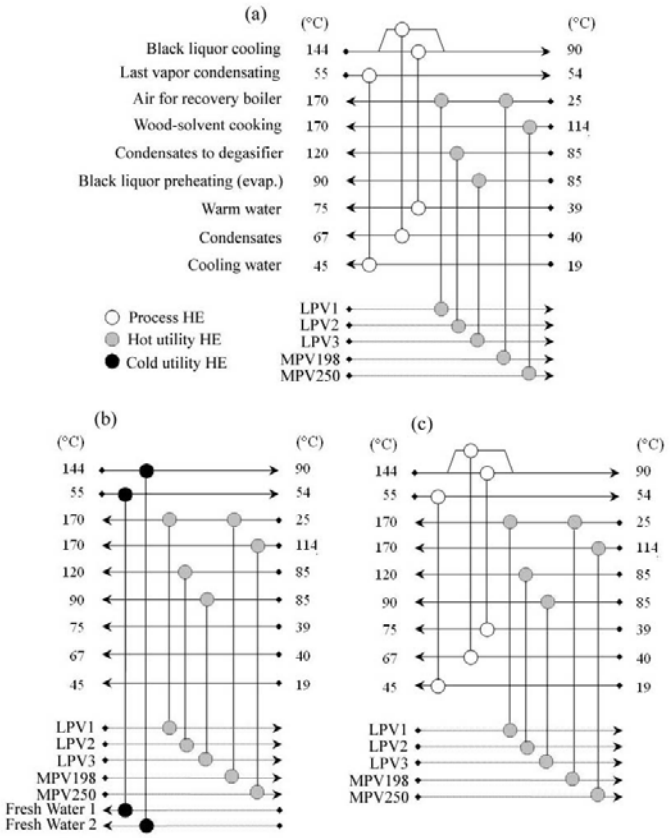

Figure 2. The HEN configuration for different scenarios: (a) Base Case, (b) Scenario 1 (without water reuse), (c) Scenario 2 (HE cost optimization).

5. Conclusions

The combination of simulation and pinch analysis has been proved to be a good tool for the study of energy optimization in real processes.

The comparison between three possible scenarios has been made, concluding that for the studied pulp mill the HEN optimization means a change in the network configuration and subsequently of the process. This can be developed by means of the use of process simulation.

A Theoretical Nucleation Study of the Combined Effect of Seeding and Temperature Profile in Cooling Crystallization

David Widenski[a], Ali Abbas[b], Jose Romagnoli[a]

[a]*Chemical Engineering Department, Louisiana State University, Baton Rouge, USA*
[b]*School of Chemical and Biomolecular Engineering, University of Sydney, Sydney, Australia*

Abstract

Crystallization is a widely used unit operation used for the production of pharmaceuticals, fertilizers, and fine chemicals. One of the most common types of crystallization is cooling crystallization. In cooling crystallization, the solution is cooled to generate supersaturation causing the formation and growth of crystals. The properties of the product are dependent on the shape of the supersaturation curve. Nucleation will occur at high rates if supersaturation increases to excessive levels, this being an undesired outcome. A commonly used crystallization objective is to produce large crystals with minimum fines production under conditions of low nucleation rates. A typical approach to minimize nucleation known as "programmed cooling" is to utilize an optimum temperature profile. Recent research works have favored initial seed characteristics over programmed cooling for the production of unimodal crystal size distributions (CSD). In this paper, a theoretical seed chart is developed for combined seeded-cooling crystallization via fundamental crystallization kinetic modeling of potassium chloride (KCl). Fundamental analysis here shows that joint cooling and seeding optimization of cooling crystallization gives superior performance to just optimizing the seed, and that the current trend of experimentally optimizing the seed is undermined by model-based optimization approaches.

Keywords: crystallization, seed chart, modeling, optimization, cooling.

1. Introduction

Crystallization is a widely used unit operation used for the production of high-purity compounds for pharmaceuticals, fertilizers, and fine chemicals. One of the most commonly used techniques is cooling crystallization, and is the technique that is considered in this paper. In cooling crystallization the solution inside the crystallizer is cooled to a predetermined temperature profile. This cooling causes generation of supersaturation which in turn causes both the formation and growth of crystals. In order to prevent excessive nucleation from occurring it is important to maintain the solution's supersaturation below the primary nucleation metastable limit. Rapid increases in supersaturation exceeding the metastable limit will result in uncontrollable primary nucleation. The first method to minimize nucleation was to implement programmed cooling profiles (Mullin & Nyvlt, 1971; Mullin & Jones, 1974). Although this method helped reduce nucleation, it was not successfully repressed.

Another way to minimize nucleation is to seed the crystallizer with already formed crystals. These crystals minimize nucleation because any supersaturation that is formed is used to grow the seed crystals. However, it is imperative to add the correct initial amount of seed to the crystallizer in order to get sufficiently grown crystals. If the seed loading is too large, the seed will not grow sufficiently and if on the other hand it is too small there will not be enough seed to suppress primary nucleation. Jagadesh et al. (1996) investigated the effect of crystal seed on the final CSD profile. They successfully showed that a suboptimal cooling profile such as natural cooling can be utilized to produce unimodal CSD's for the potash alum system. They introduced the experimental seed chart to assist in the proper selection of seed size and mass. Once either seed size or mass is fixed, the seed chart can be used to find the corresponding seed size or mass that will maximize seed growth. Kubota et al. (2001) performed further studies producing a seed chart for potassium sulphate. They showed that using an optimum amount of potassium sulphate seed, a unimodal CSD can be produced even using suboptimal natural cooling which was something Jones and Mullin (1974) could not achieve with programmed cooling for the same system. Since then Chung et al. (1999), Choong and Smith (2004), Sarker et al. (2006) and Nowee et al (2007), have performed optimization studies to find joint optimal temperature and seed profiles for various systems.

In this paper, a theoretical seed chart is developed for a combined seeded-cooling system via fundamental crystallization kinetic modeling of potassium chloride (KCl). Fundamental analysis here shows how model-based optimization of seed mass, seed size, and the temperature profile gives superior results over the current trend of experimentally optimizing the seed.

2. Crystallization Model

The crystallization model is comprised of a solubility model, a population balance, and nucleation and growth kinetics. The solubility of potassium chloride in water was correlated using a quadratic equation over a temperature range of 0-100 °C from data taken from the CRC Handbook of Chemistry and Physics (Lide, 2006). A population balance for a constant volume crystallizer with growth independent of crystal size, and negligible agglomeration is used. The population balance is discretized into 1000 equal intervals and solved through backward finite differences. The nucleation kinetics was broken down into homogeneous nucleation (1), heterogeneous nucleation (2), surface nucleation (3), and attrition (4) with equations taken from Mersmann (2001). Further information about the parameters and variables used in these equations are detailed in Mersmann (2001). Potassium chloride crystallization is reported as being diffusion limited so crystal growth (5) is modeled as a mass transfer process using a mass transfer coefficient (Lopes & Farelo, 2006).

$$B_{hom} = 1.5 \text{ x } D_{AB}(C\ N_A)^{7/3}\sqrt{\frac{\gamma_{CL}}{kT}}\frac{1}{C_c N_A}\ \exp\left(-\frac{16}{3}\pi\left(\frac{\gamma_{CL}}{kT}\right)^3\left(\frac{1}{C_c N_A}\right)^2\frac{1}{(v\ln S)^2}\right) \quad (1)$$

$$B_{het} = \left(\frac{1}{2\pi}a_{for}d_m HE_{ad}(CN_A)^{\frac{7}{3}}\sqrt{\frac{f\gamma_{CL}}{kT}}V_m\right)\times \left(\frac{D_{surf}\ sin\,\theta}{r_c}HE_{ad}d_m^{\frac{3}{2}}(CN_A)^{\frac{1}{6}} + 3\pi D_{AB}(1-cos\,\theta)\right)exp\left(-\frac{4}{3}\pi f\frac{\gamma_{CL}}{kT}r_c^2\right) \quad (2)$$

$$B_{surf} = 9E\frac{D_{AB}}{d_m^4 L_{32}}\varphi_T \, exp\left(-\pi\frac{(\gamma_{CL}d_m^2/kT)^2}{v\,ln\,S}\right) \quad (3)$$

$$B_{attrit} = 7x10^{-4}\varphi_T\frac{H_V^5}{\mu^3}\left(\frac{\Gamma}{K}\right)^{-3}\frac{\pi^2\rho_c\bar{\varepsilon}N_v}{2k_vPo}\frac{N_{a,eff}}{N_{a,tot}}\eta_w^3\eta_g \quad (4)$$

$$G = \frac{D_{AB}}{3\rho_c\bar{L}}\left(2 + 0.8\left(\frac{\bar{\varepsilon}\bar{L}\rho_s^3}{\eta^3}\right)^{1/5} Sc^{1/3}\right)\Delta C \quad (5)$$

In order to investigate the effect of the temperature profile, three different temperature profiles were considered. These three profiles represent three popular cooling profiles, linear, natural, and programmed cooling, and are shown in Figure 1. For each temperature profile the temperature was decreased from 55 °C to 10 °C over 30 min.

To investigate the effect of the size of the seed, three different seed sizes were evaluated 75, 250, and 500 microns with various mass loadings. The seed loadings were carefully chosen to occur where the critical seed loading would be for each different seed size. Since it has been proven by Kubota et al. (2001) that the critical seed loading is dependent on the seed size, the seed loadings were specified differently for each seed size. The 75, 250, and 500 micron seed loadings ranged from 0.1-1, 1-40, and 10-100 g of KCL per kg of H_2O respectively. The seed was then added at the beginning of each simulation before cooling was initiated. Stochastic experimental simulations comprised of 25 seed loadings were subsequently executed using the gPROMS modeling package (Process Systems Enterprise, UK) for each unique size and temperature profile combination.

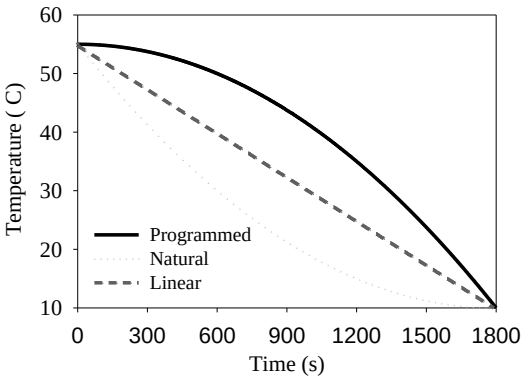

Figure 1: Implemented Temperature Profiles

3. Seed Chart Results

By organizing the data into a seed chart, as shown in Figure 2, it can be seen that the simulations produced a very similar result to the experimental seed charts published by Jagadesh et al. (1999) and Kubota et al. (2001). Each data point on the seed chart represents the ratio of the final volume mean size to its initial volume mean size for a given seed size, seed loading, and temperature profile. Similar to their seed charts, ours shows that the smaller seed sizes grow more compared to their initial size and require less loading than the larger sizes. It also shows that the temperature profile does not

have an effect on the final crystal size until the seed loading approaches the critical seed amount for that profile. Crystal growth follows the ideal growth line until the seed loading becomes insufficient and nucleation occurs. This causes the deviation of the curves away from the ideal growth line. Since this deviation is dependent on the temperature profile it follows that the critical seed amount is a function of the temperature profile. This is because some cooling profiles are superior to others at minimizing nucleation and maximizing the final crystal mean size. Thus, if the objective is to maximize the growth of the crystals then both the temperature profile and the seed loading are important.

While inspecting the seed chart it may seem that it is always better to seed small sizes. This is not always true. It is true that small seed sizes will grow more than the larger seed sizes due to the limited amount of mass available in the solution. However, if the objective is to make large crystals it may be necessary to seed moderate to high seed sizes at the expense of higher seed loading. For example the 75 micron seed was only able to grow to 330 microns before the temperature profile affected the size. However, the 250 and 500 microns seed sizes were able to grow to 425 and 630 microns respectively regardless of the temperature profile.

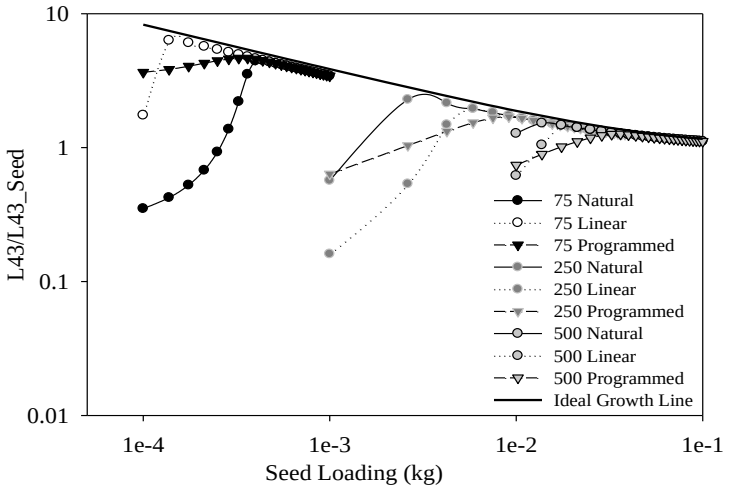

Figure 2: Seed Chart of KCl for Different Seed Sizes and Cooling Profiles.

4. Joint Seeding and Cooling Optimization

As shown earlier there are benefits to optimizing the temperature profile, namely larger crystal size and less seed loading. The chosen objective function in this study is the minimization of the zeroth moment. This is the same as minimizing the total amount of nucleated particles. This objective function should ensure a unimodal distribution. The four constraints used are the desired final crystal size, the maximum cooling rate, and the initial and ending temperatures. The optimization determines two control variables, the initial seed loading and the temperature profile. The temperature profile was discretized with 30 one minute control intervals. The three optimized temperature profiles for the 75, 250, and 500 micron seeds are displayed in Figure 3.

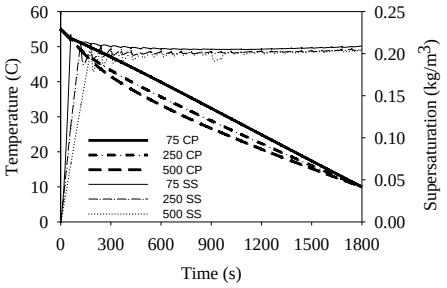

Figure 3: Optimized Temperature & Supersaturation Profiles

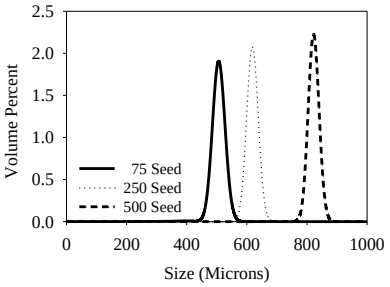

Figure 4: Optimized Volume Percent CSD

All three profiles are very similar in shape. They all have a quench cooling section followed by linear cooling. The initial quench cooling has the effect of quickly raising the supersaturation to the metastable limit, whereas the subsequent linear cooling keeps it at that limit until the end of the batch. This ensures maximum growth over the batch. All three seed sizes grew to larger sizes with the optimized temperature profiles than with the previous profiles used in generating the seed chart as shown in Table 1. The optimized size is 7-8% larger than the size possible from using the best seed chart temperature profile/ seed mass combination, and 23-33% larger than seeding the crystallizer at the critical seed mass, which corresponds to temperature profile independent operation. In addition, all three final volume percent CSD's shown in Figure 4 have unimodal distributions which show nucleation was successfully suppressed. Due to the optimized temperature profiles less seed loading was also required. These optimization studies show the benefit of optimizing the temperature profile and the seed conditions, and that joint optimization of the seed loading and temperature profile is superior to the seed chart in creating unimodal distributions of large mean size.

Table 1: Optimization Results

Seed Size (microns)	Seed Loading (kg)	Optimized L_{43} (microns)	Seed Chart Best L_{43} (microns)	Temperature Profile Independent L_{43} (microns)
75	1.26×10^{-4}	505	474	336
250	2.71×10^{-3}	617	572	425
500	1.11×10^{-2}	822	761	631

5. Conclusion

When the seed chart was introduced in the late 1990's it was a very useful tool. However, with the recent advances of both crystallization modeling and computational efficiency its usefulness is undermined. The disadvantage of the seed chart is that it does not optimize the temperature profile, and many experiments are required to

generate it. If another temperature profile is desired then more experiments need to be done to add that temperature profile to the seed chart. This is laborious and time consuming. However, an accurate crystallization model developed from carefully planned experiments cures these limitations. The crystallization model will work for any temperature profile or seed size. The crystallization model can be used to optimize both the seed loading and the temperature profile for any objective function which the seed chart cannot do. Experimental time spent creating a seed chart is better spent toward the development of a crystallization model. In conclusion, the seed chart has been a very useful tool for crystallization processes, but the advantages in crystallization modeling and model-based optimization make it the preferred method for the future.

Abstract

In this paper we propose a multi-objective decomposition algorithm for the design of multipurpose batch plants, which avoids the direct solution of the fully detailed MILP model. Most of such design problems involve the maximization of the total revenue, as well as the minimization of the total cost. The way to deal with these two terms simultaneously is either to combine them into a single criterion (e.g., profit), or to define the efficient frontier that offers the optimal solutions by multi-objective optimization. In this work the latter approach, while more elaborate, was adopted, since the exploration of this frontier enables the decision maker to evaluate different alternative solutions. A combination of the proposed decomposition algorithm and the ε-constraint method is employed, which supports the application of this approach to perform economic assessments. The proposed algorithm allows the identification of the plant topologies, scheduling, equipment design and storage policies, subject to the plant's cost minimization and revenue maximization. A comparative analysis is presented between the detailed model proposed by Pinto *et al.* (2008b) and the proposed algorithm.

Keywords: Scheduling, Design, ε-constraint, Multipurpose batch facilities.

1. Introduction

In multipurpose batch facilities a wide variety of products can be produced via different processing recipes, by sharing all available resources, such as equipment, raw material, intermediates and utilities. In order to ensure that any resource in the design can be utilized as efficiently as possible, an adequate representation is necessary in order to address such type of problems without creating ambiguities in the process/plant mathematical model. The Resource-Task Network (RTN) is one of the possible adequate representations to describe the design of multipurpose batch plants as suggested by Pinto *et al*. (2008a).

Like most real-world problems, the design of multipurpose batch facilities involves multiple objectives, while most of the existing literature on the design problem has been focused on single objectives (Barbosa-Povoa 2007). Therefore, the multi-objective optimization of such problems requires the development of an adequate modelling approach, as a pre-requisite for the resulting models to be useful as decision making tools where trade-offs among objectives can be investigated. In order to guarantee

optimal solutions, most of the published mathematical design formulations consider a large number of potential equipment items, out of which a selection is made of those that will be incorporated into the optimal plant configuration. This factor and the diversity of products' recipes, gives rise to large MILP problems and consequently to an increasing computational burden. For this reason, effective solution tools are still an open area of research in the design of batch plants.

In this paper, we aim to overcome some of these computational difficulties and also to avoid the direct solution of the fully detailed design and scheduling MILP model. With that aim, we propose a decomposition algorithm that exploits the hierarchical structure of the problem: the original detailed design and scheduling model is decomposed into an upper-level (UL) and a lower-level (LL) models; the UL uses profit maximization as the objective function and selects the so-called complicated variables, which in the current case are the design variables responsible for equipment selection; the LL comprises both the equipment design and the scheduling problem.

Applying the ε-constraint method (Chankong and Haimes, 1983), the procedure iterates until the Pareto-optimum surface is completed. This allows the identification of a range of plant topologies, design facilities and storage policies that minimize the total cost of the system while maximizing revenue, subject to product demands and operational restrictions.

2. Decomposition Algorithm

To avoid the direct solution of the MILP model, we propose a decomposition algorithm (DA) that exploits the hierarchical structure of design/scheduling models, and employ it together with the ε−constraint method. As referred to previously, the original detailed design and scheduling model is decomposed into one UL design problem and one LL design plus scheduling problem. The UL determines the necessary equipment to satisfy the demand along the entire time horizon, with the design constraints being omitted, leading to a relaxation of the original, DM, or detailed problem and therefore to an upper-bound on profit. In the LL, the DM is solved by fixing the equipment obtained from the UL. The LL corresponds to a sub-problem of the original MILP problem, in a reduced space and at iteration *i*. It considers the selected subset of equipment obtained from the UL, producing a lower-bound on profit. The procedure iterates until the difference between the upper-bound and the lower-bound is less than a specified tolerance. To expedite the search, integer cuts are added to the UL to exclude previous solutions.

The DA is subject to an objective constraint function that defines the maximum cost available for the optimal solution. The initial restriction takes the value of the necessary cost to generate the maximum revenue (C_{max}). This restriction is decreased by small values, $\Delta\varepsilon$, and successive optimization steps ($i=1,\ldots,n$) undertaken until the intended range is covered and the Pareto front defined.

2.1. Integer Cut

If the upper-bound obtained from the UL and the lower-bound obtained from the LL do not lie within a pre-defined tolerance, it is necessary to obtain a new solution from the UL. Then an integer cut on the binary design variable, Δ_r^{UL}, where *r* characterizes the equipment obtained from the UL model, is added to the UL problem so as to avoid the solution in the previous iteration *i*. For iteration $s > k$, this is defined as:

$$\sum_{r\in U_1^k} \Delta_r^{UL} - \sum_{r\in U_0^k} \Delta_r^{UL} \leq \left|U_1^k\right| - 1 \qquad (1)$$

Where $U_0^k = \ r \mid \Delta_r^{UL} = 0$ and $U_1^k = \ r \mid \Delta_r^{UL} = 1$. The U_0^k and U_1^k are obtained from the optimal UL solution, in terms of the assignment variable in iteration *k*.

2.2. ε-constraint

In order to obtain the Pareto front, we used the ε-constraint method combined with the decomposition algorithm. The ε-constraint requires a cost constraint which is activated in both models (UL and LL) and imposes limits on the objective functions. The detailed model, LL, uses the objective functions FO1, which defines the revenue, and FO2, which reflects the cost associated with both equipment and operational tasks. To obtain each point in the Pareto front, the cost constraint is activated and decreased by $\Delta\varepsilon$:

$$F02 = C_{\max} - i\,\Delta\varepsilon \qquad i=0,\ldots,n. \tag{2}$$

The final decomposition algorithm is illustrated in Figure 1.

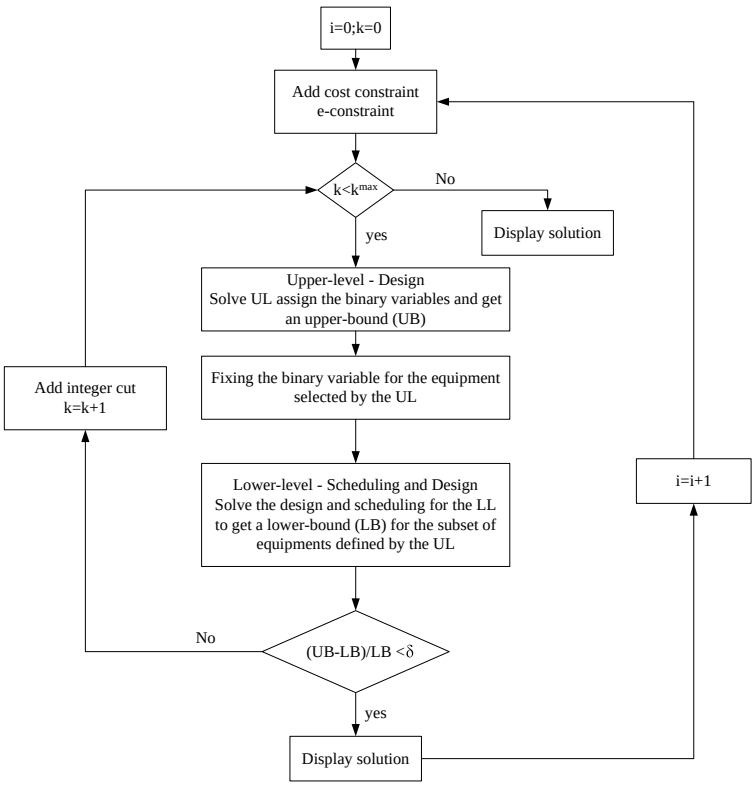

Figure 1: Flow chart for the decomposition algorithm.

2.3. Algorithm Steps

An overview of the proposed decomposition follows:

1. The indices *k* and *i* control, respectively, the inner loop for estimating individual points on the Pareto front and the outer loop for generating successive points.

Initially these are set at *k*=0 and *i*=0, while the upper-bound at UB=∞, the lower-bound at LB=- ∞ and a value δ assumed for the optimality tolerance.

2. Within the inner loop the cost constraint is activated; the MILP aggregated model solved for the upper-bound; the following sets defined:

$$U_0^k = \{ r \mid \Delta_r^{UL} = 0 \}\ ,\ U_1^k = \{ r \mid \Delta_r^{UL} = 1 \}\ ;\ \text{and}\ \ \Delta_r = \Delta_r^{UL} \quad \text{for} \quad r \in U_1^k\ ;$$

3. Still within the inner loop, the LL is solved; an optimal solution obtained, which is a lower-bound of the problem that defines the equipment design, scheduling and storage policy for each point of the Pareto front.

4. The convergence criterion $\frac{UB - LB}{LB} < \delta$ is tested.

If it is satisfied the solution corresponding to the lower-bound is the optimal solution and the outer loop is entered, where *i* defines the next point on the Pareto front.

5. If this convergence criterion is not satisfied an integer cut given by $\sum_{r \in U_1^k} \Delta_r^{UL} - \sum_{r \in U_0^k} \Delta_r^{UL} \leq \left| U_1^k \right| - 1$ is added to the UL and the inner loop controlled by *k* is again calculated.

3. Example results

In this example, the design of a multipurpose batch plant for a non-periodic mode of operation is performed. A production of [0; 170] tons of products S5, [0; 166] tons of S9 and S10, [0; 270] tons of products S6 and [0; 143] tons of products S11 is defined. Three raw materials, S1, S2 and S7, are used over the horizon of 24 h. The materials S5 and S6 are both intermediate and final products. S3, S4 and S8 are intermediate material. S3 and S8 are unstable and S4 is storable in V4 if necessary (Pinto *et al.* 2008b). There are available six main reactors (R1 to R6) and nine dedicated vessels. In terms of equipment suitability, only reactors R1 and R2 may carry out the two processing tasks, T1 and T2, while each storage vessel and reactors R3, R4, R5 and R6 are dedicated to a single State/Task. T1 may process S1 during 2 hours in R1 or R2; T2 may processes S2 during 2 hours in R1 or R2; T3 may process 0.5 of S3 and S4 during 4 hours in R3; T4 process 0.5 of S3 and S4 during 2 hours in R4; T5 process S6 during 1 hour to produce 0.3 of the final product S11 and 0.7 of S8 in R5, and finally T6 processes S8 during 1 hour in reactor R6 to produce the final products S9 and S10. The connections capacity range is assumed between 0 to 200 [m.u./m^2] at a fix/variable cost of 0.1/ 0.01 [10^3c.u.]. The capacity of R1, R2, R5 and R6, range from 0 to 150 [m.u./m^2], while the others range from 0 to 200 [m.u./m^2] (m.u. and c.u. are, respectively, mass and currency units).

3.1. Comparative analysis for the Example

In this section a comparative analysis of the performance is made, between the DM previously presented (Pinto *et al.* 2008b) and the currently proposed algorithm.

The optimality gap used for the UL was 7% followed by an additional 5000 seconds. For the LL and DM it was used a 5% of optimality gap and an additional 5000 seconds time for solution polishing. The results obtained for these specifications correspond to an approximation to the optimal set. The models characteristics are presented in Table **1**. Points A, B, C, D and E are those where there is a change caused by the addition of one or more main equipment units to the previous topology (Pinto *et al.* 2008b). Table 2 presents the optimal design of the main equipment for each point in terms of capacities, while Table 3 presents the final product and their quantity.

Table 1: Model characteristics.

Model	Bin.Var.	Tot.Var.	Equat.
DM	612	2582	4378
UL	228	1809	2478
LL	606	2583	4379

Table 2: Design for the main equipment using the decomposition algorithm.

Equipment	A	B	C	D	E
R1	76.2	93.3	103.4	141.2	120.3
R3	76.2	62.2	103.4	141.2	180.5
R4	-	155.5	129.3	140.5	159.1
R5	-	-	-	21.8	138.2
R6	-	-	-	15.3	96.8
V4	-	-	-	-	120.3
V5	76.2	-	51.72	170	170
V6	-	155.5	258.6	270	270
V9/V10	-	-	-	7.6	145.1
V11	-	-	-	6.5	124.4

Table 3: Quantities produced for each final product using the decomposition algorithm.

Final Products	A	B	C	D	E
S5	76.2	-	-	170	170
S6	-	155.5	258.6	270	270
S9	-	-	-	7.6	145.1
S10	-	-	-	7.6	145.1
S11	-	-	-	6.5	124.4

A comparative analysis between results obtained for the DM model (Pinto *et al.* 2008b) versus the DA model is shown in Table 4. The first column characterizes the different points on the Pareto curve. There were topology changes only in points A to E. The second column quantifies the relative performance of the two models. The one with the highest performance is identified on the third column. From the gap column it can be noted that the execution for the DM and the LL ends when the optimality gap reaches (5%). In run 3, the DM model reached the maximum CPU time available without attaining the optimal gap. Looking at the best performance column, we verify that in most runs the DA model shows a better performance than DM, except for runs 1 and 9, where the latter took around 12% and 10%, i.e. less CPU time than DA. For all runs the DA converged in the first iteration. Despite the computational results, the equipment design and amounts of final products remained equal for both models.

Table 4: Comparative analysis.

Run/Point	$(CPU_{DA} - CPU_{DM}) / CPU_{DA} \times 100$	Best performance	DM Cpu (s)	DM Gap (%)	DA Cpu (s)	LL Gap (%)	Iteration
1	12.145	DM	2.17	2.15	2.47	3.6	1
2/E	-261.27	DA	461.92	4.99	127.86	4.99	1
3	-256.691	DA	5000	5.77	1401.77	4.99	1
4	-168.921	DA	210.27	4.99	78.19	4.99	1
5	-324.125	DA	227.84	4.99	53.72	4.99	1
6/D	-102.481	DA	1843.45	4.99	910.43	5.0	1
7	-131.622	DA	596.45	5.0	257.51	5.0	1
8/C	-87.147	DA	415.0	4.99	221.75	4.99	1
9/B	10.271	DM	103.75	4.99	115.63	4.99	1
10/A	-99.78	DA	217.78	4.99	109	4.99	1

4. Conclusions

A multi-objective decomposition algorithm is proposed for the design of multipurpose batch plants. The model aims to overcome some performance difficulties from the direct solution of the fully detailed MILP model. A combination of the decomposition algorithm with the ε–constraint is applied allowing the definition of a range of topologies, schedules, design facilities and storage profiles in the vicinity of the efficient frontier.

The performance of the proposed methodology is illustrated with an example. As seen in Table 4 the proposed model presents an all-round better performance than the detailed one. Despite these results some future work must be undertaken to improve the optimality gap and the model performance.

Abstract

During two-phase electrolysis for aluminium, hydrogen or fluorine industrial production, there are bubbles which are created at electrodes which imply a quite important electrical properties and electrochemical processes disturbance. Bubbles are motion sources for the electrolysis cell flow, and then hydrodynamic properties are strongly coupled with species transport and electrical performances. Bubbles presence modifies these global and local properties: the electrolysis cell and the current density distribution are modified. This disturbance can lead to the modification of the local current density and to anode effects for example. There is few works concerning the local modelling of electrochemical processes during a two-phase electrolysis process due to the difficulty of measurements in such electrolytes. Produced bubbles involve a great hydrodynamic acceleration at the electrode interface which leads to great chemical composition modification and, sometimes, also the mechanical the electrode consumption due to both erosion and flow accelerated corrosion. Nevertheless, effects like the anode effect, particularly expensive on the point of the process efficiency, should need a better understanding.
The goal of this proposition is to present the electrochemical engineering modelling of two-phase electrolysis properties at electrode vicinity. This work is due to the necessity of a better knowledge of the actual interface condition during electrolysis, for example to have a better process optimisation or electrode consumption prevention. The numerical simulation is performed from the single bubble scale to the macroscopic electrochemical cell. The present work shows both scales theoretical modelling and also performances changes during the two-phase electrolysis processes.

Keywords: Two-phase Electrolysis Modelling Electrochemical Engineering.

1. Introduction

Gas release and induced fluid flow at electrodes are characteristic for several electrochemical processes such as aluminium, fluorine, chlorine and hydrogen production. Many authors have investigated these processes. The two-phase phenomena at gas evolving electrodes are in general neglected because of the major difficulty to be correctly taken it into account. With the increasing interest in hydrogen production,

clean, sustainable aluminium production and fluorine production for nuclear industry, these processes have to be revisited for further optimization.
The classical alkaline water electrolysis has been chosen as a representative two-phase electrolysis process:

$$2\ H_2O + 2\ e^- \rightarrow H_2 + 2\ OH^-_{aq} \qquad E° = -0.83\ V/ENH \qquad (R1)$$

$$2\ OH^-_{aq} \rightarrow 0.5\ O_2 + H_2O + 2\ e^- \qquad E° = 0.40V/ENH \qquad (R2)$$

Note that the alkaline water electrolysis, with minimal cell voltage equal to 1.23V, is generally chosen as the reference process for industrial hydrogen production. Many researchers have studied and exposed the difficulties in the two-phase electrolysis processes.The main problem is the existence of several effects, surface and volume effects, at the bubble scale but as well at the macroscopic electrochemical cell or reactor scale. This is the reason why zero gravity experiments are planfied to avoid natural convection.

2. Experimental set-up

Figure 1 shows the used experimental one dimensional set-up with general geometrical parameters definition. The configuration is axis symmetric for all input parameters chosen. The counter electrode has a large diameter D = 70 mm and height H'=17 mm with a geometric surface area $S=\pi\ D{\cdot}H$ = 440 mm^2 if H=h=2mm (height of the electrolyte free surface). The stainless steel 316L, working pin electrode is cylindrical with diameter d = 0.4 mm and a geometric surface area $s= 0.25\ \pi\ d^2 + \pi\ d{\cdot}h$ = 5.5 mm^2 for an immerged length h=2mm.

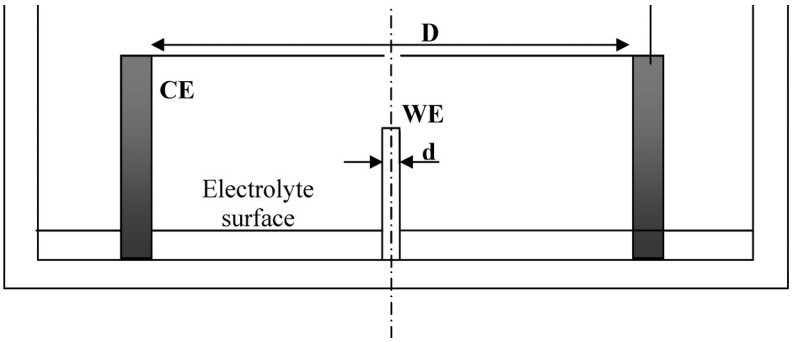

Figure 1: experimental set-up.

The cell voltage scan rate dV/dt, the electrolyte composition and temperature, the working electrode material and the counter electrode diameter factors have been explored.

3. Experimental results

Figure 2 shows an exemple of steady two-phase boundary layer which take place at the working electrode vicinity. The shape is said like an "inverted pyramid" due to the Archimede vertical forces applied on each bubbles, like the weight force.

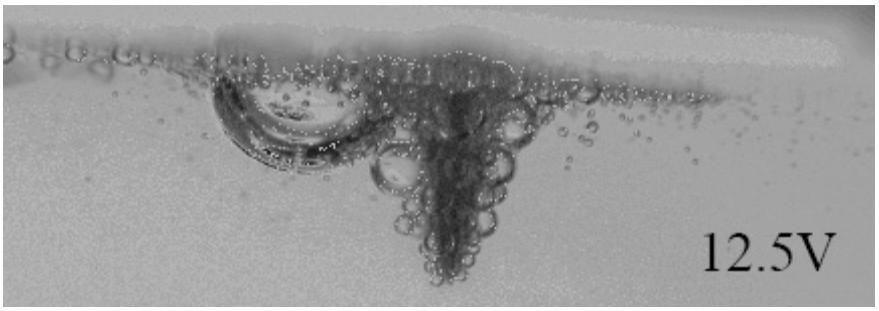

Figure 2: Bubble accumulation at 12.5 V around the working electrode during alkaline water electrolysis

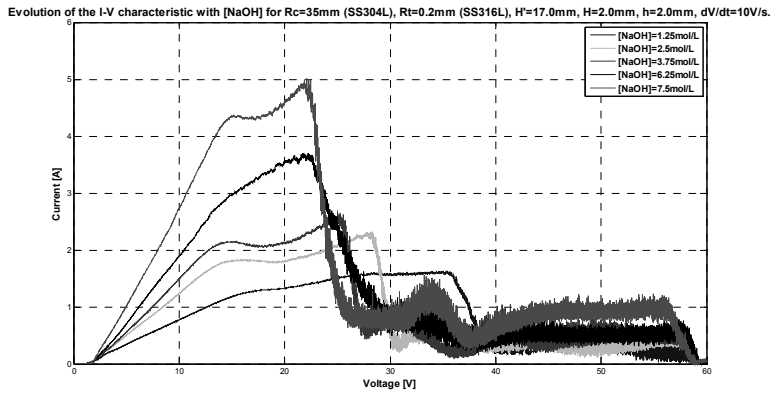

Figure 3: I-V characteristic evolution with the electrolyte NaOH concentration with stainless steel SS316L working electrode, D=70 mm, d=0.4 mm, h=H=2mm and dV/dt=10 V s^{-1}.

Figure 3 shows the effect of the electrolyte concentration upon the experimental resistance R_{exp}. The larger the concentration, the smaller the measured resistance is.
Table I shows these results quantitatively. The Bruggeman modelling is used to model the electrical resistance:

$$R_{theo} = \ln(1+2\delta/d)/(2\,\pi.h\sigma)+\ln(D/(d+2\delta))/(2\pi h.\sigma) \quad (1)$$

With: δ is the average two-phase boundary layer thickness (m), d and h the working electrode diameter and height (m), D the counter electrode diameter (m) and σ the electrical conductivity (S m^{-1}) given by Bruggeman law:

$$\sigma = \sigma^{\circ}.(1-\varepsilon)^{1.5} \quad (2)$$

with σ° the without gas (or bulk) liquid electrolyte conductivity (S m^{-1}) and ε the volume void fraction.
The minimum resistance is obtained for δ=0 m and is called R_{theo}, which is reported in table I.

As shown in table I, the under estimated theoretical resistance R_{theo} largely over-estimate the experimentally measured electrical resistance R_{exp} for all concentration explored. This primary modelling (only ohmic resistance description) is not sufficient to be realistic. For the two-phase electrolysis processes, the bubble motion rotational and translational, in the boundary layer, increases a lot the mass transfer in the working and

counter electrodes. The bubbles promote the mass transport. The equivalent impedance is not only ohmic, like for the Warbur impedance.

Table I: Evolution of the electrical resistance with the electrolyte concentration.

NaOH %wt	5	10	15	25	30
C° (mol/L)	1.25	2.5	3.75	6.25	7.5
$\sigma°$ (S m^{-1}) [I. Zaytsev (17)]	27	35	41	37	31
R_{exp} (Ω)	11.7	7.1	6	4.4	3
R_{theo} (Ω)	15.2	11.7	10	11.1	13.3

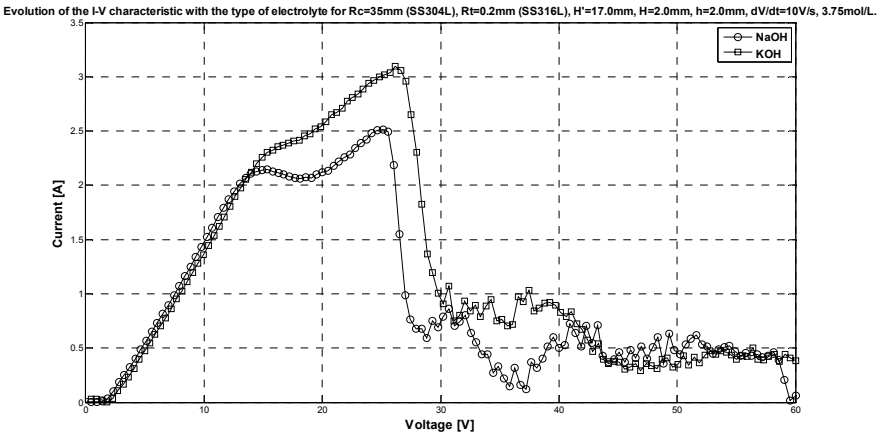

Figure 4: I-V characteristic evolution with the electrolyte species NaOH or KOH; concentration is 3.75 M with stainless steel SS316L working electrode, D=70 mm, d=0.4 mm, h=H=2mm and dV/dt=10 V s^{-1}.

Figure 4 shows that the electrical resistance is non dependent, for an identical molar concentration, of the electrolyte nature NaOH or KOH. The electrolysis cell resistance is non dependent with the electrical conductivity $\sigma°$, which is not in accord with theoretical expression (1). According with this expression the resistance should decrease with the electrical conductivity $\sigma°$.

The table II shows the evolution with concentration of the electrical conductivity $\sigma°$ for both species. This conductivity reaches a maximum at electrolyte concentration about 3.75 M. For smaller concentration, both conductivities are approximatively equal. But at 3.75 M, there is 34% difference between the conductivity values. Nevertheless, this large difference leads to identical resistance: once again, the ohmic primary description of the charge transport in inacurate for concentration around 3.75 M.

Table II: evolution of the electrical resistance with the electrolyte composition

Concentration [mol/L]	1.25	2.5	3.75	6.25	7.5
Conductivity NaOH [S/m]	27	35	41	37	31
Conductivity KOH [S/m]	28	39	58	58	44

Figure 5 shows an other contradiction of the ohmic-primary theoretical formulation for the electrical resistance. The electrolysis cell resistance is non dependent with the counter electrode diameter D, which is not in accord with theoretical expression (1). According with this expression the resistance should increase with diameter D.

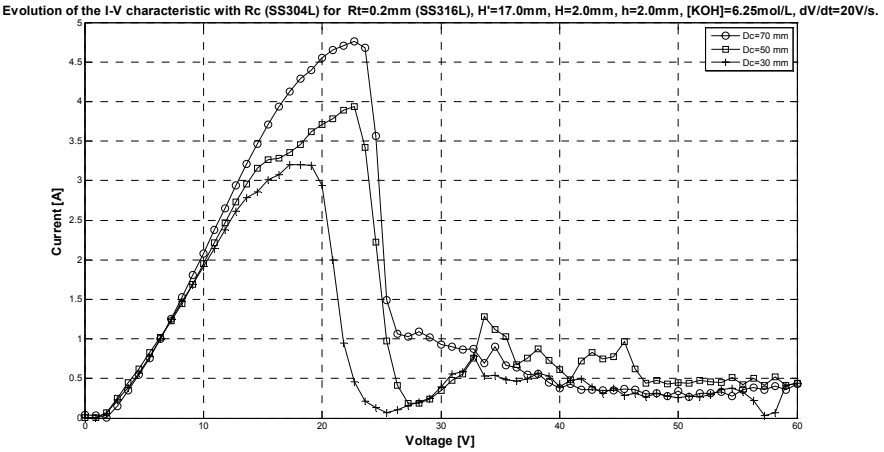

Figure 5: I-V characteristic evolution with the counter electrode diameter D: the electrolyte is NaOH the concentration is 6.25 M, with stainless steel working electrode, d=0.4 mm, h=H=2mm and dV/dt=10 V s^{-1}.

4. Conclusion

As it has been shown in this work, the electrical resistance obtained with 1G experiments doesn't obey the ohmic-primary theoretical modelling given in equation (1). Nevertheless, as shown in the second work of this session, for zero gravity experiments, this modelling is in good accord with experimental observation. Then, for two-phase electrolysis under normal Earth gravity, the induced natural flow has strong effect on the mass transport at electrodes. This effect is macroscopic (in the whole electrolysis cell), but also microscopic, at the bubble scale.

Abstract

Simulation of three-phase (vapor-liquid-liquid) distillation is still lacking of reliable mass transfer correlations to describe the rate-based (or nonequilibrium, NEQ) mass transfer process. The objective of this paper is to extend existing mass transfer correlations for three-phase distillation simulation in packed column. The transfer parameters in these correlations are classified into two categories: packing-related parameters and flow-related parameters, which are estimated using a (double-layer) hierarchical methodology based on our comprehensive experimental researches. The experimental database consists of 162 different data sets (both two-phase and three-phase distillations) of n-Butanol/Water/n-Propanol system for three different packings (Montzpack B1-350, Raschig Super-Ring 0.3, Rombopak 9M). The estimation problem with multi-data-set and multi-packing turns out to be a large-scale optimization subjected to a large number of nonlinear model equations. Three widely used correlations in packed column (i.e. Billet & Schultes correlation, Shi & Mersmann correlation, Rocha correlation) are adjusted for rate-based mass transfer calculation of three-phase distillation. Substantial improvements on the simulation predictive ability are observed by using the NEQ model with the adjusted correlations.

Keywords: three-phase distillation, parameter estimation, mass transfer correlation.

1. Introduction

There are many examples of extractive and azeotropic distillation processes, in which binary azeotropes are broken by adding a third component that creates a vapor-liquid-liquid (three-phase) heterogeneous distillation. Modeling three-phase distillation, however, is a complicated task due to the strong influence of the second liquid on the mass and heat transfer (Repke & Wozny, 2000).

Traditional method of modeling three-phase distillation assumes equilibrium condition among all three existing phases, which however is seldom realized in real processes. The non-equilibrium (NEQ) condition is dominated by the rate-based inter-phase mass transfer rates, which can be calculated based on film model and theory of multi-component mass transfer (Taylor & Krishna, 1993), i.e.

$$\dot{V}_i = N_i a_{ph} = \left(J_i + z_i \sum N_i\right) a_{ph} \tag{1}$$

The molar diffusion flux J_i is the most dominating term of mass transfer flux N_i, and can be computed by Taylor and Krishna (1993) method using the Maxwell-Stefan equation.

$$\mathbf{J} = -c_t[\mathbf{k}]\nabla\mathbf{z} = c_t[\mathbf{B}]^{-1}[\mathbf{\Gamma}](\mathbf{z}^{\mathbf{I}} - \mathbf{z}) \tag{2}$$

where the thermodynamic matrix [**Γ**] can be derived from certain activity coefficient model (NRTL, UNIQUAC etc.), and the [**B**] matrix has the elements

$$B_{ij} = -z_i\left(\frac{1}{\beta_{ij}} - \frac{1}{\beta_{in}}\right) \text{ and } B_{ii} = \frac{z_i}{\beta_{in}} + \sum_{k=1(i\neq k)}^{n}\frac{z_k}{\beta_{ik}} \quad i,j = 1,\cdots,n-1 \quad (i \neq j) \qquad (3)$$

where the binary mass transfer coefficients β can be calculated using empirical mass transfer correlations in multi-component distillations. For packed columns, one widely used correlation to describe vapor/liquid mass transfer on random packing was developed by Shi & Mersmann (1985). The first overall investigation about structured (gauze) packing was conducted by Bravo et al. (1985). The results were called SRP (I) model, which was lately improved and updated by Rocha et al. (1993, 1996), i.e. SRP (II) model. An attractive characteristic of SRP (II) model is that the mass transfer and hydraulic performance of packing are related by liquid holdup. Billet & Schultes (1999) also considered this point in their model for mass transfer calculation, filled with either random or structured packings, in the entire loading range. Detailed formulations of the above mass transfer correlations are given in table 1.

Table 1. A summary of mass transfer correlation for packed column

Name	β_V, β_L, a_e
Shi & Mersmann	$\frac{a_e}{a_P} = 0.76 m d_h^{1.1}\frac{U_L^{\theta_1}\nu_L^{\theta_2}}{1-0.93\cos\gamma}\left(\frac{\rho_L}{\sigma_L g}\right)^{\theta_3}\frac{a_P^{0.2}}{\varepsilon^{0.6}}$ $\beta_V = K_V D_V / d_h (Re_V)^{\theta_4}(Sc_V)^{\theta_5}$, $\beta_L = 1.19\sqrt{\frac{D_L}{d_h}}\left(\frac{U_L^{1.2} g^{1.3}\sigma_L^{0.3}\varepsilon^{1.2}(1-0.93\cos\gamma)^2}{\nu_L^{1.3}\rho_L^{0.3}a_P^{2.4}}\right)^{\theta_6}$
Rocha, SRP II	$\frac{a_e}{a_p} = F_{SE}\frac{29.12(We_L Fr_L)^{\theta_1} S^{0.359}}{Re_L^{\theta_2}\varepsilon^{0.6}(1-0.93\cos\gamma)(\sin\theta)^{0.3}}$ $\beta_V = 0.054 D_V / d_h (Re_V)^{\theta_3}(Sc_V)^{\theta_4}$, $\beta_L = 2\sqrt{\frac{D_L}{\pi\cdot t_{res}}} = 2\left(\frac{C_E D_L}{\pi\cdot d_h}\frac{U_L}{\varepsilon h_L \sin\theta}\right)^{\theta_5}$
Billet & Schultes	$\frac{a_e}{a_p} = 1.5\frac{1}{\sqrt{a_p d_h}}\mathrm{Re}_L^{\theta_1} We_L^{\theta_2} Fr_L^{\theta_3}$ $\beta_V = C_V\sqrt{\frac{a_p}{(\varepsilon - h_L)d_h}} D_V (Re_V)^{\theta_4}(Sc_V)^{\theta_5}$, $\beta_L = 1.514 C_L\left(\frac{U_L}{h_L}\right)^{\theta_6}\left(\frac{D_L}{d_h}\right)^{\theta_7}$

These correlations, however, were originally developed for vapor-liquid (two-phase) absorption or distillation. No mass transfer correlation for three-phase packed distillation can be found in literature. In this paper, three most used correlations, (i.e. Rocha correlation, Shi & Mersmann correlation, Billet & Schultes correlation), are adjusted for three-phase mass transfer calculation. A set of parameters used in the correlations is re-estimated by a hierarchical estimation methodology based on our comprehensive experimental researches of two-phase and three-phase distillations.

2. Parameter Estimation Problem

2.1. Experimental Design

To estimate the transfer parameters for three-phase distillation, a laboratory-scale packed column (Fig. 1, left) was built up in the Institute of Process Engineering (TU Berlin) to produce representative experimental database. The column has an inner diameter of 0.1m and whole height of 6.2m. The column was operated under total reflux and can achieve a maximum reboiler heat duty of 30KW (F-factor up to 2.8 $Pa^{0.5}$).

In this study, the experimental database contains 162 different experiments of n-Butanol/Water/n-Propanol system for three different packings (Montzpack B1-350, Raschig Super-Ring 0.3, Rombopak 9M). For the same experimental setup, both the two-phase and three-phase distillations experiments were carried out. Four vapour and four liquid samples are taken from suitable locations of the column.

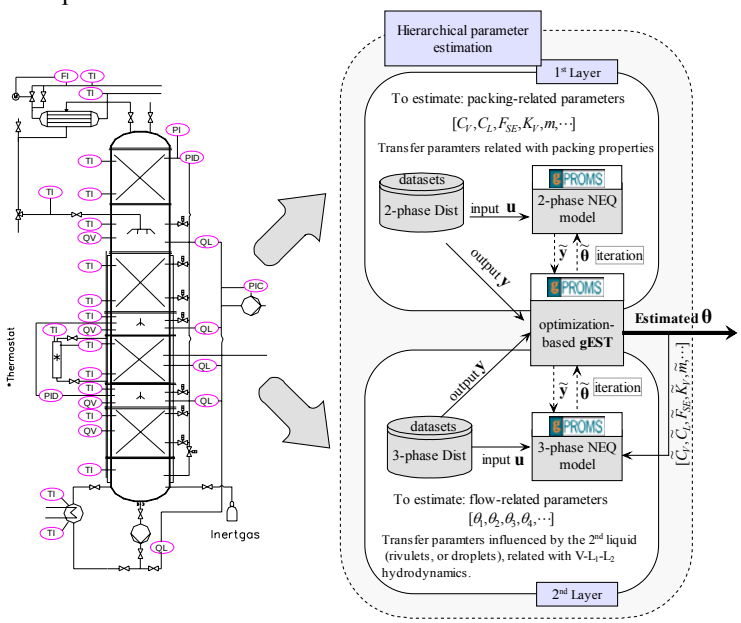

Fig. 1. Experiment details and estimation strategy

2.2. Hierarchical Methodology

Considering three-phase distillation, there are two kinds of transfer parameters should be determined based on the above experimental design.

1. "Packing-related" parameters (e.g. parameters such as C_V, C_L, F_{SE}, K_V, m in the correlations in table 1) are used to express the influence of geometric packing properties on mass transfer. For certain packings, the values of packing-related parameters are available; for other packings, however, these values are still not available and have to be experimental determined.
2. "Flow-related" parameters (as exponential $[\theta_1, \theta_2, \theta_3, \cdots]$ in table 1) reflect directly the influence of flow-behavior and hydrodynamics. In three-phase distillation, the 2nd liquid appears and could change the hydrodynamics in a dramatic way. Hence, these parameters have to be re-estimated using three-phase distillation database.

To estimate both kinds of transfer parameters, a hierarchical (two-layer) parameter estimation methodology (Fig. 1, right) is proposed in this paper. The packing-related parameters only reflect the influence of packing properties on mass transfer, and should be identical for two- and three-phase distillation. Hence, two-phase experimental data are utilized to estimate these parameters in the 1st layer. The estimated parameters are then passed into 2nd layer as given values to estimate the exponential flow-related parameters $[\theta_1, \theta_2, \theta_3, \cdots]$. These parameters account for the three-phase hydrodynamics. They are estimated based on experimental data sets of three-phase distillations.

The parameter estimations are carried out in gPROMS®. NEQ models of two-phase distillation and three-phase distillation are developed for simulation. The mass transfer correlations in table 1 are used for rate-based mass transfer calculation. The gEST®

entity is used to integrate simulation model and experimental database, and to minimize the deviations between them. Detailed mathematical formulation of the principle model-based parameter estimation is discussed in next section.

2.3. Mathematical Formulation

The main idea of the parameter estimation is to formulate a multi-data-set optimization problem subjected to the NEQ model equation system. A general parameter estimation problem with multiple data sets is formulated as in Eq. (4). To estimate the parameters $\boldsymbol{\theta}$, there are normally several experimental data sets of output variables $\mathbf{y}$ ($\tilde{y}$, simulation predictions), and the input (manipulated) variables $\mathbf{u}$. There are also many unmeasurable state variables $\mathbf{x}$ in the model equations $\mathbf{g}$ and inequality constrains $\mathbf{h}$. In this study, we assume the output variables $\mathbf{y}$ are subjected to measurement error, while the manipulated variables $\mathbf{u}$ are free from error (i.e., only the covariance matrix $\boldsymbol{\omega}$ of output variables was considered in the maximum likelihood objective function $\boldsymbol{\Phi}$).

$$\begin{aligned} &\boldsymbol{\Phi}(\boldsymbol{\theta}) = \frac{N}{2}\ln(2\pi) + \frac{1}{2}\min_{\boldsymbol{\theta}} \sum_{i=1}^{NDS}[\sum_{j=1}^{NV}\ln(\omega_{i,j}^2) + (\mathbf{y_i} - \tilde{\mathbf{y}}_\mathbf{i})^T \boldsymbol{\omega}_\mathbf{i}^{-1}(\mathbf{y_i} - \tilde{\mathbf{y}}_\mathbf{i})] \\ &s.t. \\ &\quad \mathbf{g_i}(\mathbf{x_i}, \mathbf{y_i}, \mathbf{u_i}, \boldsymbol{\theta}) = \mathbf{0} \\ &\quad \mathbf{h_i}(\mathbf{x_i}, \mathbf{y_i}, \mathbf{u_i}, \boldsymbol{\theta}) \geq \mathbf{0} \quad i = 1, \cdots, NDS \\ &\quad \boldsymbol{\theta}^L \leq \boldsymbol{\theta} \leq \boldsymbol{\theta}^U \end{aligned} \tag{4}$$

Considering the proposed hierarchical parameter estimation, here

$$\boldsymbol{\theta} = \begin{cases} \boldsymbol{\theta}_1 = [C_V, C_L]^T, or\ F_{SE}, or\ [K_V, m]^T & 1^{st}\ \text{layer estimation} \\ \boldsymbol{\theta}_2 = [\theta_1, \theta_2, \theta_3, \theta_4, \cdots]^T & 2^{nd}\ \text{layer estimation} \end{cases} \tag{5}$$

The output variables are

$$\mathbf{y_j} = [y_{in,1,j}, y_{in,2,j}, y_{in,3,j}, y_{out,1,j}, y_{out,2,j}, y_{out,3,j}]^T \tag{6}$$

where $\mathbf{y_{in}}$ and $\mathbf{y_{out}}$ are the vapor concentrations (experimental measurements) for each packing section and each component, respectively.

The parameter estimation turns out to be a large-scale problem (Chen, Repke, Wozny, 2008). Using the hierarchical estimation methodology the problem is divided into four sub-problems with smaller problem dimension, and the coupling between packing-related and flow-related parameters is removed. This is the benefit of the strategy.

3. Results and Discussion

3.1. Case Study: Extending Rocha Correlation

As an illustrative example, Rocha correlation (SRP II model) is adjusted using the hierarchical parameter estimation methodology.

1st Layer Estimation. In the SRP II model, all packing-related contributions to mass transfer are attributed in parameter F_{SE}. A number of 30 data sets (two-phase distillation, F-factor, 0.2-2.6 $Pa^{0.5}$) are adopted to estimate F_{SE} for three packings (10 experiments for each packing). The estimation problem contains about 3,000 variables (equations). The estimated values are listed in table 2.

Table 2. Estimation results of packing-related parameters

Packing	F_{SE}	95% t-value	Standard deviation	HETP (exp)
Montzpack B1-350	0.313	8.5	0.018	0.326m
Raschig super-ring 0.3	0.484	7.8	0.031	0.288m
Rombopak 9M	0.489	15.4	0.016	0.286m

The estimated results show a rather high 95% t-value compared with the reference 95% t-value 1.68, and rather small standard deviation, which suggest reasonable acceptance of the estimation. The results indicate that Super-ring 0.3 and Rombopak 9M have larger effective interfacial areas than Montzpack B1-350. This conclusion agrees well

with the experiment measurement of HETP values (table 2), which also implies better separation efficiency by using Super-ring and Rombopak.

2nd Layer Estimation. There are five exponential flow-related parameters, i.e. $[\theta_1, \theta_2, \theta_3, \theta_4, \theta_5]$. 60 data sets of three-phase distillation are used to estimate the flow-related parameters. It's a large-scale parameter estimation problem include around 44,000 variables (equations). The CPU time needed is about 1500s. The results are listed in table 3 for different F-factor operations. Enhancement factors f_E are defined (Fig. 2) to visualize the enhancement ($\pm$) achieved by new parameters.

Table 3. Estimation results of flow-related parameters

	a_e		β_V		β_L
	θ_1	θ_2	θ_3	θ_4	θ_5
Three-phase, L①	0.150	0.210	0.743	0.040	0.489
Three-phase, H①	0.179	0.216	0.810	0.276	0.457
Three-phase, A①	0.163	0.197	0.769	0.241	0.468

①: L, low F-factor (1.0-2.2Pa$^{0.5}$); H, high F-factor (2.2-2.8Pa$^{0.5}$); A, all F-factor (1.0-2.8Pa$^{0.5}$)

Mass Transfer Coefficients. For vapor side mass transfer coefficients, they have +10% enhancement under high F-factor conditions and –30% under low F-factor conditions (see Fig. 2). For liquid side mass transfer coefficients, positive enhancement is observed for all experimental cases.

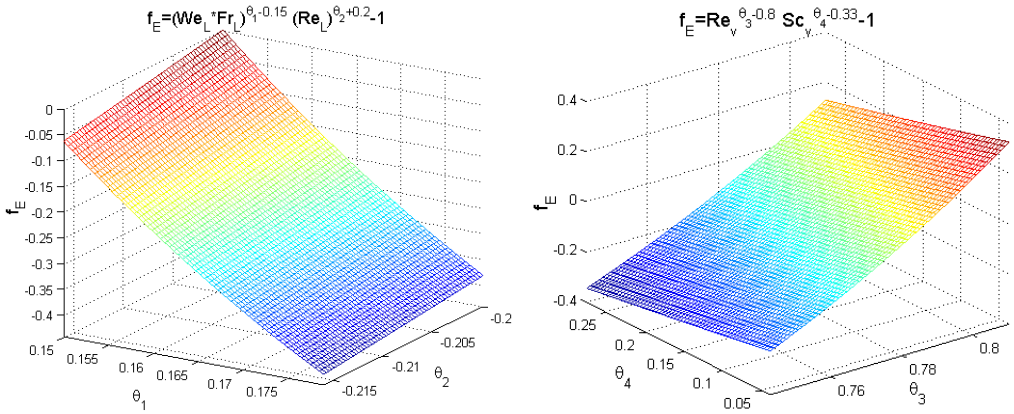

Fig. 2. Enhancement of transfer parameters (left: a_e, right: β_V)

Effective Interfacial Area. Compared with two-phase distillation, an obvious reduction of a_e is found. However, under low F-factor, f_E is only –5%, indicating Rocha correlation can be used for low-factor three-phase distillation; under high F-factor, f_E is about 30%-40%, indicating the unreliability of Rocha correlation. In these cases, the newly estimated flow-related parameters should be preferred.

3.2. Summary and Remarks

Rocha correlation has been adjusted for simulation of three-phase distillation. The updated parameters are summarized in table 4. To verify the benefit of using the adjusted correlation, a comparison of simulation (sim) results with another 48 experimental (exp) data is shown in Fig. 4. Obviously, the results using the adjusted correlation show much better prediction for light component n-Propanol and Butanol.

Table 4. An extension of Rocha correlation

	θ_1	θ_2	θ_3	θ_4	θ_5	$[F_{SE}]$		
2-phase	0.15	0.20	0.80	0.33	0.50	Super-ring 0.3	Montzpack B1-350	Rombopak 9M
3-phase	0.163	0.197	0.769	0.241	0.468	0.484	0.313	0.489

In a similar way, Shi & Mersmann correlation has been successfully adjusted. The results are listed in table 5. The adjusted parameters for Billet & Schultes correlation are summarized in table 6.

Table 5. An extension of Shi & Mersmann correlation

	θ_1	θ_2	θ_3	θ_4	θ_5	θ_6	$[K_V, m]$		
2-phase	0.40	0.20	0.15	0.67	0.33	0.17	Super-ring 0.3	Montzpack B1-350	Rombopak 9M
3-phase	0.417	0.199	0.149	0.651	0.111	0.165	[0.441,159]	[0.422,145]	[0.473,166]

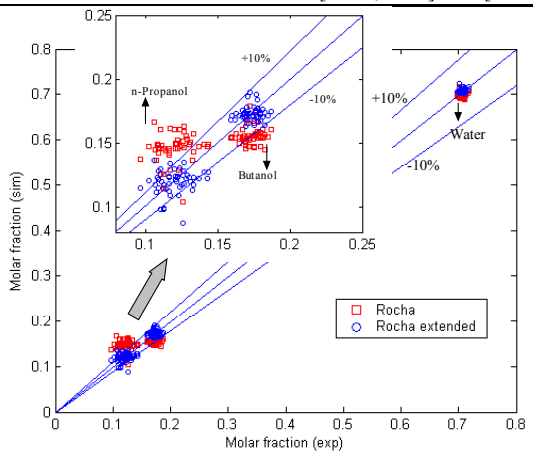

Fig. 4. Comparison of simulated and experimental results for vapor molar fraction

4. Conclusion

A hierarchical methodology is proposed in this paper to extend the transfer correlations for three-phase mass transfer calculation. A set of parameters used in the correlation is re-estimated based on our comprehensive experimental research on both two-phase and three-phase distillations in packed column. Three most widely used correlations, (i.e. Rocha correlation, Shi & Mersmann correlation, Billet & Schultes correlation), are adjusted. Substantial improvements on the NEQ model prediction have been observed.

Abstract

A production optimization problem concerned with the water removal in the press section in a paper machine is considered in the present paper. The proposed model seeks to determine the planning of production of paper in order to minimize a cost function that consists of replacement of the felts in the press section, cost of energy to operate the press and cost of energy in the drying section. The proposed model corresponds a mixed-integer nonlinear programming (MINLP) where the most important decisions in the paper machine are: a) the sequence of paper to produce, or when to produce the paper, b) the need to exchange the felts, and c) when to exchange the felts. Numerical examples are presented to illustrate the performance of the model. This work was developed considering a real case with data from a Brazilian paper plant.

Keywords: Optimization, Schedule, GAMS, MINLP

1. Introduction

With increased interest in optimizing parts of paper machines in recent years, there has been much work addressing to solve those problems. Most of the works that has been reported have focused in optimizing different parts in a paper producing mill, for example in paper-converting Westerlund et al (1980). Also, several authors have studied water removal in the press section, and we can find references using as a basis pressing defined for one nip of vertical flow Wahlstrom (1960). Different models and mathematical models for that part of paper machine are reported in Kerekes et al (1991). The process for the manufacture of paper is common to any plant, initially preparing the mass of the paper, following the formation sector, going to the press section for water removal the web of paper, and finally going to the drying sector for drying the web with hot air. In a paper machine, specifically in the press section, we have two important parts, the felts whose function is to carry the wet web through the press nip Farouk (1991) and the nip which is the zone of contact between two rolls, where the water is transferred from the web to the felt. In the press section, which is the object of study of this work, the average life of a felt is different, depending on the type of the felt, but in general it is around 35-45 days. We consider in this work the press section, which is an important part of the machine, affecting the properties of the paper, as well as having an impact on the final cost of manufacture. Low efficiency of this section causes difficulties like reduction of the tensile strength, increase in the steam consumption in the drying section of the machine, and in many cases, the reduction of the productivity due to reduction of the speed of the machine. A reduction of 1% of humidity in the leaf results in a reduction of steam consumption in the order of 4.5%. This work described in

this paper has the novelty of minimizing the replacement of the felts, by using an optimal sequence of paper production, in order to improve the water removal in press section. The model for optimizing the press section has as an objective to obtain better sequence of production of the reels, aiming at the increasing the water removal for the press section.

2. Press section

The sector of press in a paper machine is responsible for the removal of approximately 18 20% of water of the sheet of paper, this represents about 12% of the total cost of water removal in the machine. The biggest amount of water that can be removed of the paper, before this enters in the drying sector represents a great economy, since the sector of responsible drying and for 78% of the cost of water removal in the sheet of paper. Its main function, then, is to remove the maximum amount of water contained in the paper for half mechanics. The humid prensagem is based on the compression mechanics of the leaf and paper, in contact with felt between two coils, combined with the suction of the water for the inferior coil. Bigger removal determines efficiency of the section better, leading in account the economic aspect of the operation and the final quality of the production. The way with that the felt and the leaf enter in the NIP (contact zone enters the coils) of prensagem, both load obtain a restrained water film for the superficial tension of its respective structures fibrosa. The water extration in the press is folloied by a compression of the leaf, in the ticket between the two coils. The prensagem directly is related with, the applied pressures, the width or area of the NIP which is submitted to the compression, the time of permanence under pressure of the leaf on the felts and the capacity of retention and water conduction for the felts.

3. Model

First of all we divide the programming for "reels in the end of the process", independently of the time of processing of each one. Since in this work we do not assume unexpected changes or a plant recess for unexpected problems in the felts, the total time T is exactly independently of the processing order. However, the final humidity of each processed reel depends on the one that was dried before, which influences the felt used for drying. We define the binary variable for production of the reels as follows:

$$x_{ik} = \begin{cases} 1 & \text{for roll } i \text{ process in interval } k \\ 0 & \text{otherwise} \end{cases} \tag{01}$$

The following constraints them hold: each reel (or group of reels) can only be processed in one time interval; each time interval can only process one reel at a time (or group of reels). These assignment constraints are, given by:

$$\sum_{k=1}^{N} x_{ik} = 1 \qquad i = 1,\ldots,N \tag{02}$$

$$\sum_{i=1}^{N} x_{ik} = 1 \qquad k = 1,\ldots,N \tag{03}$$

Considering that at the beginning of the production all the felts are new, we define the binary variable y_{jk} for representing potential replacement of a felt in position *j* at the beginning at interval *k*. Each position is one of the press machines (there are four of them). We then define the binary variable for exchanges of felts as follows:

$$y_{jk} = \begin{cases} 1 & \text{if the felt in position } j \text{ was changed at the begining of interval } k \\ 0 & \text{otherwise} \end{cases}$$

Since the production starts with new felts (at the beginning of interval $k = 1$):

$$y_{j1} = 1 \qquad j = 1,2,3,4 \tag{04}$$

In this model, the objective function includes the cost of new felts, the cost of energy in the press section, and the cost of energy in the drying section. Since we are using a fixed total time horizon, the objective function uses the mass of water removed from the reels in the drying section at each interval k, m_k, and not the mass flow rate, $\dot{m}_k$.

The objective function is then given by:

$$\min z = \sum_{k=1}^{N}\sum_{j=1}^{4} CF_j \cdot y_{jk} + \sum_{k=1}^{N}\sum_{i=1}^{N} CP_{ik} \cdot x_{ik} + \sum_{k=1}^{N} cs_k \cdot m_k \tag{05}$$

The first two terms in the right hand side of Equation (05) are linear. The most complicated term is the last one. The model was then rearranged as follows:

$$\min z = \sum_{k=1}^{N}\sum_{j=1}^{4} CF_j \cdot y_{jk} + \sum_{k=1}^{N}\sum_{i=1}^{N} CP_{i,k} \cdot x_{ik} + \sum_{k=1}^{N}\sum_{i=1}^{N} CS_{ik} \cdot ma_{ik} - \sum_{k=1}^{N}\sum_{i=1}^{N} CS_{ik} \cdot U_i^s \cdot A_i \cdot x \tag{06}$$

Subject to restrictions (02)-(03) and to:

$$t_k = \sum_{i=1}^{N} T_i \cdot x_{ik} \tag{07}$$

$$\bar{\tau}_{jk} = \theta_{jk} + 0.5 \cdot t_k \tag{08}$$

$$\tau_{jk} = \theta_{jk} + t_k \qquad k = 1,\ldots,N \tag{09}$$

$$\theta_{jk} = \tau_{j,k-1}^{(2)} \tag{10}$$

$$\tau_{j,k-1} = \tau_{j,k-1}^{(1)} + \tau_{j,k-1}^{(2)} \tag{11}$$

$$0 \le \tau_{j,k-1}^{(1)} \le M_1 \cdot y_{jk} \tag{12}$$

$$0 \le \tau_{j,k-1}^{(2)} \le M_1 \cdot \left(1 - y_{jk}\right) \tag{13}$$

$$v_k = \sum_{i=1}^{N} \left(\ln\left(U_i^e \cdot A_i\right)\right) \cdot x_{ik} - \sum_{j=1}^{4} \ln\left(1 + \exp\left(u_{jk}\right)\right) \tag{14}$$

$$u_{jk} = \sum_{i=1}^{N} \left(\ln \lambda_{ij}\right) \cdot x_{ik} - \alpha_j \cdot \bar{\tau}_{jk} + \ln \xi_{0,j} - \ln\left(1 - \left(1 - \xi_{0,j}\right) \cdot \exp\left(-\alpha_j \cdot \bar{\tau}_{jk}\right)\right) \quad (15)$$

$$ma_{ik} = m_{ik}^{(1)} \quad (16)$$

$$m_{ik}^{(1)} + m_{ik}^{(2)} = \exp\left(v_k\right) \quad (17)$$

$$0 \le m_{ik}^{(1)} \le M_2 \cdot x_{ik} \quad (18)$$

$$0 \le m_{ik}^{(2)} \le M_2 \cdot \left(1 - x_{ik}\right) \quad (19)$$

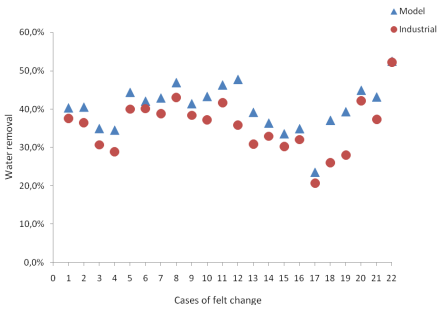
$$v_k \ge \sum_{i=1}^{N} \left(\ln\left(U_i^s \cdot A_i\right)\right) \cdot x_{ik} \quad (20)$$

The MINLP model is then formulated as the minimization of the objective function given by equation (06), subject to the constraints given by equations (02) - (03), and (07)-(20).

4. Results

4.1. Water removal

The challenge faced by the proposed mathematical model was the reduction in the replacement of felts through the selection at an optimal sequence of the reel production, in this way increasing the water removal in the press section and thereby reducing the cost of energy in the drying sector. This represents an annual increase of the order of 5% in the water removal, which is a significant result.



4.2. Cost reduction

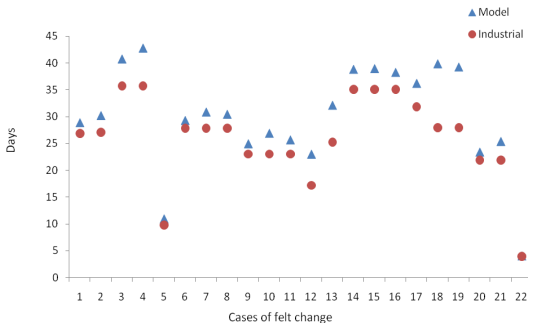
From the results we can also see a clear total cost reduction in the operation of the plant, the total cost was reduced by 4%. Some costs have not changed, like the costs in the press reduction, but the cost reduction in the drying section and the lower cost in the replacement of felts were the main reason for the total cost reduction.

Table 1: Costs for the optimized problem and the industrial case study

Cost	Model	Industrial
Felts	US$ 5,178,960.03	US$ 5,833,774.48
Press	US$ 16,420.31	US$ 16,420.31
Drying	US$ 23,538,536.13	US$ 24,082,059.66
Total	US$ 28,733,917.03	US$ 29,932,254.45

4.3. Felt lifetime and replacement

The lifetime of the felts can also have a significant impact on the cost. The main issue in the replacement of the felts is to find a point where they can stay in the machine without losing much their capacity of absorption. Through the proposed model, we obtained an average increase of 15% in the useful life of the felt, using the optimal sequence predicted from the mathematical model. Hence, besides the increase of the water removal, we can have an increase of the useful life of the felt. And about felts replacement, we obtained a reduction of 46% in average in the reduction of exchange of the felts, clearly due to the increase of lifetime of the felts, because we have fewer replacements of felts in the machine.



6. Conclusions

The optimization to reduce costs and replacement of the felts were considered in the present paper. An MINLP model has been proposed to determine the replacement of felts in the press section in a paper machine. It was shown that the problem could be efficiently solved yielding better results. The improvement obtained for a case study with 22 cases of the felt resulted in a 5% increase in water removal, 15% increase in felt lifetime and 4% reduction in the total cost.

Nomenclature

Sets

i reel

j felt

k interval

Variables

m_k amount of water in the entrance of the press section

ma_{ik} mass of water in the exit of pressing of the reel i in interval k

t_k time of interval k

u_{jk} auxiliary variable for the extraction coefficient of water in pressing

v_k auxiliary variable for water in the exit of the pressing in interval k

x_{ik} reel i processed in interval k

y_{jk} felt in press j exchange in initial time k

τ_{jk} time of life of the felt *j* in interval k

$\overline{\tau}_{jk}$ average of the time of the felt *j* in interval k

θ_{jk} initial time of the felt *j* in interval k

Parameters

A_i total area of the processed reels

CS_{ik} steam cost in the drying section ($/mass of water) in interval k

CF_j cost of buy/change ($/felt)

CP_{ik} energy cost expense in the press section of i ($/reel) in the interval k

M_1 big number (time)

M_2 big number (mass of water)

T_i time to process reel i

U_i^e humidity of the paper in the entrance of the press section (mass of water/area)

U_i^s humidity of the paper in the exit of the drying sector (mass of water/area)

α_j coefficient of reduction of the useful life of the felt

λ_{ij} extraction factor of the new felt j with reel i paper

$\xi_{0,j}$ volumetric fraction of fiber in the new felt j

Abstract

The minimization of the use of water source and, therefore, the reduction of effluent generation, has been an increasing concern in the chemical industry. Because of that, heuristical algorithms have been developed trying to supply systemic approach to the mass transfer network optimization`s problem. The main objective of these heuristical algorithms is to get a mass transfer network [1], where contaminants of rich streams are transferred to other poor streams, in an optimized structure of linked mass transfer operations. This optimization is measured in terms of pure or low concentration water source consumption, in relation to a structure in which only these sources are used. In this network, the streams have a maximum inlet and outlet concentrations to be respected, which characterizes mathematical restrictions in an optimization context. These restrictions make the best solution attainment difficult. A distinguished method to attainment mass transfer networks is the Water Source Diagram (WSD). This method uses hand calculations being, particularly, a useful tool for processes engineers. From WSD, it is possible to consider a variety of situations as reuse, multiple water sources, loss of water throughout the process, outflow restrictions, regeneration and recycle [2]. The WSD has resulted satisfactory solutions for the single contaminant case [2]. For the multi-contaminant one, a similar approach increased of the mass transfer ratio concept has been proposal. This approach was used in some simple cases [2], revealing it satisfactory. However, its application is still necessary in complex cases to prove the method`s robustness and efficiency. The aim of the present work is to apply the Water Sources Diagram methodology, as well as a proposal variation, in multiples contaminants and multiple water sources problems, to compare its results with more complex approaches presented in literature. As a base case it was used the solution proposed by Jin-Kuk Kim [3] to the problem proposed by Alva-Argaez[4]. The results obtained from WSD methodology was about 1% higher than base case in terms of mass flow used and about 5% in terms of costs. Considering the difference in complexity between the methodology used in the base case and the one presented in this study, we can concluded that WSD generate satisfactory results with less work, becoming very useful to problems that requires fast solutions and as a initial estimation in more complex ones.

Keywords: minimization, water source diagram, mass balance network.

1. Introduction

The sources of water usage minimization implies in a change of attitude when industries have to carry out how much effluent is treated. Typically, the "end of pipe" approach is used in new processes project. The concern is focused only in the treatment of generated flow lines, however the global concern with the conscientious use of the sources and the search for more economic processes has modified the profile performance of industries as for the use and treatment of the water used in processes.

1.1. Heuristical Algorithms

The main objective of the heuristical algorithms is getting mass transfer networks[1], where series of rich contaminants lines are transferred to another poor lines series, in an optimized structure of linked operations of mass transfer. This optimization is measured in terms of the source of pure water consumption, or low concentration water source, comparing with a structure in which only clean sources are used. In this network, the maximum concentrations of entrance and exit lines have to be respected. In the optimization method context, they figure mathematical restrictions. These restrictions make the process to find the optimal solution a harder work.

1.2. Water Source Diagram(WSD)

The Water Source Diagram is a simple methods that brings acceptables solutions and it can be applied where water is treated and supplied. This method uses simple calculations that can be carried through manually, being a particularly useful tool for engineers of processes. From the WSD, it is possible to consider a variety of situations as reuse, multiple water sources, loss of water throughout the process, restrictions of outflow, regeneration and recycle [2].

1.3. Multiple Contaminants Problem

The WSD has resulted satisfactory for the case of exists only one contaminant [2]. In case of multiple contaminants, there is a similar approach, however with additional systematic concept as "mass transfer ratio", has been proposal. This method was used in some simple cases [4], showing also satisfactory. However, it is still necessary apply it in more complex cases so that its robustness and efficiency can be proven.

In this context, Jin-Kuk Kim et al. [3] had studied a multiple contaminants system composed by ten mass transfer operations, four contaminants and two different sources of water. In this study, not only the mass integration and minimization of the water use had been studied, as well as the energy integration and the minimization of the use of hot and cold utilities. In this context, the model could be formulated through non- linear entire mixing programming, it has being used in such a way, an adequate but complex strategy of optimization. In this process, two basic cases had been studied: one considering the possibility of mixing lines at the end of the mass transfer operations (BASE1) and another, with direct thermal exchange between lines (BASE2), otherwise, the mixture of these lines for temperature adjustment is not allowed. These situations still had been compared with a base case where the *pinch* methodology for mass and energy were applied(BASE3).

2. Problem Description

The problem studied in this work contains ten operations of mass transf, four contaminants, respectively called contaminant A, B, C and D, and two water sources. The first source (Source A) contains null concentration of the four contaminants, the first source is constituted of pure water. The second source contains a few and equalized amount of all contaminants. In this, each contaminant is present in equal amount of ten

parts per million (Source B -10 ppm). There costs are respectively 0,5 and 0,1 $/ton. Jin-Kuk Kim [3] shows the the range of concentrations of each operation, hence called opportunity table.

3. Applied Solutions

They had been elaborated at all four distinct solutions for the problem; two using methodology WSD for current multiple contaminants (WSD -MC1 and WSD -MC2), one using analysis for inspection (IA) and the fourth implementing a modified WSD methodology (WSDR-MC). It is assumed that each mass transfer operation has a constant load removal of contaminants. The opportunity table represents the information of entrance for the models of synthesis of mass transfer networks. For the developed heuristical methods, a detailed analysis of the opportunity table becomes necessary. In this process, each choice can influence directly in the final result, where the flowcharts are generated from the interconnections of the operations. As premise is assumed, that there is no possibilities of incorporation of regenerators that could reduce the concentration of contaminants supplying new sources. The opportunity table can be rearranged of graphical to visualize all the intervals and opportunities at reusing lines as flow. A schematic graphic is built as a stair structure representing all the operations and components commanded in the possible intervals of concentration. An important propertie that can be observed is the monotonically, where the order is guaranteed according to the sequence of operations. The sequence follows the increasing of concentration of entrance and exit. In this way, a selection of the operations becomes necessary that can promote this monotonically.

The first rule for the selection of the operations involves the choice of a reference component. In this work, it was chosen as reference that one that after the ordinance and the exclusion of the operations that violate the monotonically, presents the biggest involved operation number. In case of same operation number, other criteria of sattle of matter had been considered, as outflow, levels of concentration etc. This increases the possibilities to occur a bigger integration between the involved operations. Table 3 illustrates, for each contaminant, the sequence operations capable to take care of the monotonically criteria.

Table 1. Sequence of the operations that guarantee of monotonically for component

COMPONENT	OP.SEQUENCE	NUMBER OF OPERATION.
A	10,8,3,2,4 10,9,3,2,4 10,9,7,5,6	5
B	10,7,8,4,5,6/2 10,9,3,4,5,6/2	6
C	10,8,4,2/5/9	4
D	**10,6,4,2,8,7,1**	**7**

It's necessary to choose one contaminant as reference, initially it is the D that presents 7 commanded operations. So far they had not been considered in the heuristic, factors as the outflow, that can make impracticable a flowchart on account of the low one reuses.

Selected the reference component, the second stage is the choice of the reference operatio. The reference operation must be that one that contains the lesser concentrations of entrance and exit, and that it has reuse potential in all the other

operations, in other words, it is the first operation of the described order previously. The reference operation is the code 10. Therefore, component D as reference and operations 10 and 6 will be developed two proposals of solution using.

Only evaluating the operations that will go to be integrated by the diagram. All the operations limits should be adjusted based on the reference operation. The mass transfer ratios are calculated considering the ratio between the differences in each operation and in the reference operation, for each component. But, adjusting the inlet concentration, the denominator is given by the differential of reference component's concentration, in the reference operation, whereas, in the outlet adjustment of concentration, the denominator is defined by the delta of reference component´s concentration in the operation that is being shift. In the calculation of displacement what he looks himself it is the concentration of the component of reference in the evaluated operation. For in such a way, use of the equation becomes:

Equation 1. Calculation of the concentrations shift of the reference component in the reference operation

$$C_{XR}^{Op} = \frac{(Cf_X^{Op} - Ci_X^{Op})}{\Delta ad} + Cad_{XR}^{Op}$$

Where:

Δad Delta (ton) to be defined. It is 1(one), in case of beeing calculated the inlet flowrate, and 2(two) when based on outlet concentration.

Cad Concentration (ppm), to be defined. It is the same as the used source in the reference operation, or the same as the inlet shift concentration, to get the shift outlet.

After the calculation of the shifts concentration for each operations that limit the possibility of reusing the reference operation., the procedure considered for Pessoa et al[5] for an only contaminant is executed. In this procedure, it is calculated in each interval, how much it must be transferred of water to the lines, having itself in sight the available sources, and prioritizing the reuse of the bigger concentration sources.

4. Results and Discussion

From the results obtained it was easy observed that appear situations in which is much more advantageous to use a clean source instead of reuse some dirty line, and cause a forward necessity of dilution, because of the components constraint. In this context, the methodology presented in the WSD-MC differs from the simple ones for the proposal of a new heuristic. This would come to answer the following question: "Which is it more advantageous to directly use water sources in the operation or a forward dilution for concentration adjustment ?". This advantage is translated by the amount of water to be used in the two situations. This rule comes to supply the lack of method WSD-MC evaluating the concentrations of all the components. Thus, the following definitions are necessary:

Operation source: Operation that, the principle, has available water for allocation;

White operation: Operation that, the principle, can be white of a water allocation;

Critical concentration Difference: It is the biggest difference of concentration, amongst all the contaminants (except the one of reference) enters the concentration of exit of the operation source and the concentration of entrance of the white operation;

Critical component: Component that supplies the concentrations of the difference of critical concentration.

Performing a simple mass balance, it is possible to determine which operation should be done, checking the lower final consumption. The entire permitted transfer match should be tried in pairs, but it is not necessary try all the matches, because the monotonically is guaranteed. The tables presented below (Table 2) shows the results for each applied solutions, considering respectively the sources flow rates and costs associates.

Table 2. Source flow rate consumption and respective costs

	FLOWRATE (ton/h)						
	BASE1	**BASE2**	**BASE3**	**WSD-MC1**	**WSD -MC2**	**AI**	**WSDR -MC**
SOURCE 0 ppm	432,46	432,46	432,46	478,30	432,10	431,20	464,36
SOURCE 10 ppm	178,86	179,05	179,54	138,81	8463,66	186,67	155,43
TOTAL	611,32	611,51	612,00	617,11	8895,76	617,87	619,79
COST ($/year)							
RELATIVE COST (%)	100,00%	100,01%	100,03%	453,80%	108,08%	100,06%	105,81%

It can be observed that the base cases continue to have less cost. A great discrepancy between solution WSD-MC1 and the cases is also observed. Moreover, the solution evaluated by inspection (AI) presented best results amongst the news evaluated. However, considering a systemic approach of reproducibility, the solution WSDR-MC appeared as the most interesting. Getting the best results in the family of WSD solutions.

Concerning the previously sections explains, to maintain the monotonically is an extremely important factor for the applied method WSD with multiple contaminants. Its application is associated with the use of the reference component concept, that turn its great responsible for the simplicity of the method. The proposal of the WSD -MC include the selection of an adjusted reference component, setting up the mass transfer correlations of other components, it is possible to find an optimal network with an analogous procedure to the WSD for simple contaminants. The unique constraint regarding the simple contaminant method is the guarantee a monotonic sequence of operation However, the results obtained from solutions 1 and 2 (WSD-MC1 and 2) evidence that considering only one reference compound, omitting the other concentrations constraints, takes the solution to a non-minimum water allocation. Analyzing just mass transfer correlations takes, in both solutions, the necessity of dilution in operational lines to close mass balance and follow the inlet and outlet concentrations constraint.The method does not ponder the better water relocation, to use a clean source or reuse some another outline. The method WSDR-MC brings up this concept and takes in consideration the advantageous possibility of directly water source allocation in the operations. Through the insertion of the concept of critical concentration difference it is possible to calculate the amount of used water source to dilute a possible reused line and compare it within the amount of source spends directly in the operation. This proposal heuristic complement the method WSD-MC prevents the necessity of water source usage for simple dilution at the end the built network, to close mass balance.

The solution obtained for inspection analysis, although it has the best result amongst the solutions carried through in this study, it is not acceptable as a reasonable process to find it out, because of it is not based in a systematic approach, and can`t be replied for other problems.

5. Conclusion

From the study presented it can be concluded that the use of the heuristic presented in solution WSDR-MC keeps the simplicity of the Water Sources Diagram method and presents a superior lightly result. In addition, it prevents the dilution after the set up of the network operation connections. Although these method`s results do not surpass the base cases, its simplicity and the small difference within the cited results, it guarantees a great applicability in optimization chemical processes. A detailed WSDR-MC method should be developed and it shows promissory..

Abstract

Sugar and alcohol market are increasing, due humanity needs to find alternatives for fossil fuels dependence. Brazil joins climactic and technologic features to place itself at the forefront of this industry. Sugar-alcohol industry is professionalizing and rising portfolio of product and the electric energy became an important product of these new ones. In this context, an increase in energy efficiency and actions to maximize this product shows it essential for these sites become competitive and reach their goals. Visual Mesa is a process on-line analysis tool to support decisions on energy reduction costs. This work describes how Soteica and Usaçúcar teams have modeled the site and implemented this new way to evaluate energy on this kind of industry. A full model of the energy system has been developed. All the constraints have been included and the model is continually being updated with live data. Performance monitoring was done and it includes the tracking of equipment efficiencies by utilizing updated data for its continuous calculation. By auditing the energy system, imbalances can be identified and reduced. Planning for a better operation of the energy system by performing case studies is usually done by using the validated model. As a result of the project, new sensors have been installed and a completely new way to evaluate energy on the site was implemented.

Keywords: sugar and alcohol industry, on-line energy analysis software, electric energy.

1. Introduction

In the last 30 years it was become clear that here are humanity concerns about the scarcity of fossil fuel supplements. It gets worse with the growth of the worldwide consumption and the geopolitics changes of the period.
This scenery intensified the humanity needs of a substitution of the energetic matrix, based on the oil, by a renewable, less pollutant and that cut down the carbon emission on the atmosphere.
Sugar and alcohol market are in constant expansion and it shows as an alternative to Brazil dependence of oil.
Brazil has the suitable climatic and technologic features to the development of an industry that produces a clean fuel, according to this new order and that stand on the leadership of the sector, as we can notice nowadays.

To maintain this leadership, sugar-alcohol industries are focusing in process optimization and costs reduction and one of the most important points of optimization is energy balance as described in the work of Sartori et al (2007), who developed a mathematical model to improve industries profits and better use of energy potential.
On this change of scenery, the sugar and alcohol industry has also been changing and improving its portfolio and adding new products, as a sale of electric energy to the energy supply network and carbon credits appear as a promising market in the next 20 years in Brazil as described by La Rovere et al (1994).
The alcohol and industry engagement on the electric energy production is very important to maintain the supply and increase the fraction of energy produced (in %) by sustainable process. Lora et al (2007) shows that it is an innovation in Brazilian market that was supported by the government and electricity companies and achieve d approximately 4,4 % of the total electric energy amount generated and this participation is growing.
The energy comes from the steam generated in the boilers that burn sugar cane bagasse from the milling process.
For the sugar and alcohol industry carries on producing energy and it is economically suitable, the energy balance must be monitored and improved.
To achieve this goal, Soteica used its on-line energy management system, Visual Mesa, which is the worldwide market leader on petrochemical sector to supervise and optimize the energetic balance in the sugar and alcohol industry.
The work of Ruiz et al (2005) describes how this tool is being used successfully around the world to optimize Energy Systems in petrochemical industries.
This is the first time that a tool for on-line management system is used to manage energy balance in real time on the sugar and alcohol market.
Soteica and Usaçúcar join their teams to develop a model for an industrial plant that produced sugar, alcohol and electric energy.
This work consists of experiences exchanged between the teams, one that knows about energy management and the other that knows about sugar-alcohol production technologies.

2. Project objectives

The main objective of the project was to have a tool available for the on line optimization, auditing and monitoring of the energy system of Tapejara Plant.
The secondary objective is to gain knowledge, develop a methodology and mapping the difficulties on the implementation of this kind of software in sugar-alcohol industries.

3. Usaçúcar Company

Usaçúcar is a company with about 50 years of experience in sugar and alcohol production and today at the forefront sector in the State of Paraná, where it is located in Brazil.
In Usaçúcar Group there are also trading companies and a distribution center at Paranaguá's Port, where the production is exported to many countries, mainly to Asia.
In the productive arm of company it has 7 productive units distributed in the North of Paraná State, in Brazil. Two of these productive units have alcohol as unique product and others units work with sugar too.
As the entire sugar-alcohol sector in Brazil, Usaçúcar is booming and improving its portfolio and one of those new products is the electric energy.

This improvement on the portfolio took optimization focus to the plants energy balance and how to achieve contracts and product specification, producing energy to export.
Nowadays Usaçúcar Group has two plants that are producing electric energy and selling to distribution companies. One of them was chosen to place the first implementation of a real time on line energy management system in sugar and alcohol industry.

4. Tapejara Plant

The plant chosen for the implementation was the Tapejara Plant. This plant has a capacity to process about 19,5 kt of sugar cane per day and produces 62.000 m^3 of alcohol and 316 kt of sugar each season. It is the largest productive plant of Usaçúcar Group.
Based on these numbers and in the expectation of higher profits, Tapejara Plant was chosen for the first implementation.
The layout can be organized in 7 sectors. A similar division was used in model building.

- **Steam generation:** This sector has two boilers that burn sugar cane bagasse and produce superheated steam with pressure of 65 bar and a temperature of 400 °C.
  Boiler 3 can produce 100 t/h of steam and Boiler 4 produces 300 t/h of steam. Boiler 4 is the biggest biomass boiler operating in the world.
  All steam produced here feed electric generator or is used in productive process.
- **Electric generation:** Electric generation sector has two generators that are fed with the superheated steam produced by the boilers, generates electric energy and reduces steam to 21 bar. The steam that was produced here will be used in the milling process.
- **Sugar cane preparation and milling:** This sector is a consumer of steam at 21 bar and it is used to operate machines that prepare and process the sugar cane to remove juice that will be used in other stages of production process.
- **Evaporators:** Tapejara Plant has two lines of evaporators, this equipment is used to concentrate sugar cane juice and specify the flow, raising the brix to about 65 °C.
  Evaporation is the plants energy core, because here is consumed steam at a high pressure and generates steam at a low pressure.
- **Crystallization:** Crystallization is a sector that consumes steam at a low pressure and the consumption depends on the amount of equipments that is on-line at each moment.
- **Distillation:** As with the crystallization, the distillation sector is a low pressure consumer and depends on the alcohol types that are produced.

5. Visual MESA

Visual MESA software was developed to work with global optimization of energy systems in an industrial plant and lead with its restrictions in order to bring the operation of system utilities for the lowest possible cost. It is a computer program designed to model steam, Boiler Feed Water, condensate, fuel, electrical systems and CO_2 emission costs.

It operates on-line with Plant Information System via standard OPC interface and it is also capable of dealing with historical data used in the optimization.
Visual MESA is installed for two types of use, the Stand Alone use and Client Server use:

- **Client Server use:** The purpose of this installations is to share the solutions, supporting multiple users. Visual MESA server runs as a service on a PC and gives solutions automatically with no interruption every 5 minutes, writing results on the plant information system and generating reports. With this architecture any PC connected to the plant network can be configured to access the model and the reports. So teams from operation to management, including engineering monitoring is able to evaluate and use the results supplied by the tool.
- **Stand Alone use:** The purpose of this installation is for individual users able to run cases studies on their own PC, using a snapshot of the current data or historical data. Data can be achieved automatically taken from the plant information system via standard OPC Historian Data Access. This kind of use also supports "What If" studies that are useful to assess revamps and changes in production schema.

In terms of optimization, Visual MESA has mathematical features and built-on optimization routines that make it possible to calculate how to the steam runs and electrical systems operate at a minimum overall cost while still meeting the required plant steam demands and other constraints.
The software determines which boilers or steam generators should make incremental steam and which turbines or letdown valves will most efficiently let the steam down between pressure levels. It uses a successive quadratic programming (SQP) optimizer, which is grouped into four levels:

- **Level 1:** includes the pressure control-related devices; boilers, letdown valves and vents are optimized to minimize cost.
- **Level 2:** adds the optimization of other continuous variables, including turbo generators and extraction/ induction/ condensing turbines.
- **Level 3:** adds turbine-motor switching optimization, like discrete variables.
- **Level 4:** optimizes variables that are potentially unsafe or affect process yield.

The program's objective function is able to optimize the total operating cost of the system, which is described in equation (1).

$$\text{Operating cost} = \text{total fuel cost} + \text{total electricity cost} + \text{inlet costs} \quad (1)$$

The SQP optimizer's job is to minimize this objective function, subject to operating constraints in the system. Total fuel cost is determined by the fuel use of each boiler and combustion turbine, multiplied by their respective fuel prices. Total electricity cost is determined by the electrical use of each motor, load and generator, multiplied by their respective electricity prices. The model takes into account the fact that electricity costs vary throughout the day.
Inlet costs normally include charges for demineralised water coming into the system, but can cover other arbitrary costs too.

6. Implementation Description

Soteica's teams in Brazil and Argentina in partnership have worked together with Usaçúcar – Tapejara Plant, Operations and Process teams, in the implementation project on the following activities:

- Layout analysis,
- Data collection,
- Linking of Visual Mesa to the Plant Information System,
- Build of Interface to the Historic Plant Information Data,
- Model building,
- Build on-line optimization,
- Model adherence analysis,
- Reports generation

The model built is the most important step of the implementation and is the basis for others steps.

It contemplates an overall and detailed description of the Energy System that includes bagasse stock, steam qualities, boilers, water, condensate, valves and electrical system.

Tapejara´s Plant was divided into 8 main areas on the Visual MESA model.

- **Steam generation:** that includes 2 boilers, one of them that produces 300 ton/h of superheated steam and the other produces 100 ton/h.
- **Reduction valves 67->21:** modeling of valves that reduce steam of 65 bar to 21 bar. That is a valve where condensate water is input in the steam and the pressure was reduced.
- **Reduction valves 21->1,5:** modeling of valves that reduce steam of 21 bar to 1,5 bar.
- **Electricity generation:** comprises two turbines to generate electricity to feed plants consume and exportation to energy supply network.
- **Sugar cane processing**: comprises turbines that move equipment of sugar cane preparation and milling. These equipments consume steam of 21 bar
- **Evaporators:** evaporation sector is composed by 2 evaporators lines, A and B. these lines consume steam of 1,5 bar and produce vegetable steam, that is the steam generated by sugar cane juice, of various levels of pressure below 1,5 bar that will feed distillation and crystallization sectors.
- **Crystallization:** modeled as a consumer of vegetable steam.
- **Distillation:** modeled as a consumer of vegetable steam as crystallization sector.

A main view of the models and the areas can be seen in Figure 1. By navigating through the model, each individual Unit of the system can be monitored in detail.

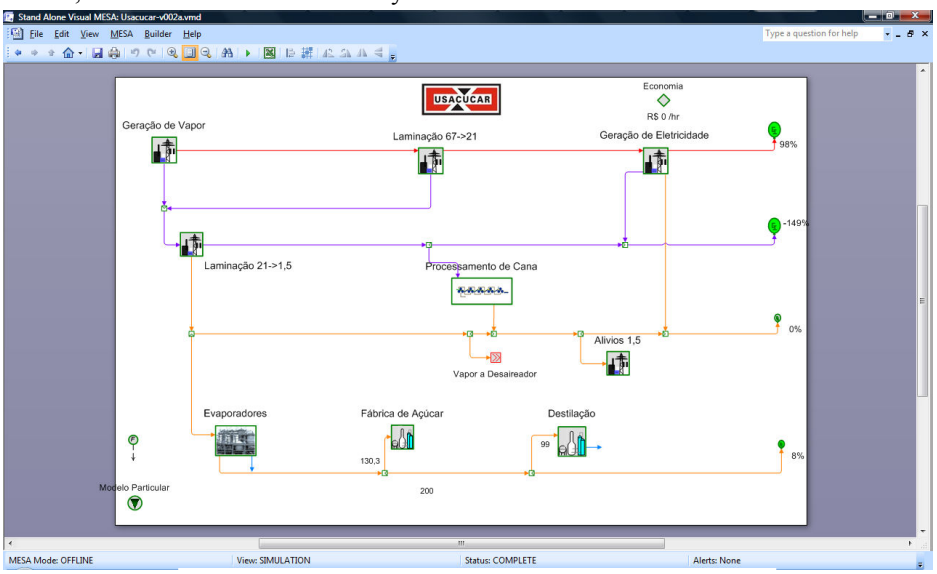

Figure 1: Main view of Tapejara Plant model

Electricity contracts and details of purchase and sale have been included in the model that made the model capable to evaluate energy trade.
Bagasse stock purchasing is modeled in order to manage the purchase of others Usaçúcar Group units and others companies too, focused on maximizing the production of electric energy.
During the implementation lacks of measurement was identified and programmed to be installed in the maintenance period.

7. Model adherence analysis

The model was run on-line under test conditions at the end of the 2008 season and obtained good results in adherence and ability to represent and optimize energy process.
First profits achieved in test phase are around 90,00 USD/h. Taking into account these profits and a season of 220 working days, it has estimated an annual profit of 475 kUSD.
The plant instrumentation will be improved on an annual maintenance and this work will give more data to the model, making the optimization more efficient and improving the reliability of the system.

8. Conclusions

The target was achieved, the model was built and the first implementation on sugar-alcohol industry was in course and presented initial results within the expected in terms of implementation time and costs.
With the implementation of new measurements, the model will be on-line in 2009 season and it will be the most important tool for monitoring and optimization of energy balance on Tapejara´s Plant.
This work will be used as a basis for new implementations of the software on others units in the Usaçúcar Group and others groups of the sugar-alcohol sector.

Abstract

Understanding the interaction between a fluid and a solid phase is of fundamental importance to design of an adsorption process. Because the heat effects associated with adsorption are comparatively large, the assumption of isothermal behaviour is a valid approximation only when uptake rates are relatively slow. In this article, we propose to determine when it is needed to choose the isothermal or non isothermal assumptions according to two physical parameters α (ratio convection/capacity) and β (ratio quantity of energy/capacity). The proposed problem was solved by a mathematical method in the Laplace domain.

Keywords: Adsorption, Non Isothermal, Energy, Pellet.

1. Introduction

A basic adsorption heat pump cycle consists of four main parts: an adsorber, which is a container filled with an adsorbent (such as zeolite, active carbon, silica gel, etc.); a condenser; an evaporator; and an expansion valve. Basically, adsorption heat pump operates by cycling adsorbate between adsorber, condenser, and evaporator. In the adsorption heat pump cycle, adsorption phenomena play the same role of mechanical power, so that the working fluid can be circulated in the cycle without any mechanical power (Demir et al., 2008).

In recent years, the importance of adsorption heat pumps and adsorption refrigeration systems has increased since these kinds of systems can directly utilize the primary thermal energy sources and additionally the waste heat generated in various industrial processes. The important advantages of the adsorption heat pumps can be described as follows (Demir et al., 2008):

- they can operate with thermal driving energy sources such as waste heat, solar, and geothermal energies, etc.;
- they can work with low temperature driving energy sources;
- they do not require moving parts for circulation of working fluid;
- they have long life time;
- they operate without noise and vibration;
- they have simple principle of working;
- they do not require frequent maintenance;

- they are environmental friendly since they do not contain any hazardous materials for environment; and
- they can be employed as thermal energy storage device.

On the contrary, the main disadvantages of the adsorption heat pump systems are as follows (Demir et al., 2008):

- they have low COP values;
- they are intermittently working principles;
- they require high technology and special designs to maintain high vacuum; and
- they have large volume and weight relative to traditional mechanical heat pump systems

AHPs are thermally driven and can, therefore, make use of waste heat as well as thermal renewable energy resources. Moreover, AHPs can utilize high energy fuels more effectively than modern condensing boiler heating systems and, consequently, a reasonable amount of the resulting environmental pollution could be avoided. One of the most interesting working pairs for AHPs is zeolite-water. This working pair is non-poisonous, non-flammable and, moreover, has no ozone depletion potential. The adsorption of water vapour into a porous solid adsorbent, such as zeolite, results in the release of the heat of adsorption. Accordingly, the temperature of the adsorbent particle rises, which reduces its water uptake capacity. Therefore, the heat of adsorption has to be removed before a further vapour mass transfer into the adsorbent particle may take place. The evaluation of the heat and mass transfer rates accompanying such an adsorption process is therefore a very important aspect in designing and optimizing the operation of an adsorption heat pump.

In this study, a methodology to choose a good adsorbent in particular according to its thermodynamic properties is presented. We focused our attention on the interaction fluid/solid. The simplest case to consider is a single microporous adsorbent particle exposed to a step change in sorbate concentration at the external surface of the particle at time zero. Heat transfer is assumed to be sufficiently rapid, relative to the sorption rate, so that temperature gradients both through the particle and between particle and surrounding fluid are negligible. Two cases were developed in this article, firstly the isothermal conditions and secondly adsorption behaviour with temperature effect. A mathematical development is presented for each case. According to two developed parameters α (ratio convection/capacity) and β (ratio quantity of energy/capacity), the difference between isothermal and non-isothermal was analysed.

2. Isothermal Assumptions

During adsorption, heat generated is partly transferred to the surrounding fluid and partly accumulated in the particle leading to an increase of the temperature. The calculation of the temperature uptake curves is based on mathematical model of different complexity depending on the simplifying assumptions being made. Since adsorption is exothermic and the heat of sorption must be dissipated by the heat transfer, there is, in general, a difference in temperature between an adsorbent particle and the ambient fluid when sorption is taking place. Whether or not this temperature difference is significant depends on the relative rates of mass and heat transfer. By the simple theoretical analysis it may be shown that in a batch adsorption experiment it is the

dissipation of heat from the external surface of the adsorbent sample, rather than the conduction of heat within the adsorbent, which is generally the rate limiting heat transfer process. The conditions under which heat transfer resistance may be neglected and the system treated as isothermal case.
Firstly, we considered some isothermal conditions in the pellet and the isotherm was $q = q_0$. The isotherm is supposed to relate the concentration q inside the pellet (or at the external boundary) to the concentration of the external fluid. Another basic assumption is that the pellet is treated as a homogenous medium (contact with the fluid occurs only at the external boundary). So, the diffusivity Dc is constant in the pellet.

The system was modeled by the following equations (1):

$$\begin{cases} \dfrac{\partial q}{\partial t} = D_c\left(\dfrac{\partial^2 q}{\partial r^2} + \dfrac{2}{r}\dfrac{\partial q}{\partial r}\right) & \forall t > 0, \forall r\ (0^+ < r < r_c) \qquad (1-a) \\ q(r, t=0) = q'_0 & \forall r\ (0^+ < r < r_c) \qquad (1-b) \\ q(r_c, t) = q_0 & \forall t > 0 \qquad (1-c) \\ \left.\dfrac{\partial q}{\partial r}\right|_{r=0^+} = 0 & \forall t > 0 \qquad (1-d) \end{cases}$$

The value $q(r_c,t)$ is equal to $q_0 \neq 0$, for solving the system analytically.
With $\tau = D_c t/r_c$, the analytic solution is given by the familiar expression

$$\frac{m_t}{m_\infty} = 1 - \frac{6}{\pi^2}\sum_{n=1}^{\infty}\frac{e^{-n^2\pi^2\tau}}{n^2} \qquad (2)$$

Where m_t represents the quantity adsorbed in the pellet at time t and m_∞ the quantity adsorbed in the pellet at final time. We denote $\overline{Q}(\tau) = m_t / m_\infty$. In practice m_t/m_∞ will be approximated by (Ruthven et al. 1980): $\overline{Q}_N(\tau) = 1 - \dfrac{6}{\pi^2}\sum_{n=1}^{N}\dfrac{e^{-n^2\pi^2\tau}}{n^2}$

Let us check by the following simple error estimation:

$$\begin{aligned} \left|\overline{Q}(\tau) - \overline{Q}_N(\tau)\right| &= \frac{6}{\pi^2}\sum_{n=N+1}^{\infty} e^{\frac{-n^2\pi^2\tau}{n^2}} \le \frac{6}{\pi^2}\sum_{n=N+1}^{\infty}\frac{1}{n^2} \\ &\le \frac{6}{\pi^2}\int_N^{\infty}\frac{dx}{x^2} = \frac{6}{\pi^2 N} \end{aligned} \qquad (3)$$

This inequality gives for $N=5$ an absolute error of approximately 0.12. But, notice that, in reality, the error is much smaller at least if τ stays away from zero. Indeed, if $\tau \ge \tau_0 \ge 0$, then the upper estimation can be improved to the following exponential error bound:

$$\left|\overline{Q}(\tau)-\overline{Q}_N(\tau)\right|=\frac{6}{\pi^2}\int_N^{\infty}\frac{e^{-n^2\pi^2\tau_0}}{x^2}dx\le\frac{3}{\pi^4\tau_0}\frac{e^{-N^2\pi^2\tau_0}}{N^3} \quad (4)$$

For example, if the reduced time is at least $\tau_0 = 0.01$ and if again $N = 5$ then we get for the absolute error a much better approximation of 0.000418.

3. Non Isothermal Assumptions

In this case, we assume that intracrystalline diffusion is the only significant resistance to the mass transfer. The sorbate concentration at the surface of each particle in the sample is therefore always in equilibrium, at the temperature of the sample with the sorbate concentration in the ambient fluid . In addition, the thermal conductivity is assumed to maintain an essentially uniform temperature throughout the entire adsorbent particle. The rate of heat transfer between the adsorbent and the ambient fluid which is assumed to obey Newton's law, was finite, so that during the course of the transient adsorption there was a time-dependent temperature difference between the adsorbent and ambient fluid. The system was subjected at time zero, to a small difference step change in ambient sorbate concentration from a previously established equilibrium condition. We assume that concentration equilibrium between fluid phase and adsorbed phase is established quickly at the free surface of the pellet and the equilibrium adsorbed phase concentration is assumed to vary linearly with both temperature and fluid phase concentration. Subject to these approximations, the system may be described by the following equation *(10)* in reduced value ($Q=q(t)/q\infty$), $\eta=r/r_c$ and $\tau=D_c t/r^2_c$).
In opposite to the previous part, the reduced value permitted to find an analytic solution in the Laplace domain.

$$\frac{\partial Q}{\partial\tau}=\frac{1}{\eta^2}\frac{\partial}{\partial\eta}\left(\eta^2\frac{\partial Q}{\partial\tau}\right) \quad (5\text{-a})$$

$$Q(\eta,\tau)=0,(\tau<0)\qquad Q(\eta,0^+)=0,(si0\le\eta<1) \quad (5\text{-b})$$

$$Q(1,\tau)=Qs(T) \quad (5\text{-c})$$

$$\left.\frac{\partial Q}{\partial\eta}\right|_{\eta=0}=0 \quad (5\text{-d})$$

$$\rho(-\Delta H)\frac{d\overline{Q}}{d\tau}=\frac{\rho Cp}{q_\infty-q_0}\frac{dT}{d\tau}+\frac{ha}{q_\infty-q_0}\frac{(T-T_0)}{D/r_c} \quad (5\text{-e})$$

The equilibrium relationship at the crystal surface is assumed to be linear with respect to both concentration and temperature:

$$Qs=1+\frac{\partial q^*}{\partial T}\left(\frac{T-T_0}{q_\infty-q_0}\right) \quad (5\text{-f})$$

The final result is similar to Ruthven(1984), and the mathematical discussion is described in L. Montastruc (2009) then:

$$\overline{Q}(\tau) = 1 + \sum_{n=1}^{\infty} \frac{-9\left(\frac{q_n \cot(q_n) - 1}{q_n^2}\right)^2 e^{-q_n^2 \tau}}{\frac{1}{\beta} + \frac{3}{2}\left[(q_n \cot(q_n))\left(\frac{(q_n \cot(q_n)) - 1}{q_n^2}\right) + 1\right]} \qquad q_n \in \Re \quad (6)$$

where q_n are the roots of the equation

$$\left(\alpha - q_n^2 - 3\beta\right)\sin(q_n) + 3\beta q_n \cos(q_n) = 0 \qquad (7)$$

With $\alpha = \frac{ha}{\rho Cp}\frac{r_c}{D}$ and $\beta = \frac{\Delta H}{Cp}\left(\frac{\partial q^*}{\partial T}\right)$

The parameters α and β were in a first approach variables used to solve the PDE system. These two parameters represent respectively the ratio between the conductivity and the heat capacity and the ratio between the quantity of energy and heat capacity.

4. Non Isothermal and Isothermal Comparison

In the non-isothermal model, the uptake curve commonly shows a rapid initial uptake followed by a slow approach to equilibrium because the external heat transfer controlled the adsorption. Let us recall that the isothermal model represents the ideal condition in the heat adsorption process.

In fact, in the isothermal case, the equilibrium was reached very quickly. The maximum difference between the two models is obtained in the first phase of the batch adsorption. This phenomenon is due to the fast temperature rising when the adsorption starts. The heat of adsorption produced in the pellet is not transferred into the fluid due to the external heat transfer. In the figure 1, different graphs represent the square distance between the adsorbed quantity with an isothermal model and a non isothermal assumption at different reduced time. To calculate, the N choice terms is 20, the α value is comprised between 0 to 40 and β between 0 to 10. If α is near zero and β is large, we observed that when the reduced time is lower that 0.25, the calculated errors increased with the reduced time. And when the reduced time is higher than 0.25, the calculated errors decreased.

To increase the process efficiency, it is necessary to raise the external heat transfer. It can be modified by the hydrodynamics around the pellet. The values of α and β can determine the "efficiency" of the heat adsorption process. In fact, if the β value is small and /or near to zero, the adsorption curve can be analyzed as in the isothermal case. But it means that the heat pump process cannot be operated because it will not produce enough heat. The α value is more significant, because it represents the ratio between the convection and the thermal capacity. To reach the ideal case, α should be very large. The external heat transfer will then not be a limiting phenomenon, and the adsorption is closed to the isothermal case.

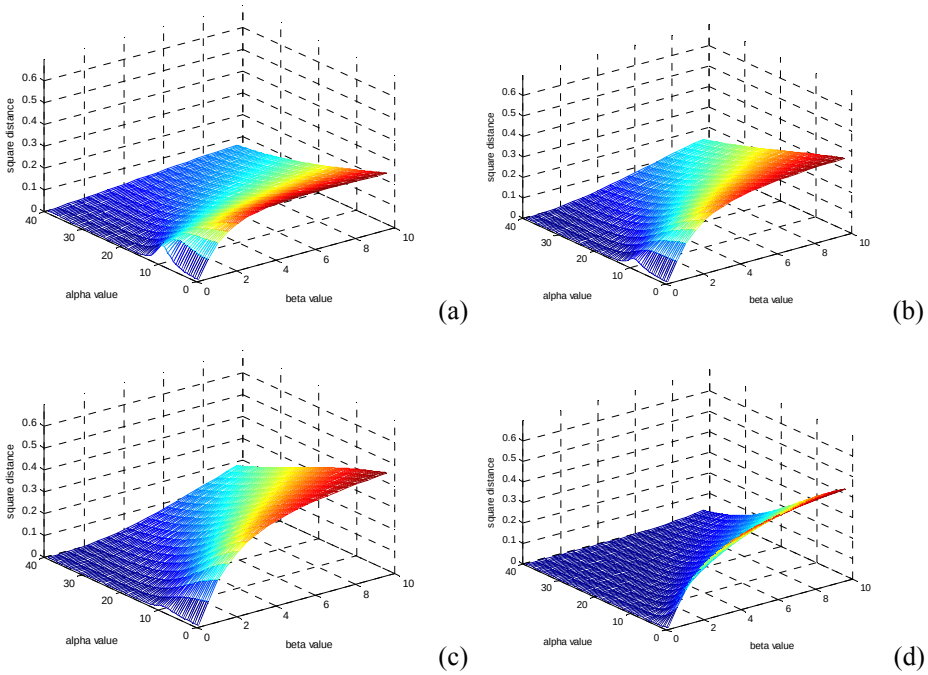

Figure 1. Square distance between the isothermal and the non isothermal model for different α value between 0 to 40 and for different β value between 0 to 10((a) reduced time = 0.01, (b) reduced time = 0.05, (c) reduced time = 0.1, (d) reduced time = 0.5)

5. Conclusion

In this article, we show the importance of the pellet adsorption study before designing a heat adsorption process. The difference between the two models - isothermal or non isothermal - could be measured by the value of two parameters α and β. In fact, when $\alpha \to \infty$ (infinitely high heat transfer coefficient) or $\beta \to 0$ (infinitely large heat capacity), the limiting case was isothermal. When diffusion was rapid (α small) the kinetics of sorption was controlled entirely by heat transfer. If the adsorption process might be used as a heat pump, it shall be represented by an isotherm model with α and β as higher as possible. Then, these two parameters could determine if the couple adsorbant/ adsorbate can be used in the case of an adsorption heat pump process.

Abstract

In this paper a software tool, which was called a Model Partitioning for Simulation and Optimization (MP4SO), is presented. It carries out the partitioning and solving of industrial-process models to be employed for simulation and optimization. It integrates GAMS' computational functionalities with the matrix-decomposition capabilities of the Direct Method. *MP4SO* was tested for the simulation and optimization of several industrial cases. The results show the advantages of using this partitioning-model approach in Process-Systems Engineering.

Keywords: Matrix Partitioning, Graph Theory, Simulation, Optimization, GAMS.

1. Introduction

The inherent complexity in the mathematical models employed for the simulation and optimization of industrial processes hinders their analysis and computational resolution tasks. A well-known strategy used to reduce the complexity of algebraic systems is their decomposition into simpler subsystems of equations [Duff *et al.*, 1986]. However, most of the methods based on this strategy are guided towards the resolution of square or lineal systems, thus limiting their application range. In particular, the simulation of industrial processes requires the mathematical resolution of square equation systems (non-singular systems), where the model contains the same number of equations and variables, being the solution that satisfies the system unique [Perkins, 1983]. On the other hand, optimization models are rectangular (singular), where the number of variables is greater than the number of equations, and they yield multiple possible solutions. It is important to stress that the models are strongly non-linear in both cases. These are the reasons why, if we wish to carry out a decomposition of these mathematical models, we need algorithms that allow us to work with square or rectangular models, with either linear or non-linear equations.

Recently, a new method for structural decomposition of equation systems for observability analysis was published. This algorithm, known as Direct Method (DM) [Ponzoni *et al.*, 2004], has characteristics that overcome the limitations presented by other decomposition algorithms. The DM, which is based on graph theory, carries out a structural reordering of the incidence matrix corresponding to the steady-state model of a process. This restructuring leads to a block-lower triangular form, which implicitly defines a block-decomposition and

the precedence order among blocks for the efficient resolution of the system of equations associated to the matrix. In contrast with other partitioning methods [Pothen & Fan, 1990; Gustavson, 1976; Madron, 1992, Duff & Reid, 1978], its main difference is that the DM allows the decomposition of both structurally singular and non-singular matrices. They may correspond to either linear or non-linear models. In this way, DM can be useful for the treatment of high-dimensional problems, as those that arise in process engineering. On the other hand, GAMS (General Algebraic Modeling System) [Brooke *et al.*, 2004] is a commercial equation-oriented tool for modeling, simulation and optimization of chemical processes. This software owns a great variety of mathematical solvers and it offers facilities to solve block subsystems, although it does not possess an integrated technique to carry out the decomposition. Then, it would be desirable to have a software that integrates the potentialities of the DM with the commercial software GAMS.
In this paper, we present a software called *MP4SO* (*Model Partitioning for Simulation and Optimization*), which is based on the equation-oriented strategy. *MP4SO* consists in a user-friendly tool that works in an interoperative way with GAMS, and bases its operation on the DM. The application of *MP4SO* to big problems facilitates overcoming the main disadvantages that the equation-oriented strategy naturally exhibits. Firstly, the partitioning of a complex system into subsystems achieves a decrease in the computational resources required to reach the solution. Secondly, the model partitioning facilitates the process analysis that should be carried out by the user. Some variables always have to be initialized for simulation or optimization studies. In these cases, this *MP4SO* feature allows an effective identification of the initial variables, by analyzing subsystems and their precedence order for the calculation. This feature is useful since the cumbersome procedure of initializing all the model variables through trial and error becomes easier.
In the next section, we present a brief description of the Direct Method as well as its integration with GAMS. Section 3 describes the *MP4SO*'s main components. Finally, in section 4 we present the performance analysis of the software and the general conclusions.

2. Using DM and GAMS for the simulation and optimization of industrial processes

A brief description of the DM is presented here. We also detail how the integration with GAMS was designed to use the capabilities of both tools so as to constitute *MP4SO*.

2.1. Decomposition of mathematical models using the Direct Method

The DM [Ponzoni et al., 2004] carries out a reordering of the structural incidence matrix corresponding to the steady-state model of a process, taking it to a block-lower triangular form. In a few words, this method is based on a graph-theory node classification technique similar to the one proposed by Dulmage-Mendelsohn[1963], but the reordering matrix pattern obtained by the DM is different and more suitable for our industrial application than Dulmage-Mendelsohn's method. In order to avoid a lengthy account, the main differences between both techniques as well as the DM algorithm are omitted here. Nevertheless, a detailed explanation about this topic can be found in Ponzoni et al. (2004).
The DM carries out a reordering of the structural incidence matrix corresponding to the steady-state model of a process, taking it to a lower-triangular block form. In this way, a subsystem decomposition is obtained, as well as a precedence order to carry out an efficient resolution of them. The technique constitutes a very robust and time-efficient matrix-partitioning approach. It is robust since it can be applied to any type of matrices, whatever their structural pattern, increasing their efficiency as problems grow in dimension and complexity. Therefore, it is possible to claim that this technique constitutes a solid foundation for the development of a methodology for the resolution of systems of

sparse non-linear equations. This reordering simplifies the resolution of the original system. Moreover, it is even applicable to rectangular systems.
The DM yields different kinds of variables according to the feasibility of their calculation:

- Observable variables: unmeasured variables that can be evaluated from the available measurements by using the equations.
- Unobservable variables: the remaining unmeasured variables.

Transferring this classification from the observability analysis to the mathematical resolution of models, observable variables are those calculated from the square blocks detected by the algorithm (simulation), while unobservable variables belong to rectangular blocks with more variables than equations (optimization).

2.2. Subsystem resolution using the Direct Method and GAMS
MP4SO is applied to solving simulation and optimization problems. Its operation is based on the application of the DM, followed by the resolution of the subsystems, by using some of the solvers provided by GAMS, which depend on the kind of problem to be solved. In a first step, the user feeds the mathematical model to *MP4SO*, by using GAMS notation. Then, the model is partitioned by means of the DM, thus obtaining a decomposition in subsystems and their resolution order. In a second stage, *MP4SO* invokes GAMS internally with the previously obtained decomposition. This invocation can be carried out for simulations (square systems) or optimizations (rectangular systems). Finally, the system is solved using built-in GAMS solvers, by carrying out the resolution of each subsystem.
From a mathematical point of view, the differences between a simulation and an optimization problem can be found in the structure of the equation system obtained for each case. The simulation of an industrial process involves the resolution of a square equation system with a unique solution. In terms of the structural analysis made by the observability algorithm, the same one gives a sequence of square subsystems conformed by the equations and variables of the model, which are completely classified as observable variables. Then, the simulation of this model implies carrying out the block-to-block resolution of all these subsystems. On the other hand, the optimization of a model gives a different structural analysis as a result, since this is a problem with more variables than equations. When analyzing the observability in these cases, a sequence of square blocks conformed by observable variables (independent of the optimization variables), followed by a rectangular block (singular) is obtained, which is integrated by observable variables belonging to previously computed blocks, but also unobservable variables; giving a block with multiple feasible solutions as a result. The model optimization should be carried out in two stages: a first one where the square blocks, which are independent of the optimization variables, are solved; and a second one, where the rectangular block is solved.

3. *MP4SO*: A software tool for the integration of DM and GAMS

Next, a description of the main menus that integrate *MP4SO* is included.
Model: This item controls the model analysis and summarizes its information clearly. It is made up with the following items:

- *Preprocessing*: It analyzes the mathematical model, specified with GAMS notation, by extracting the data required by the DM in order to carry out the decomposition.
- *Dimension*: It informs the model dimensions.
- *Parameters*: It shows a list with the model parameters, as well as their values.
- *Variables*: It shows a list with the model variables, as well as their values.

From this menu the user has the possibility of modifying the values of the parameters and variables. Then *MP4SO* automatically changes them on the model.

Partition: This menu allows the user to run the DM and carries out the model partitioning, clearly showing the obtained results. It has the following items:

- *Run*: It starts the partitioning using the Direct Method.
- *Subsystems*: In a simple way it informs the equations and variables that integrate each one of the obtained blocks. The blocks are colored in light blue and white (see Fig. 1).
- *Equations*: It shows the complete list of equations, following the order given by the DM.
- *Variables*: It shows a list of the variables arranged in accordance with the obtained partition. It also shows bounds and initial values. The user can modify these values here.

Optimization/Simulation: Depending on the nature of the problem (a simulation or an optimization), the user will use one of these drop-down menus. The menu options are:

- *Run*: It runs GAMS in order to solve the model.
- *Results*: It shows the corresponding GAMS output file.
- *Subsystems*: It shows all the blocks of the model, coloring in red (see Fig. 1) those blocks that, for any reason, could not be solved by GAMS (infeasible blocks).
- *Variables*: It shows the calculated values for the variables.

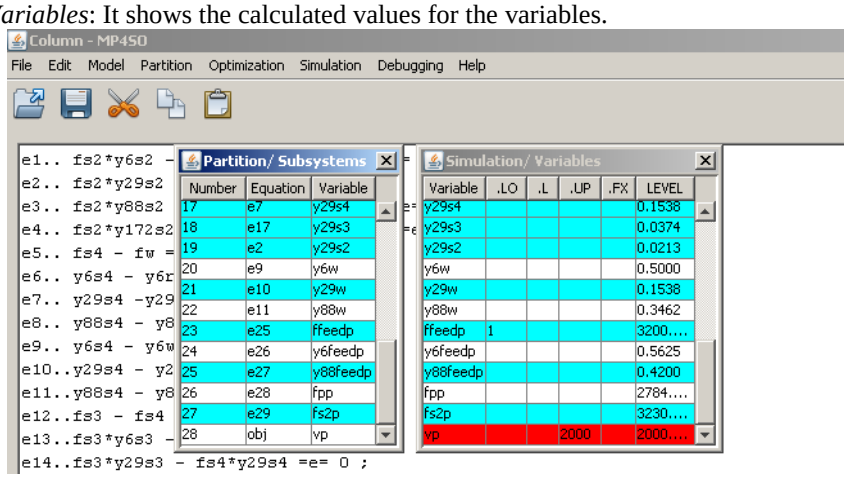

Figure 1: *MP4SO* screen capture. The figure shows the model written in the text area (background), as well as different windows (forefront) showing the DM partition (on the left) and the results obtained with GAMS (on the right).

Debugging: It is oriented to the treatment of infeasible subsystems, allowing the user to focus only on the infeasible blocks. For this purpose, *MP4SO* firstly solves the feasible part of the model, saving the results. Then, the user runs the problematic subsystem, changing initial values of variables until the block converges. Once the convergence is reached, the model is executed again looking for new infeasible blocks. It has the following items:

- *Start Debugging*: It saves the model in two different files. One with the part of the model that converged and the other one, with the infeasible block.
- *Run Feasible Part*: It runs the first file in GAMS, saving the obtained results.
- *Variables*: It shows a table with the infeasible-block variables, as well as their bounds and initial points. The user can change these values before trying to solve the block again.
- *Run Infeasible Part*: It runs the infeasible blocks in GAMS, using for the variables that were already calculated the results saved from the feasible part execution.

4. Performance software analysis and conclusions

In order to test *MP4SO*, cases of diverse dimensions and complexity were run. They correspond to mathematical models of real processes, which were in some cases simulated

and in others, optimized. For each of them, brief descriptions of the process and model dimensions are included, followed by the results obtained. For the simulation models, we detail the decomposition obtained by the software, as well as the percentage of variables that should be initialized in order to carry out the resolution in blocks. For the optimization, we specify the square blocks that *MP4SO* generated, as well as the dimensions of the optimization block. We also included data about both the percentage of the model that was assigned to simulation (square blocks) and the percentage of variables that should be initialized in order to reach the convergence of the whole model.

4.1. Process Simulation

4.1.1. Catalytic cracking of gasoil

This problem deals with the determination of the reaction coefficients for the catalytic cracking of gas oil into gas and other byproducts. This model is taken from the COPS benchmarking suite [Cops, 2009]. The mathematical model chosen to represent the plant consisted of 1299 equations and variables. Table 1 shows the results.

Nº Eq.	**Nº Var.**	**Blocks**			**% Initial. Variables**
		1x1	**12x12**	**285x285**	
1299	1299	102	76	1	**21**

Table 1. Resulting decomposition for the simulation of the catalytic cracking of gasoil.

4.1.2. Reactive distillation column

The reactive distillation column constitutes a clear example of process intensification. It can be presented as multifunctional reactors, where the reactive and separation tasks are combined into a single unit, thus reducing investment costs. The reactive distillation column is modeled as a plate column, using reactive and non-reactive stages where appropriate. A model description can be found in Domancich *et al.* (2009). The mathematical model of this section is made up of 1615 non-linear equations and variables. Table 2 shows the results.

Nº Eq.	**Nº Var.**	**Blocks**				**% Initial. Variables**
		1x1	**5x5**	**13x13**	**997x997**	
1615	1615	600	1	1	1	**61**

Table 2. Decomposition that was obtained for the simulation of the reactive distillation column.

4.2. Process optimization

4.2.1. Network of heat exchangers

This case represents a heat-exchanger network, where the main stream is cooled. To achieve this, we used a network of heat exchangers, which is divided in two parallel parts. The objective function is the summation of the exchange areas, which must be minimized. The optimization variable for this problem is the split fraction of the main stream. A more detailed description of the model can be found in Domancich *et al.* (2004). The model that represents the plant consisted of 58 equations and 59 variables. Table 3 shows the results.

Nº Eq.	**Nº Var.**	**Simulation Blocks**	**Optimiz. Block**		**% Mod. Simul.**	**% Init. Var.**
		1x1	**Eq.**	**Var.**		
58	59	40	18	19	**69**	**32**

Table 3. Resulting decomposition for the optimization of the heat-exchanger network.

4.2.2. HDA production

In this case we considered the hydrodealkylation of toluene to produce benzene. The objective function is the economic potential obtained from the sale of the different products. The optimization variables are the reactor conversion and the H_2 fraction in the purge stream

of the process. A more detailed description of the model can be found in Douglas (1988). This model is made up of 634 and 695 variables. Table 4 shows the results.

Nº Eq.	Nº Var.	Simulation Blocks				Optimiz. Block		% Mod. Simul.	% Init. Var.
		2x2	3x3	4x4	6x6	Eq.	Var.		
634	695	184	2	1	1	435	496	**32**	**68**

Table 4. Resulting decomposition for the optimization of HDA production.

4.3. Discussion and Conclusions

The resulting decompositions depend on the coupling degree that exists between the variables of the model, as well as on the kind of problem to solve. In an optimization problem, we are trying to minimize an objective function by fixing the different optimization variables of the model, giving a high coupling degree as a result. By applying *MP4SO* to an optimization problem, we can detect which part of the model is uncoupled from the optimization variables and the objective function. This is the part that the program is able to decompose. Then, a final block is generated, which will be optimized with all the equations that contain the optimization variables and the objective function.

The execution times for all the examples for both models, the original one and the partitioned one, were between 10 and 120 seconds executed with a Pentium 4 (3.00 Ghz). Most of the blocks obtained in the examples have small size (dimension 1 or 2). Therefore, once these blocks are solved, the user can focus on the larger ones. The bounding and initialization of variables in these blocks usually require a trial and error process. By comparing any partitioned model with the original one, the following advantages arise:

- A partitioned model demands less computational requirements to be solved.
- The number of variables that should be initialized to solve the partitioned problem is remarkably lower. Therefore, the cumbersome procedure of initialization is simplified.
- *MP4SO* simplifies the debugging stage, which is necessary when resolution errors appear. The software individualizes the infeasible block, in such a way that the user only needs to carry out the trial and error initialization procedure only for this block.

Abstract

The use of steam in heat exchanger networks (HENs) can be greatly reduced by the application of heat integration and optimization with the intention of debottlenecking the steam boiler and indirectly reducing the water requirement (Coetzee and Majozi, 2008). By reducing the steam flowrate the return condensate temperature to the boiler is compromised which adversely affects the operation of the boiler. A means of maintaining the efficient operation of the boiler is to reheat the return flow to the boiler to a sufficiently high temperature. A means of achieving this is utilizing the sensible heat from the superheated steam which would normally pass through a let down valve.

Steam systems typically employ turbines to generate shaft work from superheated high pressure steam. The outlet of these turbines is frequently used as a heating utility in the background process. Since turbines operate at various steam levels, a means for incorporating these steam levels into the HEN optimization framework is necessary.

Consequently this paper concerns the optimization and restructuring of all steam system heat exchangers using conceptual and mathematical analysis to create a series HEN with the aim of reducing the overall steam flowrate, whilst maintaining the boiler efficiency.

Keywords: multiple steam levels, heat exchanger network, boiler efficiency.

1. Introduction

Pinch analysis has found numerous applications in a wide range of process integration areas, most specifically mass and heat integration. Heat integration has the ultimate goal of reducing external utilities by maximizing process to process heat exchange but can also be used in the optimal placement of utilities (Linnhoff and Hindmarsh, 1983).

The work on steam network synthesis by Coetzee and Majozi (2008) encompasses a graphical targeting technique on a T/H diagram. This method is used to find the minimum steam flowrate for a particular HEN. Using this flowrate an appropriate HEN is then designed accordingly. This network design is done using an LP model to construct the network. The whole process can also be done using an MILP model.

By incorporating multiple steam pressure levels the graphical targeting technique becomes obsolete as it cannot cater for the extra dimension of various steam pressure levels. Thus the MILP model derived by Coetzee and Majozi (2008) is altered to accommodate multiple steam pressure levels and is used to target for a minimum flowrate as well as design the network.

However, the effects of minimising the steam flowrate on the entire steam system have not been considered. The efficient operation on the steam boiler is dependent on the condensate return flowrate and temperature. Reducing the steam flowrate reduces both of these operation parameters and as such affects the steam boiler.

2. Problem Statement

The problem addressed in this investigation can be formally stated as follows.

Given:

- a steam boiler with known efficiency,
- a set of heat exchangers linked to the boiler with limiting temperatures and fixed duties,
- turbines operating at multiple pressure levels with fixed power outputs which deliver saturated steam to the set of background processes through a let down valve,

Determine the minimum steam flowrate and corresponding heat exchanger network that can be achieved by integrating the steam turbine exhaust into the steam system whilst maintaining the boiler efficiency.

3. Paper Approach

Figure 1(a) shows a typical steam system in the context of this investigation. High pressure steam is produced inside the steam boiler. A portion of the steam is sent to a high pressure turbine. The remaining steam passes through a let down valve and proceeds to the process. The exhaust from this turbine is then used as process heat as well as to recover more shaft work in a medium pressure turbine. The exhaust from the medium pressure turbine can be used further as process heat.

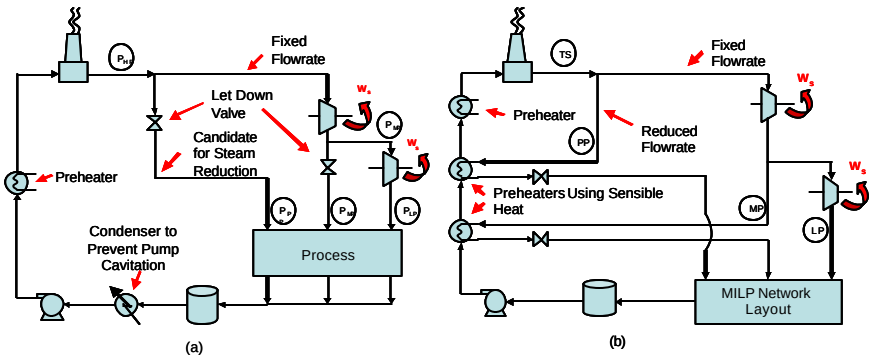

Figure 1: Steam system layouts before and after utilizing sensible heat.

3.1. Boiler Efficiency

Equation (1) relates boiler efficiency, $?_b$, to the effects of changing steam load, capacity and operating conditions as would be encountered in a realistic situation (Shang and Kokossis, 2004).

$$h_b = \frac{q\left(M/M^{\max}\right)}{\left(c_p \Delta T_{sat} + q\right)\left[(1+b)\left(M/M^{\max}\right)+a\right]} \tag{1}$$

In Equation (1), q is the heat load of the steam (i.e. the latent and superheated sensible heat), M is the steam load raised by the boiler and M^{max} is the capacity of the boiler. The parameters a and b are taken from a study by British Gas in work done by Pattison and Sharma (1980).

3.2. Methodology

The methodology consists of two parts. Firstly the minimum steam flowrate is determined and an associated heat exchanger network is found. The second part of the methodology deals with constraints concerning the boiler efficiency. An attempt is then made to reconstruct the HEN so as to maintain the initial boiler efficiency.

3.2.1. Steam Reduction and Initial Network Design

Figure 2 shows the superstructure that is used to derive the relevant mass and energy balances needed to determine the minimum steam flowrate for the particular HEN. These equations form an MILP model with the objective function being minimizing the steam flowrate. These equations are based on those of the MILP model of Coetzee and Majozi (2008) with considerations for the various steam pressure levels included.

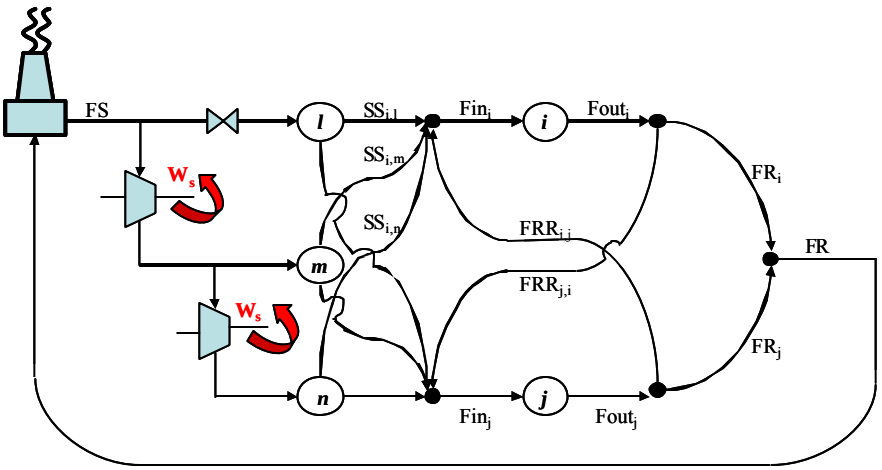

Figure 2: Superstructure used to derive mass and energy balance equations.

3.2.2. Boiler Efficiency Considerations and Altered HEN

To calculate the boiler efficiency as defined in Equation (1) several variables are required. The outlet temperature of the process must be known and can be calculated by Equation (2). The return flowrate to the boiler can take two forms, the first being saturated condensate and the other sub-cooled condensate, represented by $FRS_{i,l}$ and FRL_i respectively. Using these variables, the total return temperature to the boiler, T_{boil}, can be calculated with Equation (3). The efficiency can then be calculated using these variables in Equation (1), shown in Equation (4).

$$T_{proc} = \frac{\sum_{i \in I, l \in L} FRS_{i,l} Tsat_l + \sum_{i \in I} FRL_i Tout_i^L}{FS} \tag{2}$$

In Equation (2), T_{proc} is the process outlet temperature and FS is the total condensate flowrate.

$$T_{boil} = T_{proc} + \frac{Q_{preheat}}{FS \times c_p} \tag{3}$$

In Equation (3), T_{boil} is the return temperature to the boiler and $Q_{preheat}$ is the heat added to the return stream by the preheater.

$$h_b = \frac{q\left(FS/M^{\max}\right)}{\left(c_p\left(T_{sat} - T_{boil}\right) + q\right)\left[(1+b)\left(FS/M^{\max}\right) + a\right]} \tag{4}$$

Since the steam flowrate reduction causes a decrease in the return boiler temperature a means of reheating the boiler feed to its original return temperature must be found. It is suggested that the boiler return condensate be heated in heat exchangers which utilize the sensible heat of the superheated steam from the boiler and from the high pressure turbine exhaust. Thus using this method the energy can be reclaimed and used to maintain the boiler efficiency. Figure 1(b) shows the new steam system structure incorporating these changes. The new boiler return condensate temperature is then calculated using Equation (5).

$$T_{boil} = T_{proc} + \frac{(PP)\left(h_{\sup hp} - h_{sat,hp}\right)q + MP\left(h_{\sup mp} - h_{sat,mp}\right)j}{FS \times c_p} \tag{5}$$

In Equation (5), $h_{sup,hp}$ and $h_{sup,mp}$ are the enthalpies of the superheated high and medium pressure steam leaving the boiler and high pressure turbine respectively. $h_{sat,hp}$ and $h_{sat,mp}$ are the enthalpies of the saturated high and medium pressure steam at the boiler and high pressure turbine outlet conditions respectively. ? and f are the fractions of the sensible energy that can be used safely without the risk of condensation for the high and medium pressure steam respectively. These fractions are arbitrarily chosen with a large enough safety factor that is deemed appropriate so as to not compromise the saturated steam by condensation. For this investigation they were chosen as 80%.

Equations (2) to (5) are used to create the second part to the model. The MINLP model formed is solved using the technique of Quesada and Grossmann, (1994). Two cases are considered, each using the same basic equations but focusing on two objectives.

Case 1: Maintain boiler efficiency with slight compromise in minimum flowrate
Firstly the primary objective can be to maintain boiler efficiency. This can mean that the minimum steam flowrate may not be reached, if there is not enough sensible heat available to preheat the boiler feed stream. The minimum steam flowrate is first determined using the first part of the methodology. Then a slack variable is added to this steam flowrate and the equations relating to boiler efficiency are added. The boiler efficiency is then fixed while the slack variable is minimized, thus the total steam flowrate can be found with constant boiler efficiency.

Case 2: Maintain minimum flowrate with slight compromise in boiler efficiency
Secondly the objective could be to achieve the minimum steam flowrate with only a slight compromise in boiler efficiency. A slack variable is added to the efficiency

equation and minimized. If the slack variable is zero then the boiler efficiency can be maintained with the minimum steam flowrate. If it is not then the boiler efficiency will be compromised by minimizing the steam flowrate.

Either of these two cases can be explored depending on the circumstances of the steam system being examined. For example, arid regions may have a shortage of water and thus minimizing the steam flowrate could be the primary objective, or where water is in abundance maintaining the boiler efficiency can be used as the objective.

3.3. Case Study

The case study presented by Coetzee and Majozi, (2008) is used here to show how boiler efficiency is affected by a reduction in steam flowrate and how the formulations above can be used to maintain the original efficiency.

Using Equation (4) the boiler efficiency was calculated as 63.4%. After the first part of the methodology the steam flowrate was reduced from 10.73kg/s to 7.91kg/s, a 26.3% reduction. Figure 3(a) shows the network layout that corresponds to this flowrate. The HEN outlet temperature is consequently reduced to 63°C. This reduction in flowrate and temperature result in a new boiler efficiency of 58.2%, an 8.2% reduction.

Using the first premise of maintained boiler efficiency it was found that the boiler efficiency could be sustained without compromising the steam flowrate. This was successfully accomplished using 60.1% of the available sensible heat from the HP steam and 80% from the MP steam. With the reduction in steam flowrate, the return temperature had to be increased to 119.0°C.

Since the boiler efficiency could be maintained for the minimum steam flowrate it follows that the second premise would also yield the same answer.

3.4. Sensitivity Analysis

Both formulations gave the same result since there was enough sensible energy to heat the boiler feed to the point where the original efficiency could be maintained. By reducing the amount of sensible heat the models may show how they compromise either efficiency or minimum flowrate to maintain the other. Thus the amount of sensible heat available was reduced to 30% for both the HP and MP sensible heat sources.

To maintain boiler efficiency the minimum steam flowrate was indeed compromised. The new steam flowrate was found to be 8.33kg/s, 8.5% higher than the flowrate after the initial reduction but still yielded a 22.4% reduction from the original parallel arrangement. This new flowrate did require a new heat exchanger network to satisfy the duties of the various process streams. This network is seen in Figure 3(b).

Using the second objective to utilize the minimum steam flowrate the available sensible heat was once again reduced to 30% of the original amount. It was found that the minimum flowrate could be maintained but a small decrease in boiler efficiency was noted. The new boiler efficiency was calculated as 0.6140, a decrease of 3.2% from the original boiler efficiency. The process outlet temperature increased to 70.6°C, while the

boiler return temperature dropped to 96.8°C. The network required for this flowrate is the same as that of Figure 3(a), since there is no change in flowrate.

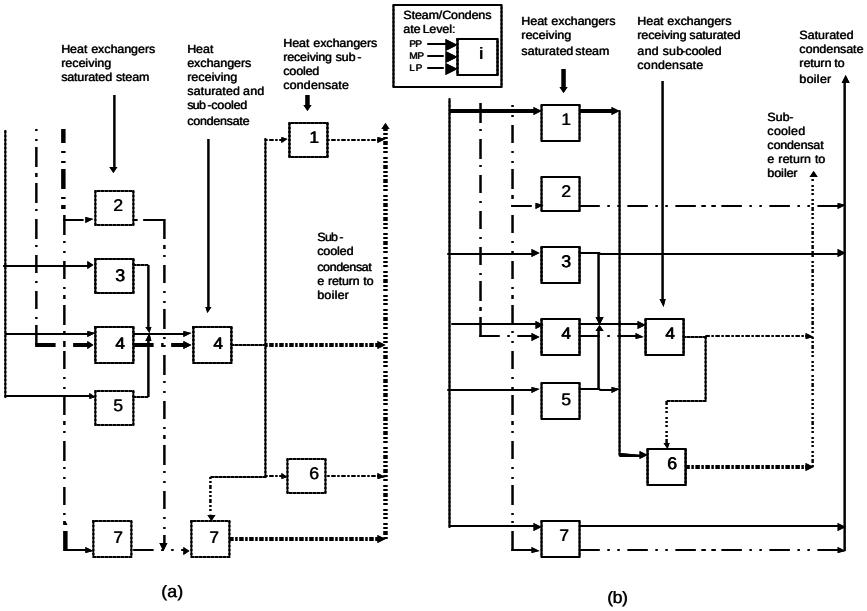

Figure 3 : HEN layouts before and after steps are taken to maintain boiler efficiency.

4. Conclusions

The following conclusions can be made with regard to incorporating multiple steam pressure levels into maintaining boiler efficiency while reducing steam flowrate:

- Preheating the return flow to the boiler to a slightly higher temperature will maintain the boiler efficiency for a reduced flowrate.
- Some of the excess exhaust from the turbines can be used in the heat exchanger network to further reduce the steam flowrate.
- In the event of insufficient sensible heat from the HP and MP steam a slight compromise in either the minimum flowrate or the boiler efficiency is necessary.

Abstract

In this work, kinetic models were obtained from experimental data in the open literature, for both the alkaline (NaOH) and acid (H_2SO_4) homogeneous catalysis of the transesterification reaction, used to produce biodiesel from vegetable oils. Two approaches, designated as statistical and empirical, were adopted to obtain these models. For both catalysis types, the kinetic models obtained show average absolute errors of approximately 4%, using both empirical and statistical approaches, well within the precision of the experimental procedures. In the alkaline catalysis, kinetic models fitted better a pseudo 2nd-order reaction, while for the acid catalysis pseudo 1st-order reaction provided a best fit.

Keywords: Biofuels, Biodiesel, Reaction Engineering, Kinetic models, Model validation.

1. Introduction and Motivation

In EU-27 and Portugal, road transport was responsible in 2005 for about 60% and 58% of the oil demand, and approximately 25 % and 33% of the final energy consumption, respectively (European Communities, 2008). These figures represent a significant ecological footprint, with great impact on the countries' GDPs and constitute a geostrategic weakness. To mitigate this scenario, and also to comply with the Kyoto's goals and guidelines, the European Directive 2003/30/EC, transposed to Portuguese legislation in 2006 has established a series of measures to promote a more intense use of biofuels, in order to achieve a share of 5.75 % in the transport sector, by 2010. Biodiesel (a mixture of fatty acid methyl esters), a substitute of fossil diesel, is one possible and attractive alternative, because of its simple and mature technology of production, and well known benefits to the engine performance and environment.

Biodiesel can be produced from distinctive renewable sources (edible and non-edible), e.g., greases, vegetable oils or animal fats, through a transesterification reaction with methanol, leading to glycerol as a main by-product, also with some interesting industry applications. Many process alternatives are available for biodiesel production, which can be classified by the type of catalytic system used in transesterification reactions: homogeneous – alkaline or acid; heterogeneous – alkaline, acid or enzymatic; non-catalytic – supercritical alcohol. Several studies regarding the kinetics of transesterification and other aspects of the biodiesel production technology have been made. Ma et al. (1999), Vasudevan and Briggs (2008) and Demirbas (2009), among others, provide insightful critical reviews. Despite the considerable amount of work done with the aim of characterizing the kinetics of this system, no systematic study

integrating experimental data from different authors is currently available in the open literature. This drawback creates difficulties in the comparison of the performance of diverse catalysts at different reaction operation conditions, and in the comparison of alternative design configurations and setup conditions for this process, based on systematic process optimization methodologies.
To overcome these issues, the objective of this study is therefore to provide results relative to kinetic models based on experimental data available in the open literature, for the transesterification reaction of vegetable oils, through homogeneous alkaline and acid systems (the most common technologies used in industry).

2. Methodology

2.1. Assumptions and considerations
Earlier works (Noureddini and Zhu, 1997; Jeong and Park, 2006; Zheng *et al.*, 2006) studied the mass transfer limitations in the reaction kinetics and concluded that the heterogeneous effect is more pronounced for low intensity mixing rates and at the beginning of the reaction, leading to the formation of a lag phase and lower reaction rates. However, they also noted that with an intense mixing intensity (N_{Re}>6000) and the formation of biodiesel (an emulsion agent), the reaction becomes chemically controlled, and therefore the mass transfer resistance between the oil and alcohol phases is no longer important. Therefore, in this situation the reactant mixture can be considered as pseudo-homogeneous.
As described in Ma *et al.* (1999) and Marchetti (2007), the alcoholysis reaction consists in a group of parallel and reversible reactions. To prevent low yields of biodiesel and to avoid the formation of intermediary chemical components, an excess of alcohol is commonly used to push the equilibrium towards the products. Normally, a minimum molar ratio methanol/oil of 6:1 is chosen, making the reaction behave as practically irreversible, with a pseudo single step mechanism (Freedman *et al.*, 1984).
Freedman *et al.* (1984), Ma *et al.* (1999), and Canacki and van Gerpen (1999) reported that the free fatty acid (FFA) and water contents may have a significant inhibition effect on the reaction, for both catalysis types. In the alkaline catalysis, it was stressed that the FFA and water contents in oil should be below 0.5 % (w/w) and 0.3 % (w/w), respectively, to avoid soap formation that consumes catalyst and reduces the yield. With the acid catalysis, it was concluded that water and FFA strongly inhibit the reaction for concentrations above 0.5 % (w/w) and 5% (w/w), respectively. Water promotes the hydrolysis of triglycerides, fatty acids or esters, which is undesirable because it reduces the conversion efficiency of biodiesel. Hence, in industry, pretreatments are usually included to eliminate water and FFA in the transesterification reactors, preventing this negative effect (Zhang *et al.*, 2003).
To obtain kinetic expressions for the acid and alkaline catalysis as functions of the operating variables, the following major assumptions were considered: intense mixing rate; excess of methanol; negligible water and free fatty acid contents. Literature data was selected to fulfill the former conditions; consequently, the kinetic models obtained are only applicable to those situations.

2.2. Problem formulation
The procedure used to obtain the kinetic models for the acid and alkaline homogenous catalysis is now described. Considering the conversion of the limiting reactant (A), the mass balance for a batch system with a *nth* order of reaction is $dX/dt = kC_{Ao}^{n-1}(1-X)^n$.

At constant temperature, for the 1st and 2nd orders, if the initial time and conversion are both zero, k can be evaluated using values of conversion X_i and time t_i from:

$$k_i^{'} = \frac{-\ln(1-X_i)}{t_i} \quad [\text{min}^{-1}], \qquad k_i^{''} = \frac{X_i}{(1-X_i)C_{Ao,i}t_i} \quad [\text{min}^{-1} \cdot \text{w(oil+methanol)/w oil}] \tag{1}$$

These expressions were used with available experimental data and fixed operating variables, such as temperature (T) in Kelvin, catalyst concentration (xa) in % (w/w oil) and dimensionless molar ratio methanol/oil (xm). In this case, oil is the limiting reagent, since an excess of methanol is used.

Two approaches, here designated as *statistical* and *empirical*, were used to fit the experimental data to the mathematical models, for each catalysis type. In the statistical approach, each experimental data set was used to fit the dependent variables to a set of possible predictors, using linear regression. The dependent variables considered were the kinetic constants for first ($k^{'}$) and second ($k^{''}$) order reactions, and their respective logarithmic transformations. As predictors, the main operating variables (T , xa , xm), and their inverse, logarithmic and square roots transformations were considered. The quadratic terms of these predictors and their cross products were also included. For each dependent variable, a multivariate linear regression model was computed, using two different procedures to select the best set of predictors. Both a forward stepwise regression procedure (Al-Subaihi, 2002) and an optimization procedure based on the direct minimization of the Bayesian Information Criterion (BIC) (Duarte *et al.*, 2008) were implemented. During this procedure, data points that presented a standard residual greater than 2σ were considered outliers, and were consequently eliminated.

In the empirical approach, equation rates of the form $r_j = \alpha_j k(T,xa,xm) C_{oil0}^{\beta_A}(1-X)^{\beta_A}$, with

$$k(T,xa,xm) = A \cdot e^{-\frac{Ea}{R \cdot T}} \cdot \prod_{i=1}^{n} \gamma_i^{\beta_i} = f(T) \times f(xa) \times f(xm) \tag{2}$$

were considered. A first estimate of $k(T,xa,xm)$ was obtained through evaluation of the functions $f(T)$, $f(xa)$ and $f(xm)$ from careful chosen subsets of experimental data, changing only one variable at a time. For instance, to obtain $k(T,xa,xm)$ with a first order reaction in the acid catalysis, $f(xm)$ can be determined by choosing data with $xa = 3$ and $T = 333.15$ K. The partial expressions obtained were sequentially used to estimate the remaining terms. These tests also provided extremely valuable information relative to the required shape of each term $f(\bullet)$, for a good global fit. A first guess of the function $k(T,xa,xm)$ could therefore be obtained for both types of catalysis, considering both first and second reaction orders. Afterwards, the initial parameter values were used as initial guesses for a more rigorous nonlinear regression, considering all data points simultaneously. This task was performed by formulating a nonlinear least square optimization problem, employing a Least Squares criterion with respect to the residuals of the conversion. To prevent convergence to local optima, the numerical solvers CONOPT, OQNLP and BARON were used sequentially. At the end, a statistical analysis was completed for each empirical model.

3. Results

The alkaline catalyst studied was sodium hydroxide and the experimental data was retrieved from Freedman *et al.* (1984), Noureddini and Zhu (1997), Jeong *et al.* (2004) and Leung and Guo (2006). Most kinetic studies with alkaline catalysis use xm =6 (methanol/oil=6:1); therefore, in this case $f(xm) = 1$ was considered for all experiments (since no information relative to this factor could be extracted from the data), and the kinetic constant obtained is only a function of the temperature and catalyst concentration ($k(T, xa)$). In the acid catalysis, all the studies considered used sulfuric acid; experimental values from Freedman *et al.,* (1984), Canacki and van Gerpen (1999), Goff *et al.* (2004), and Zheng *et al.* (2006) were considered. Table 1 presents the correlation factors and the mean absolute relative errors for each catalysis type, modeling approach and model order.

Table 1. Mean absolute relative error of the conversions and correlation factors for alkaline and acid catalysis, using the statistical and empirical strategies, for different model orders.

Alkaline catalysis	**1st order**		**2nd Order**	
	Empirical	**Statistical**	**Empirical**	**Statistical**
Mean error / %	8.05	8.28	4.14	4.03
R^2	0.9919	0.9327	0.9975	0.9732
Acid catalysis	**1st order**		**2nd Order**	
	Empirical	**Statistical**	**Empirical**	**Statistical**
Mean error / %	4.64	4.21	8.30	4.10
R^2	0.9970	0.9900	0.9957	0.9792

For the alkaline catalysis, the range of experimental values considered was 32–70 ºC for T and 0.2–1% for xa. With the acid catalysis, the range of experimental values used 60-100ºC for T, 1-46.5% for xa, and 3.3–245 methanol/oil molar ratio (xm). Therefore, the kinetic models should only be used for reliable predictions within these boundaries. In the empirical approach and for both kinetic orders, the numerical solvers CONOPT, OQNLP and BARON were used sequentially, to ensure that the parameter values obtained correspond to global optima.

Table 1 shows that data from literature fits better to a 2nd order kinetic model for the alkaline catalysis, and a 1st order kinetic model with acid catalysis, since the mean error for both strategies are lower in these cases and the correlation factors higher. For the alkaline catalysis, the 2nd order kinetic models expressions obtained in the empirical and statistical approaches are given in Eqs. (3) and (4). The corresponding parameter values are presented in Table 2.

$$k(T, xa) = e^{\beta_0 - \frac{\beta_1}{T}} (-1 + \beta_2 xa + \beta_3 xa^2 + \beta_4 xa^3) \tag{3}$$

$$k(T, xa) = e^{\beta_0 + \beta_1 \ln(T / T_0) xa + \beta_2 (T_0 / T) \ln(xa) + \beta_3 \ln(xa) + \beta_4 2 \ln(T / T_0)}, \; T_0 = 300 \text{ K} \tag{4}$$

Table 2. Parameter values for Eqs. (3-4) considering a 2nd order reaction, using data from Freedman *et al.*(1984), Noureddini and Zhu (1997), Leung and Guo (2006), and Jeong *et al.* (2004).

	Empirical		**Statistical**	
	Parameter values	**Standard error**	**Parameter values**	**Standard error**
β_0	1.385E1	1.759E0	-1.2522E0	1.788E-1
β_1	5.362E3	4.568E2	2.372E1	4.002E0
β_2	2.160E1	5.973E0	1.198E1	2.171E0
β_3	-4.898E1	1.342E1	-1.052E1	2.116E0
β_4	4.401E1	1.400E1	-5.725E1	2.589E1

Table 3 displays the best parameter values obtained for the acid catalysis. The corresponding 1st order kinetic model expressions obtained with the empirical and statistical approaches are presented in Eqs. (5) and (6), respectively. Here, the complexity of the model obtained with the statistical approach advises against its use, due to the limited number of experimental data points used. In this case, Eq. (5) corresponds to a more parsimonious form, and should be used for the acid catalysis kinetic rate.

Table 3. Parameter values for Eqs. (5-6) considering a 1st order reaction, using data from Freedman *et al.* (1984), Canacki and Gerpen (1999), Goff *et al.* (2004) and Zheng *et al.* (2006).

	Empirical		**Statistical**	
	Parameter values	**Standard error**	**Parameter values**	**Standard error**
β_0	2.389E1	1.293E0	-9.494E0	2.047E-1
β_1	9.913E3	4.424E2	5.682E0	1.221E0
β_2	4.004E-3	3.785E-3	-8.946E-2	1.347E-2
β_3	1.865E-1	3.173E-2	2.163E1	3.805E0
β_4	1.379E0	1.172E0	1.265E-1	2.685E-2
β_5	5.739E-1	3.640E-1	-6.391E0	1.683E0
β_6	———	———	8.545E-2	2.277E-2
β_7	———	———	-5.858E-2	1.690E-2
β_8	———	———	-1.296E-1	3.853E-2

$$k(T, xa, xm) = e^{\beta_0 - \frac{\beta_1}{T}}(1 - e^{\beta_2 - \beta_3 xa})(1 - e^{\beta_4 - \beta_5 xm}) \tag{5}$$

$$k(T, xa, xm) = \exp(\beta_0 + \beta_1 \ln(T / T_0)\ln(xm) + \beta_2(1/xa)xm + \beta_3(T_0 / T)\ln(T / T_0) + \\ + \beta_4(1/xa)^2 + \beta_5(1/xa)(1/xm) + \beta_6(T_0 / T)xm + \beta_7(T / T_0)xm + \beta_8 \ln(xa)\ln(xm)) \tag{6}$$

4. Conclusions

The results obtained show that a good agreement between the available kinetic data and models proposed was reached; for both catalyst types, absolute relative errors of approximately 4% could be achieved, with limited model complexity. The best results were obtained considering a 1st order model kinetics for the acid catalysis, and a 2nd order kinetics in the alkaline case. The models obtained can either be used for preliminary process design using systematic methodologies or for delimiting operating regions where additional kinetic studies should be concentrated to reach models with better predictive performance.

Development of a Software to Analysis and Prepare Mass Balance Data to Reconciliation in Oil Refineries

Camila L. R. Santos [a], Douglas C. Mariani [a], Alexandre A. Campos [a,] Marcelo Malavazi Alves [a]

[a] *Soteica do Brasil, R. Dr. Cid de Castro Prado, 108, Planalto Paulista, CEP 04064-040, São Paulo – SP, Brazil*
E-mail address: camilaramos.soteica@petrobras.com.br

Abstract

The data utilized on daily mass balance in oil refineries are generated from the records of products movements and flow and quality measurements existing in the refining processes. This data usually shows low quality and inconsistencies and it should be examined and treated. It was used a technique of data reconciliation to assess those inconsistencies and generate a set of data that allow reliable analysis, which support decisions about process. The data generated by data reconciliation are going to feed the accounting systems and support decisions of the operation and analysis teams. In order to improve data reconciliation system management data, it became more agile and practical, it is necessary to treat raw data that come from site and were recorded in the refinery information systems. The software developed has a function of capture raw data record in the system of registration and control of operations and link these data with measurements in the refining processes. This pooling of information brings a gain of quantity and quality to the data reconciliation system, reducing mathematical problems of non-solubility drive by configuration of refining processes and allocation of measurements. The software also evaluates the closing of balance sheet of each tank and carries a previous distribution of differences, which come from low precision of measurements. This functionality of system intended that data were as close to reality of the process as possible and also attend accounting requirements, increasingly rigid, imposed to oil refining companies. To achieve this goal, it was made modifications on a consecrated numerical technique, in order to adapt this to the problem and to the singular objective function that mathematically describes the problem. All these analyses are generated by software algorithms and occur automatically in hours previously scheduled. With the data processed in the case of mathematical problems and evaluated in order to attend mass balance constraints, reports are generated and will be used by analysis accounting team of refinery. This software is deployed in the largest Brazilian oil refinery and the data generated through it as used as the basis for the accounting closure of this site.

Keywords: mass balance, software development, data analysis.

1. Introduction

For an efficient management of the process industries, especially in oil refining companies, it is necessary reliable process information that supports each decision.

This kind of information is only possible to achieve when reliable balances exist in each process unit and in all industrial plant. These balances generate reliable information, without gross errors arising from measurement problems, which were removed by appropriate treatment of data.
This information is fundamental for decision support. These data will feed planning and scheduling production systems, supervision teams, inventory and tax control systems and will compose costs and other features.
Compiling these information, there will be defined what and where to produce, buy or sell a given product volume, revamps, local market, and others.
To generate this kind of information one of the techniques available is data reconciliation that consists in a statistic technique that minimizes difference between data and gives a better estimate to mass balance.
These techniques are being used at Petrobras oil refineries through utilization of software called Sigmafine, which was developed by OSI Software, sold and operated in Brazil by Soteica team.
Use of data reconciliation has varied applications when it is needed to treat the inaccuracies of measuring instruments on a statistical methodology which converge in a more reliable mass balance for a process or equipment.
The work of Weiss (1996) presents the use of this technique to a pyrolysis reactor, in this work the problem was developed around a simplified energy and mass balance that was solved by successive linearizations. The results obtained were used in survey of the equipment operational parameters.
On this basis has the work of Placido (1998), which applies an algorithm developed for reconciliation, in language Fortran 77 to ammonia's plant of FAFEN/BA. This study showed the importance of knowledge of the plant, the need to have sufficient redundancy and the importance of addressing the non-solubility that was found.
Bonfim (2004) shows the importance of data reconciliation for the Petrobras. This importance is linked to the need to obtain reliable process data that can be used to take decisions.
In applying this technique in the refineries of Petrobras, the main problem is the presence of non-solubility alignments that result in occurrence of errors or coarse spreading of errors in the refineries models.
To combat this problem Soteica's team has developed the software that uses data from the refining units to estimate the logistic operations, reducing the problems on non-solubility, improving data quality and reducing reconciliation time.
On this work, it will be described the development and results achieved by Soteica's team with this tool on the implementation on Paulinia's Refinery. The largest oil refinery in Brazil and Petrobras.

2. Problem Description

The main problem found on reconciliation process was the logistic operation originated in tanks that are receiving some products and sending to other places at the same time. These logistic operations are classified as simultaneous.
Thus the movement quantity of these logistic operations cannot be determined by the tanks' gap, because more than one operation influences this gap.
So, the logistic operations recorded in the Petrobras database, BDEMQ, have inconsistent values, because BDEMQ use the tanks' gap to do the calculation. The example shown in Figure 1 shows the operations on the August 10th of 2006 which

involve the tank 4728 of Paulinia's Refinery. Note that the times of reception and transmission line, so the tank has simultaneously operations.

This makes the estimated values for these operations be inconsistent and often even negative, which complicate the work of teams of accounting and mass balance.
The software developed came to reduce this problem using the measured data of the refining units to make a preliminary estimate of the operations of the entire plant and provide this estimate to the accounting team and for the mass balance.

3. Software Structure

This software was developed by Soteica's team in Visual Studio 2005 with the Visual Basic and uses a database build in SQL Server.
Data is captured directly from Petrobras' database using an ODBC connection and the connection with the Plant Information System is done through the library of the OSI communication with Visual Basic.

4. Software Algorithm

The Sigmafine's model was based on nodes, which consist in points of closing balance. In these models the nodes have meters of the refining units coupled and they are source or destination of logistical operations.
The software uses data measurement and density of Plant Information System and tank stock that is recorded on BDEMQ to close mass balance in each node.
The record of logistic operations is done by transfer and storage team when they occur.
To perform this procedure the software uses a table called "Nos", which contains the information listed below:

- Process unit that the node refers;
- Node's code;
- Meters related to each node;
- Measure unit of each meter;
- Conversion factor of each node;
- Density of each meter;
- Density measure unit of each meter;
- Level of confidence in each measure, expressed in %;
- Logic of calculation of each node;

For each node, is held the following algorithm for calculation:

- Select logistic operations related to each node;
- Logistic operations divided into periods of time;
- Calculates the amount of movement for a period;
- Calculates the density and the percentage of confidence of each logistic operation;
- Record this operation in the database with the estimated value;

The procedure described above gives an estimative for the balance of each tank, but is not able to close their balance due to measurement inaccuracies.
Once chosen a tank and the operations involved with the tank, with the estimated data and the tank's gap recorded on BDEMQ.
With details of operations and tank's gap, the difference between the calculated sum of operations related to the tank and the tank's gap, which is the objective function to minimize. So, it is wanted that the difference reaches the value zero.
In the minimization is used a modification of Newton's Method, and the search is performed within a space defined by the percentage of confidence of logistic operations. That is, the estimated value of each logistic operation is the center of search space and its limits is the estimated value less the value of percentage of confidence and the estimated value plus the value of percentage of confidence, as it can be seen in equation (1).

Search space = (estimated value – value of percentage of confidence … estimated value + value of percentage of confidence) (1)

The construction of search was based on the Theory of Constraints introduced by Goldratt (1990).
To search the space is used a modification of Newton's Method, where the function to minimize is given by equation (2).

Objective Function = ∑ input logistic operations - ∑ output logistic operations – tank's gap (2)

The modification of the Newton's Method is on the derivate, which now is given by equation (3).

Value of Logistic Operation = Value of Logistic Operation – (Function / (Value of Logistic Operation * Value of Logistic Operation Estimated)) (3)

The minimization procedure is iterative and stops when the value zero of function is reached or until 100.000 iterations are reached.
If the value of zero the function will not be achieved with 100.000 iterations, it means that the algorithm not converged, and then it will begin the process of distribution of differences.
The distribution of differences procedure is the analysis of the logistic operations involved with the tank and the identification of which has a greater value of percentage of confidence. The logistic operation with the biggest value of percentage of confidence receives the difference.

The procedure for closing the balance of the tank is iterative and it is repeated for each tank that operated on the daily analysis.

5. Results

This software is operating in Paulinia's Refinery since November 2008 and it has been showing good results as it can be seen below in the reports presented in Figures 2 and 3. These reports are submitted to the accounting team in the first hours of the morning and sets values of the tanks in which mass balance is closed.

Figure 3: Reports of fuel oil accounting area

It is important to notice in these reports that the value estimated by BDEMQ to the tanks that operate simultaneously most often is inconsistent, even showing negative values, as it can be seen on column BDEMQ (m^3), in the reports demonstrated in Figures 2 and 3. What generates an enormous amount of work for the accounting team that lost a long time to make estimates with less precision.
These data also feed data reconciliation system, Sigmafine, and improve quality of initial data, reducing gross errors and time spent in the reconciliation procedure. You can also notice an improvement in quality scores of reconciliation.
One interesting thing that can be noted with the use of these data is that when for some reason the process data are not available or have very huge errors, the algorithm presents values that make clear that there are problems in the area.
As the algorithm works with each tank individually, the errors are confined to the tank and not spread in the model as a whole.

6. Conclusion

This work shows that the algorithm developed and implemented in the software was efficient and able to prepare the data for the data reconciliation system and for the accounting team, that has now consistent estimates for operations simultaneously.
Due to good results, this work should be replicated in others refining units of Petrobras by Soteica. The next to receive it will be Landulpho Alves Refinery, in Bahia.

Abstract

This study presents an optimization model based on genetic algorithm (GA) for the production of target polymer resins. Unlike most contributions in open literature, this study takes into account an economic optimization criterion while satisfying the desired polymer properties through constraints at the end of the reactor. The case study is the ethylene coordination polymerization, which takes place in a CSTR (continuous stirred tank reactor). Due to the high non-linearity of the process model, a stochastic optimization method based on GA is used. Several simulations were carried out and the results show that the GA is able to determine the optimal operating conditions satisfactorily. Binary codification proved to be more robust than real codification.

Keywords: Genetic algorithm, optimization, polymerization

1. Introduction

In last years much attention has been given to the design of tailored polymer resins through optimization models. Computer-based tools constitute an alternative to the expensive pilot plant or industrial scale experiments. The majority of contributions focuses on batch polymerization and then minimizes the batch time while specifying the polymer properties through constraints of the optimization (Sundaram et al., 2005). Another very common approach is the minimization of a single scalar objective function which corresponds to the quadratic deviation of the observed and desired polymer properties values, i.e., a sort of multiobjective optimization (Hanai et al., 2003; Lemoine-Nava, 2006). This approach however, requires the definition of weighting factors, what may not be trivial since some properties in the objective function can present conflicting behaviors.

Genetic algorithm (GA) is a powerful alternative for complex and highly non linear problems, such as the optimization of polymerization reactors. GA does not require the computation of derivatives nor an initial estimate to find an optimum, but it can still be improved if some problem knowledge is provided to the initial population (Pontes, 2008). Because of these characteristics, GA has gained acceptance in almost all areas of science and engineering, and the polymer reaction engineering is not an exception (Kasat et al., 2003). Many efforts have gone on the multiobjective optimization, which account for the polymer properties and, in some studies, for the batch time, obtaining Pareto sets (Agrawal et al., 2006) through a non-dominated sorting genetic algorithm. However, when using such approach, the decision of the best operational condition still requires process knowledge and/or intuition.

Bearing in mind the mentioned drawbacks of multiobjective optimization and that several operational conditions may yield the same polymer grade, a more robust approach should account for operational profit as objective, while satisfying the desired polymer properties through constraints of the optimization. Within this scope, the present study proposes an optimization problem for targeting polyethylene resins by means of Genetic Algorithm. An industrial scale ethylene polymerization in solution with Ziegler-Natta catalyst is taken as case study due to the scarceness on modeling and optimization of such systems in open literature. To the authors' knowledge, solely Brandolin et al. (1991), Asteasuain et al. (2001) and Agrawal et al. (2006) address the optimal operating policies problem to the ethylene polymerization. However, these works consider processes taking place at high pressure plug flow reactors through a free radical mechanism, i.e., for the production of low density polyethylene (LDPE).

The paper is structured as follows. Firstly, the process is described. In the next section the optimization problem formulation using genetic algorithm is discussed. Then, some results are shown in order to illustrate the potential of the proposed approach. Finally, some conclusions are presented.

2. Optimization Problem Formulation

The polymerization process takes place in a series of tubular and stirred reactors that can be combined in different flowsheets in order to produce a wide range of polymer grades. The focus of this study is the stirred configuration, which is illustrated in Figure 1. Monomer, hydrogen and a catalyst mixture, dissolved in a solvent, are fed to the non-ideal CSTR (continuous stirred tank reactor). The main feed is split between the top and the bottom of the reactor, enhancing the mixing effect of the agitator. The reaction is almost completed when entering the PFR (plug flow reactor).

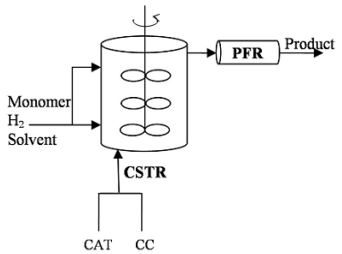

Figure 1: Typical reactor configuration: tubular (left) and stirred (right).

Pontes et al. (2008a) determined the most important variables regarding their effects on the objective function and on the polymer properties by means of a design of experiments approach. The degrees of freedom of the optimization were then determined: monomer (M), hydrogen (H_0) and catalyst (CAT) inlet concentrations, total (W_t) and side feed (W_s) flow rates and inlet pressure (P_{in}).

The polymer quality is verified through melt index (MI), stress exponent (SE) and density at the outlet reactor, i.e., PFR_b. The MI is a measure of the polymer average molecular weight: the higher the MI, the lower is the molecular weight. On the other hand, SE measures the polydispersity of the molecular weight distribution (MWD): a more heterogeneous polymer corresponds to a higher SE value. The density is greatly influenced by the comonomer content, but the present study focuses on the

homopolymerization process. Therefore, mainly MI and SE are used to specify the polymer quality. As mentioned previously, the polymer properties are attained through constraints at the outlet of the PFR. In addition to that, operational constraints on outlet variables may be accounted for in order to ensure safe operation. For example, the outlet temperature (T_{out}) and outlet pressure (P_{out}) may be constrained in order to avoid phase separation. Hence, a vector with constrains (equality or inequality) at the reactor outlet is set:

$$\mathbf{h} = \begin{bmatrix} MI & SE & T_{out} & P_{out} \end{bmatrix}^T \tag{1}$$

This reactor was modeled in previous studies (Embiruçu et al., 2000; Pontes et al. 2008b) and the parameters were exhaustively validated with actual plant data (Embiruçu et al. 2008). The numerical strategy was to use the previously developed dynamic model, taking the stationary state as response to be evaluated by the optimization model. Such approach is justified because of the difficulties encountered when initializing a set of highly non linear algebraic equations for the non-ideal CSTR. Considering the index $i = \{s, t\}$, where s indicates the CSTR and t the PFR, the optimization problem can be formulated according to:

$$\max_{\mathbf{u}} \Phi \tag{2}$$

s.t.

$$\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, \mathbf{y}, \mathbf{u}, \mathbf{p}, z), \quad \left\{ i = t : \; z \in [z_0 \; z_f], \; i = t : \; z = 0 \right\} \tag{2a}$$

$$0 = \mathbf{g}(\mathbf{x}, \mathbf{y}, \mathbf{u}, \mathbf{p}), \tag{2b}$$

$$0 = \mathbf{x}(z_0) - \mathbf{x}_0, \tag{2c}$$

$$\mathbf{u}_{LB} \le \mathbf{u} \le \mathbf{u}_i, \quad z = z_0, \tag{2d}$$

$$\mathbf{h}_{LB} \le \mathbf{h} \le \mathbf{h}_i, \quad z = z_f, \tag{2e}$$

where Φ is profit (difference between incomes with polyethylene sales and costs with raw materials), $\mathbf{x}$ are differential state variables, $\mathbf{y}$ the algebraic state variables, $\mathbf{u}$ the decision variables, $\mathbf{p}$ the invariant parameters, z the axial coordinate, the subscripts 0 and f refer to the reactor inlet and outlet, $\mathbf{u}$ and $\mathbf{h}$ are vectors with decision variables and constraints and the sub indexes LB and UB are lower and upper bounds respectively. The initial conditions of equation (2a) are the inlet conditions to the CSTR; they are given by equation (2c) or by the decision variables. The algebraic equation (2) comprehends additionally some output process variables such as conversion and polymer production rate as well as correlations for the polymer properties.

The optimization is carried out by the genetic algorithm (GA), a stochastic method that mimics the mechanism of natural selection, i.e., the fittest individuals survive in a competitive environment. The probability of an individual to survive is given by its fitness, which is related to the objective function. Each individual or chromosome has to be coded, e.g. into binary or real representation. If binary representation is used, the chromosome is composed of the so-called bits, which can assume only 0 or 1 values. This representation attempts to represent real variables with a limited number of possibilities. The variable precision is then given by the chromosome length. Real representation overcomes this by directly using the real values of the variable. Basically, three operators are responsible for the GA search potential: reproduction, crossover and

mutation. The selection of the best individuals is based on the tournament selection, which randomly selects two individuals, compares them, and selects the one with the best fitness to the next generation. When handling constraints, the potential of the tournament selection is explored (Deb, 2000): (a) when two feasible solutions are compared, the one with the best objective function is selected; (b) when a feasible solution is compared with an infeasible solution, the former is selected; (c) when two infeasible solutions are compared, the one that less violates the constraint is adopted.

In order to use the GA a number of parameters have to be set. In previous work (Pontes, 2008) a systematic procedure based on design of experiments is used to ascertain the optimum set of parameters: seed number for generation of random initial population (0.4), mutation (0.05) and crossover (0.7), population size (100) and chromosome length for binary codification (8).

3. Results and Discussion

The optimization model was implemented in Fortran code and several optimization studies were carried out in order to investigate the performance of the genetic algorithm using both binary and real codifications when targeting polyethylene resins.

According to the optimization model, GA must maximize profit in order to produce polymer resins with pre-specified properties, namely melt index (MI) and stress exponent (SE). A sequence of optimizations was carried out, and the respective MI and SE constraint limits are given in Figure 2, together with the optimum profit for each SE specification. The optimal operational conditions for the inlet concentrations of reactants are illustrated in Figure 3. Results are normalized due to confidentiality reasons.

GA shows an overall good performance at identifying optimum operating conditions for designing target polymer resins. GA with binary codification performs better than real GA. When comparing both results, it is worth observing that the real GA reproduce the random characteristic of the method since it finds most of the time just a local optimum. These local optima may be associated to the particular crossover and mutation operators used for real codification (Deb, 2000). A deeper investigation on their parameters and on other operators might improve real GA performance.

	SE_{LB}	SE_{UB}
A	0.250	0.260
B	0.260	0.270
C	0.270	0.280
D	0.280	0.290
E	0.290	0.300
F	0.300	0.310

0.282 = MI = 0.294

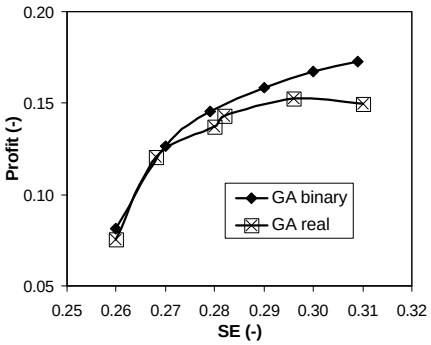

Figure 2: Profit versus SE.

Catalyst inlet concentration and side feed show to be the most important variables to control the stress exponent. A tradeoff between both variables on the polymer properties allows the desired polymer specification while a tradeoff between catalyst and monomer inlet concentrations is responsible for the increasing profit. For more details on the phenomena taking place inside the reactor the reader should address previous works (Pontes et al., 2008b; Pontes, 2008).

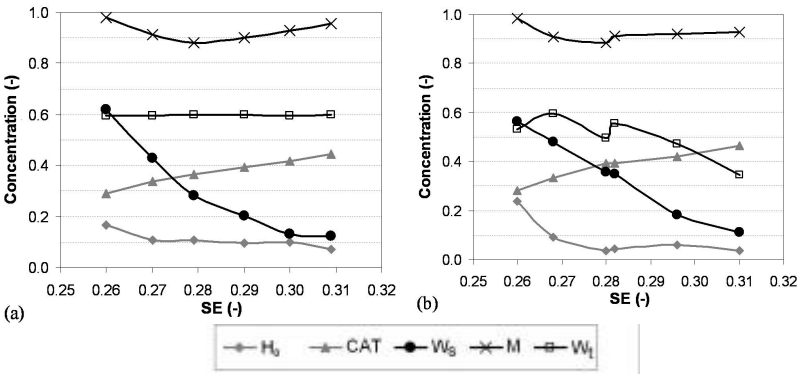

Figure 3: Inlet concentrations *versus* SE: (a) GA binary; (b) GA real.

Attempting to further investigate and compare the performances of binary and real codifications, the evolution of objective and penalty functions values over the 100 generations for example F above are illustrated in Figure 4. Real codification finds the first feasible solution around the 50th generation, whereas binary GA around the 10th generation. The decrease in objective function in the first generations is associated to the constraint handling method: unfeasible solutions with lower penalty functions are selected regardless their objective function values.

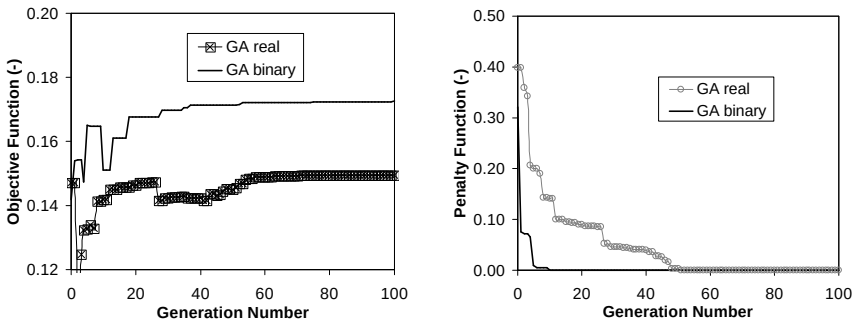

Figure 4: Comparison between binary and real codifications for example F: objective (left) and penalty (right) functions over generations.

Unlike SQP based optimization methods, the GA does not require an initial guess to find an optimum since the initial population is randomly created. However, adding valuable information to the GA initial population may guide the search for the global optimum. In this scope, a hybridization method is considered here, which incorporates into the GA initial population an initial guess based on process knowledge (GA-I). Example F is again taken as case study. No significant improvement is observed with

binary codification but with real GA, on the other hand, this approach led to an objective function 13.22% higher (Figure 5). The improvement is associated with the first feasible individual detected around generation 20th, much earlier than pure GA (Figure 5, right). However, the new optimum still is a local optimum compared to binary GA: the latter is 1.87% higher than the former (GA-I real).

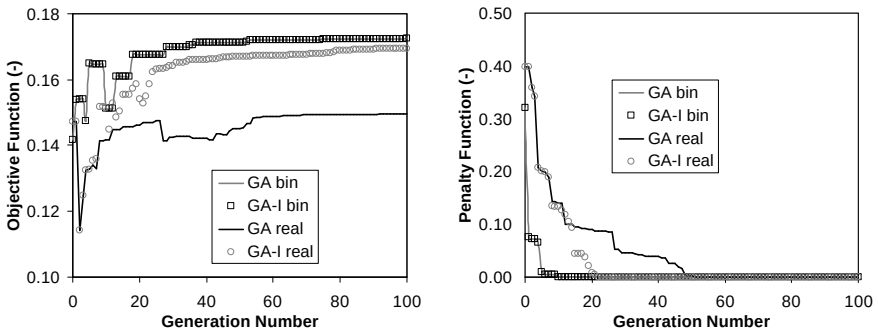

Figure 5: Hybrid GA: objective (left) and penalty (right) functions over generations.

4. Conclusions

The paper presents the application of genetic algorithm for targeting polyethylene grades. Economic objectives are considered, while satisfying the quality requirements through constraints. The method can satisfactorily predict the optimal operating conditions in order to produce a polymer with desired quality. The results illustrate that the performance of the method can be highly influenced by the codification, i.e., real or binary. The binary GA presented a more robust performance than the real one, which fails to locate the global optimum for some optimizations since a better optimum is found when using the binary codification.

It is widely known that the GA does not require an initial guess to find an optimum, but valuable process knowledge can guide the search towards the global optimum, which was observed by the hybrid approach. When designing similar polymer grades or when optimizing current industrial operating conditions, the hybrid approach can therefore be particularly useful in the search for a global optimum.

Abstract

The tubular reactor in a naphtha cracking furnace is modelled rigorously in this paper. The mathematical model can be used to predict product yields, coking buildup inside the tube wall, run length (i.e. the time between two consecutive decoking operations), residence time and pressure drop. A powerful modelling, simulation and optimisation tool gPROMS was chosen to implement the proposed work. This model provides detailed understanding of the naphtha cracking process. Steady-state optimisation was then applied to the operation of this industrial tubular reactor. The operating profit is maximised when the process gas temperature profile along the reactor and the inlet steam to naphtha ratio vary within certain ranges. The effects of coking on heat transfer, on reduction of manufacturing time and the decoking cost have been considered in the optimisation. Process simulation and optimisation based on this detailed model will give process engineers in the ethylene industry some insights on ethylene furnace design and operation.

Keywords: Mathematical modeling, tubular reactor, ethylene furnace, case study

1. Introduction

Ethylene is the one of most important building blocks used in the petrochemical industry. Thermal cracking furnace is the heart of the whole ethylene manufacturing process. A typical unit generally includes the convection section, the cross-over section and the radiation section (Sundaram *et al.* 2001). Naphtha is preheated in the convection section and then mixed with steam. The mixture of naphtha and steam is introduced into the tube reactors in the radiation section. The cracking reactions take place inside these long tubular reactors. Steam is a diluent and it is used to improve olefin selectivity and reduce coking rate.

Naphtha cracking process involves many free-radical reactions. Due to computational difficulties, models based on molecular reactions have been widely used (Sundaram *et al.* 2001). Kumar and Kunzru (1985**a**) proposed a molecular reaction mechanism for naphtha steam cracking based on their experimental research. In the meantime, Kumar and Kunzru (1985**b**) developed a kinetics model for predicting coking rate.

Shahrokhi and Nejati (2002) carried out an optimal operation study based on one-dimensional (1D) steady-state model for propane thermal cracking. Operating profit was used as objective function and the optimal temperature profile was found. Decoking

cost was counted in this study. Hu *et al.* (2004) modelled and simulated an industrial tubular reactor for naphtha cracking. This mathematic model was developed based on the molecular reaction scheme proposed by Kumar and Kunzru (1985**a**) and the coking reaction scheme proposed in Kumar and Kunzru (1985**b**). Masoumi *et al.* (2006) developed a 1D steady-state model for tubular reactors in naphtha cracking. A free-radical reaction scheme including 90 species and 543 reactions was used. An optimisation study was performed with the aim to maximize the operating profit. Han *et al.* (2006) reported a study of numerical simulation on fuel combustion and naphtha pyrolysis reactions in another naphtha cracking furnace.

Mathematical model for naphtha thermal cracking in ethylene manufacturing was developed in this paper. A real industrial thermal cracking furnace presented in Hu *et al.* (2004) was selected as benchmark. The modified molecular reaction scheme was used. The novel contributions of this paper include (a) the modeling of coking buildup and the evaluation of its impact; (b) the accounting of the effects of coking on heat transfer and reduction of manufacturing time, and the decoking cost in the optimal operation case study.

2. Mathematic modeling

The tube reactor for naphtha cracking was modeled under the following assumptions:

- One dimensional flow (i.e. negligible radial concentration gradients)
- Plug flow for process gas & ideal gas behaviour

Due to the fast dynamics of the process gas inside the tube, the mass and energy balances were expressed in steady-state form. The generic equations for modelling a typical plug flow reactor can be referred to Pantelides (2003). The coke layer was modelled specifically. The coking buildup inside the tube was modeled in pseudo steady-state (updated hourly).

3. Model validation

The simulation is based on the industrial cracking tube reactors described in Hu *et al.* (2004). The reactor parameters and operation conditions are listed in Table 1. The molecular reaction scheme proposed by Kumar and Kunzru (1985**a**) was adopted. Due to different naphtha as feedstock, the stoichiometric coefficients for the primary reaction were adjusted (Hu *et al.* 2004).

Table 1 Tube reactor geometries and operating conditions

Reactor tube		**Operation variables**	
Tube length, *m*	24.159	Naphtha feed，*kg/h*	6,666
Diameter of inlet tube, *mm*	Φ72×6.5	Steam/naphtha ratio, *kg/kg*	0.5
Diameter of outlet tube, *mm*	Φ98×7.5	Tube feed temperature, *K*	900
Number of reactor tubes	32	Tube outlet temperature, *K*	1,100
Highest temperature allowed for tube, *K*	1,373	Tube outlet pressure, *kPa*	216

Table 2 Primary reaction for naphtha cracking used in this study

Reaction equations	**K_0, s^{-1}**	**E, cal/mol**
$C_{6.5}H_{14}$ => $0.406H_2 + 0.910CH_4 + 1.06C_2H_4 + 0.176C_2H_6 + 0.504C_3H_6 + 0.001C_3H_8 + 0.001C_4H_{10} + 0.219C_4H_8 + 0.123C_4H_6 + 0.002C_4$'s	6.565E+11	52,580

The model for calculating coking rate proposed by Kumar and Kunzru (1985**b)** can be described as follows:

$$r_c = 1.95 * 10^{15} * EXP(-212,260 / RT) * C_{arom}^{1.97} \qquad (1)$$

where r_c denotes the coking rate in kg/(m^2 h) and C_{arom} denotes the total aromatics concentration in kmol/m^3.

The process gas temperature profile applied on the tube reactor is shown in Figure 1, which is the same as in Hu *et al.* (2004). In Table 3, the main product yields from the base case simulation in gPROMS were compared with the industrial data published in Hu *et al.* (2004). As can be seen, simulation results are generally in good agreement with industrial values. When the tubular reactor is operated under the same conditions as listed in Table 1 and shown in Figure 1, the model predicts that the production time before a decoking operation is 38 days and the coking thickness is 7.73 mm at the coil outlet. This is very close to real life production time 39 days. These two aspects indicate that the developed model can reflect the real naphtha cracking process.

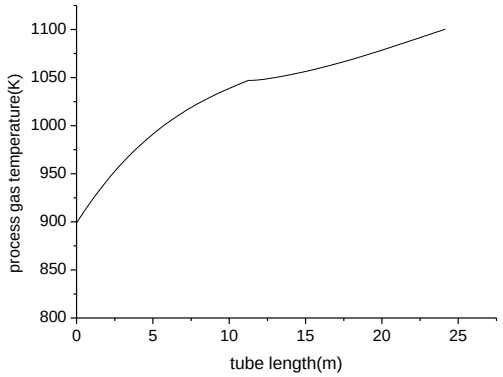

Figure 1 Process gas temperature along the tube reactor

Table 3 Comparison of product yields between simulation and industrial measurements

Components	**Yields, % (industry)**	**Yields, % (simulation)**
C_2H_4	29.16	30.36
C_3H_6	14.94	14.86
CH_4	14.94	15.28
H_2	0.96	0.97
C_2H_6	3.80	3.66
C_4H_6	5.14	4.45
C_4H_8	5.08	4.86
Process gas outlet temperature, K	1,109	1,103
Process gas outlet pressure, kPa	171	170.3

4. Naphtha cracking process analysis

This section is to analyse the naphtha cracking in the whole manufacturing cycle.

4.1. Tube outlet wall temperature

Figure 2 indicates the change of the tube external wall temperature along tube length with production time. It can be seen that the highest temperature is at about the middle of whole tube reactor at the beginning of production. With the production time going on, outer tube temperature is growing gradually and the position of highest temperature moves to the outlet of tube. When the outer tube temperature reaches 1373K which is the allowed highest temperature, the cracking furnace has to be shut down for decoking. From Figure 2, the run length is 38 days, which matches the industrial data 39 days very well.

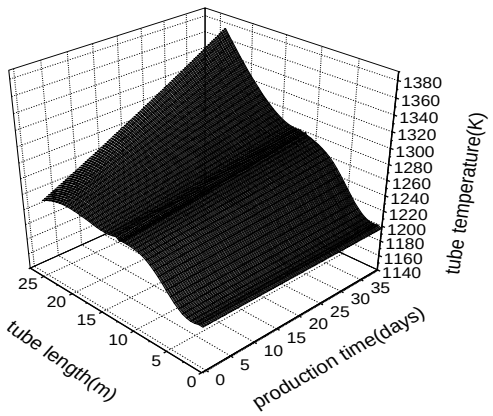

Figure 2 Outer tube temperature changes along tube length with production time

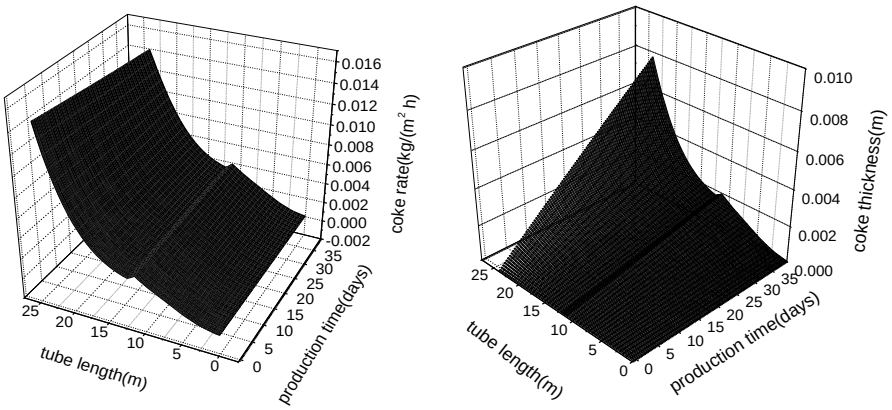
4.2. Coking rate and coking buildup



(a) Coking rate along tube reactor length with production time

(b) Coke thickness growth along tube with production time

Figure 3 Coking process inside reactor tube

Figure 3 shows coking rate and coke thickness vary with tube length and production time. Form Equation (1), it can be seen that coking rate depends upon both process gas

temperature and aromatics concentration in process gas. Although aromatics concentration drops along tube reactor, coking rate increase along the two pass of the tube reactor due to process gas temperature going up. But there was a decrease of coking rate along the joint bend tube due to aromatics concentration drop sharply. Figure 3(b) shows coke thickness growth with tube length and production time (days). The reactor outlet has thickest coke built-up obviously at the end of the production cycle.

5. Optimal operation case study

The following assumptions have been made for formulating this optimisation problem: (a) No downstream product separation costs are counted; (b) The tubular reactor operates in steady-state.

5.1. Mathematical formulation

The operating profit was used as the objective function. It was defined as the income from desired products minus various costs. Costs include raw material cost (naphtha here), cost for steam, cost for radiant heat plus the decoking cost. A fixed value (denoted by DCC) was used for decoking cost (per time). The objective function was calculated on a yearly basis.

$$f_p = Income - Cost \tag{2}$$

$$Income = (t_p - n_d t_d) * \sum F_i c_i \tag{3}$$

$$Cost = (t_p - n_d t_d) * (F_0 c_0 + F_H c_H + Q c_Q) + n_d * DCC \tag{4}$$

Where f_p represents the operating profit, F_i the desirable product flow rate, F_0 the naphtha flow rate; F_H the steam flow rate; n_d denotes the decoking times per year. The meaning for other parameters can be referred to Table 4.

The decoking frequency is calculated via Equation (5).

$$n_d = \frac{t_p}{t_d + t_e} \tag{5}$$

Where t_e denotes the production time between consecutive decking processes (unit in hours). In this study, t_e is predicted by the mathematical model with the criteria that the outlet metal temperature is greater than and equal to 1373 K.

Table 4 gave all the parameters assumed for this case study. Most of the price factors were taken from *ICIS Chemical Business* (2007).

Table 4 Parameters for optimisation function

Physical meaning	Parameters	Values
The yearly production time	t_p, hour	8,160
decoking time	t_d, hour	48
ethylene price factor	C_1, \$/t	1,200
Propylene price factor	C_2, \$/t	1,180
naphtha price factor	C_0, \$/t	541
Steam price factor	c_H, \$/kg	0.0129

Heat price factor	c_Q, *$/kJ*	1.26E-05
Decoking cost	*DCC* ($/time)	66,600

5.2. Results and discussions

After performing steady-state optimisation in gPROMS, optimisation results were summarised and then compared with the operating conditions described in Hu *et al.* (2004) in Table 5. From Table 5, it can be seen that the operating profit was improved obviously after optimisation.

Table 5 Steady-state optimisation results

Items	Original value	Optimal value
Coil outlet temperature (K)	1,100	1,118
Steam to naphtha (kg/kg) ratio	0.500	0.670
C_2H_4 yield (wt%)	0.315	0.341
C_3H_6 yield (wt%)	0.148	0.138
heat flow(*kJ/h)*	624,858.2	759,304.0
Objective function, $/year	70,054	85,291
Production time(days)	39	27

6. Conclusions

In this paper, mathematical model for tubular reactors in the industrial thermal cracking furnace for ethylene manufacturing was developed first. The coking layer inside the tube wall has been modelled, the coking impact on heat transfer and pressure drop has been considered. Process analysis based on this model provides detailed understanding of the naphtha cracking process. Steady-state optimisation was applied to the operation of this industrial tube reactor for maximum operating profit. The decoking cost has been considered. This study will provide some insights to process engineers in the ethylene industry on ethylene furnace design and operation.

Abstract

This paper describes the mathematical modeling of a set of rotating biological contactors (RBC) used for ammonia removal by nitrification of the wastewater stream that comes from a petroleum refinery. The entire biological wastewater treatment unit is composed by an aerated facultative lagoon, four sets of RBCs, and a pair of clarification decanters. In this paper we are concerned with the nitrification step. It has two sequential biochemical pathways (nitritation and nitratation) for the nitrification process and the existence of two distinct biological agents, related to *Nitrobacter* and *Nitrosomonas* autotrophic bacteria. We discuss some characteristics about the kinetics and important points that should be concerned for such a study. We also propose an alternative way to model the spatial distribution on the rotating bioreactor, with necessary simplifications and the discussion on their limitations. Available data sets from on-line analyzers for ammonium, composed by 3-hours sampled input and output, were used for parameter estimation and model validation. The process modeling, dynamic simulation, and parameter estimation were completely accomplished in the software EMSO. The results show the good prediction capability of the proposed model. It is expected to use the developed model for monitoring the wastewater treatment and for operator training. Meanwhile, the acquired knowledge obtained during the model development has improved the efficiency and the operational procedures of the industrial unit.

Keywords: nitrification, modeling, wastewater, RBC.

1. Introduction

Most of the industrial wastewaters have ammonia to be removed, and the most common way to fulfill this task is by a biological process known as nitrification, on which ammonia is oxidized to nitrite and nitrate, combined with a further denitrification stage. In this last stage, nitrite and nitrate act as electron acceptors for heterotrophic bacteria, under anoxic condition, converting them to nitrogen gas [2].

The nitrification part is usually divided on two most important steps, known as nitritation, on which ammonium is oxidized to nitrite by the autotrophic bacteria of the genus *Nitrobacter*, and nitratation, on which the nitrite formed previously is oxidized to nitrate by the autotrophic bacteria of the genus *Nitrosomonas*. These two steps occur under aerobic condition and are very sensitive to several factors, such as dissolved

oxygen, pH, temperature, presence of inhibitory compounds, and even the concentration of the own nitrification products [4]. Any attempt to analyze a nitrification process should concern all these variables.

These biological processes can be run on several manners, if their conditions are fulfilled. Older processes use suspended biomass that requires higher residence time and their efficiencies will depend on the contact between the biological agents and the nitrogenous compounds, on the mixture conditions, on the quality of the biomass flake formed and so on. Those processes are simple to design, but are generally less efficient than processes with immobilized biomass that grows on the surface of the equipment (or over the filling) and the affluent flows through it. In the later, the biomass reaches much larger concentration of bacteria, comparing to disperse flakes, resulting on a more effective removal of ammonia [1]. One example of such equipments is the Rotating Biological Contactors (RBC), which is composed by several disks of polymeric material, good for attaching the biomass, connected by a central axis, and with very large available surface for biomass growing. These disks spin around the axis by a mechanical system in a frequency between 1 and 2 rpm, and the RBC is usually designed to operate about 40% of the disks submerged in the affluent, providing good aeration for the immobilized biomass. The aeration of the affluent is also due to the turbulence generated by the disks movement.

On the next sections, it will be discussed the kinetics of the nitrification process, and how it should be treated for a mathematical modeling procedure. Further, it will be presented an industrial case and practical results to illustrate the model application.

2. Nitrification kinetics

Nitrification is held by autotrophic bacteria, which have smaller growth rates than heterotrophic bacteria and are more sensitive to adverse conditions. Usually it is the most critical process of the biological treatment in a wastewater unit and, therefore, its mathematical modeling has to be treated carefully. From now on, it is described the procedure to model this process, the parameters meaning, and some relations among them.

2.1. Modeling the growth rate

The traditional equation to describe the relation between the substrate (ammonium, in this case) and the specific growth rate of the microorganism (μ, units of h^{-1}) is the Monod equation, Eq. 1, which has the advantage of simplicity (just two parameters to estimate) but cannot represent the process on high loads of ammonium, because of the phenomenon of auto-inhibition, when the growth rate starts to decline as the concentration of ammonium increases [6]. For concentrations of 50 g $N\text{-}NH^{4+}/m^3$ or higher, alternative equations must be considered. Carrera et al. [1] compared different equations and concluded that, for nitrification with immobilized biomass, the equation that best fits experimental data is the Aiba's model, Equation 2.

$$\mu = \mu_{\max} \frac{S}{k + S} \tag{1}$$

$$\mu = \mu_{\max} \frac{S}{k + S} \exp\left(- S \middle/ k_i \right) \tag{2}$$

In these equations, μ_{max} is the maximum specific growth rate, which stands for the case when there are no limitations of the substrate for the microorganism. It is a characteristic of the microorganism and, according to Ferreira [2], the maximum specific growth rate is larger for the nitrifying bacteria of the type *Nitrobacter* than for the type *Nitrosomonas*. The parameter k is called half-saturation coefficient and

measures the affinity between the microorganism and the substrate (the less, more affinity) and the parameter k_i measures the auto-inhibition relation.
The actual growth rate of the biomass is the product between the specific growth rate and the microorganism concentration. Other influences can be added to this equation to consider the effects of other operating conditions.

2.2. Operating conditions influence
Ferreira [2] presented the relations of nitrification under several operating conditions and their applications are briefly discussed below.

2.2.1. Dissolved oxygen
This is the most important condition to control a nitrification process, due to its high influence on the biochemical pathways and its very low solubility in water. Experimental results and experience show that nitrification efficiency is limited significantly when the dissolved oxygen reaches 2 mg/L, under normal operating conditions. If it decays even more, it can accumulate nitrite instead of nitrate, since *Nitrobacter* bacteria are more sensitive to lack of oxygen [9]. This could be problematical because nitrite will inhibit the microorganisms to grow on smaller concentrations than nitrate.
To take this influence into account, a similar formulation to the Monod equation can be used, and multiplied by the main growth rate equation. As an example:

$$\mu = \mu_{\max} \frac{S}{k+S}\left(\frac{OD}{k_{OD}+OD}\right) \tag{3}$$

The parameter k_{OD} measures how much the microorganism is sensitive to the lack of oxygen, so it can be assumed that its value for the *Nitrobacter* type of bacteria is greater than for the *Nitrosomonas* type.

2.2.2. pH and alkalinity
The control of the pH can be as important as the dissolved oxygen control, if the affluent has high variations on the nitrogen concentrations. Its influence can be added by an efficiency term based on experimental results [2], or by considering the ammonium equilibrium [3]. Free ammonia is very toxic for the biological agents and should be avoided.
Alkalinity control, on the other hand, is necessary for nitrification, but usually is not so crucial. A simple stoichiometric balance should define the minimum amount of alkalinity.

2.2.3. Temperature
Temperature influence on biological processes is modeled with the Arrhenius equation until the maximum growth rate, followed by a steep decrease, due to cellular lyses. For the nitrification, the maximum growth rate is around 30 ºC.

2.2.4. Inhibitor compounds
Other compounds that are not related in the biochemical pathway can affect its efficiency. Wastewaters can have several different compounds that can inhibit nitrification such as phenol, ethanol, acetone, free ammonia, and nitrite [2,4,6]. There are several equations to model inhibition effects in literature.

3. Study of an industrial case

The wastewater treatment facility from a petroleum refinery located at the south of Brazil is composed of a complete primary wastewater treatment, that is, a fully removal of free and emulsified oil and particulates by physicochemical processes, followed by an aerated lagoon that promote the biological removal of organic carbon and by a newer

plant of rotating biological contactors (RBC), with 4 sets of RBCs: the first two are used for nitrification, the third one (with submerged disks) for denitrification, and the last one for polishing (excess organic carbon remover).
A previous study on the biological processes revealed that the facultative lagoon cannot promote nitrification, but it removes all the biodegradable organic carbon and also acts as an equalization tank, to relief intense disturbances on the wastewater composition, that are typical of this kind of industry.

4. Modeling the nitrification process

Usually, the data available from an industrial plant is limited to the necessary for the process control. Therefore, we developed a model simple enough to be evaluated from readily available data, which needs to contemplate the most important phenomena on the process. Lin [7] has published a more complex model that could be of interest if there were more available data.
Our model is applied to the second set of RBCs, since they have instrumentation that provides on-line data for inlet ammonia concentration and outlet ammonium concentration, dissolved oxygen and pH. The analyzers provide measurements with 3-hours sampling time and the data were selected from time windows when the process was considered to be running without major disturbances or abnormal operation.

4.1. Mass balance

The basis of the model derives from the mass balance on the volume V of liquid around the disks and a mass balance on the volume occupied by the attached biomass (called the biofilm). The first basic assumptions are that the volume of liquid is well mixed and the biological activity of the suspended biomass in the liquid is negligible ($X_{liq} << X$). Therefore all the biological transformations occur on the biofilm. Also neglecting the mass transfer resistance of ammonium from the liquid to the biofilm, we get the following preliminary form of the mass balance for the biomass and ammonium:

$$\frac{d}{dt}\left(V_{biofilm}X\right) = \int\left(\mu - b_{metabolism}\right)XdV_{biofilm} - \int b_{shear}XdA_{biofilm} \tag{4}$$

$$\frac{d}{dt}\left(V\ NH_4^+\right) = F\left(\ NH_{4\ in}^+ - NH_{4\ out}^+\right) - Y_{NH_4^+|X}\int \mu XdV_{biofilm} \tag{5}$$

To model the biofilm growth we use the hypothesis that the biofilm is homogeneous, based on the idea that the *Nitrobacter* type of bacteria should grow near to the *Nitrosomonas* type (and the available nitrite), in agreement with the work of Carrera et al. [1], when comparing experimental data from immobilized and suspended nitrification biomass. In this way, the biofilm has variable volume and constant biomass concentration. Although, if both biological agents had independent dynamics, it could be necessary to consider a biofilm composed of two components with distinct dynamics and growth.
Considering that the biofilm is a thin layer, with the occupied area $A_{biofilm}$ much larger than its depth L, we can rewrite the left hand side of the Eq. 4 as:

$$\frac{d}{dt}\left(V_{biofilm}X\right) = XL\frac{dA_{biofilm}}{dt} \tag{6}$$

Defining ε as the fraction of occupied area on the RBC by the biofilm, $A_{biofilm}/A_{total}$, and combining both metabolism and shear loss parameters in one, b, Equation 4 can be rewritten as:

$$\frac{d\varepsilon}{dt} = \left(\mu - b\right)\varepsilon \tag{7}$$

In order to consider limitations on the growth and loss terms, we multiplied them by factors of ε, Eq. 8, implying that the growth should decrease as the available area gets fully occupied and the loss (considering it mostly by shear forces) should decrease as the occupied area also decreases. The new parameter β should be chosen (or estimated) to fit these limitations in the best way.

$$\frac{d\varepsilon}{dt} = \left[\mu\left(1-\varepsilon\right)^{\beta} - b\varepsilon^{\beta} \right]\varepsilon \tag{8}$$

The final form for the ammonium balance is the following::

$$\frac{d}{dt}\left(V\ NH_4^+\right) = F\left(\ NH_{4\,in}^+ - NH_{4\,out}^+\right) - Y_{NH_4^+}\mu\varepsilon \tag{9}$$

4.2. Operating conditions influence

As stated before, pH, temperature, and alkalinity are well controlled on this case, so their influence would not be appreciable on the model. Also, due to the long contact time between the biofilm and the air and turbulence around the disks, the RBCs are very effective with the aeration. The dissolved oxygen analyzers, located after the set of RBCs, indicate that it is always above 4 mg/L, which is safe to neglect its influence.

4.3. Nitrification kinetics

Since the affluent of the studied set of RBCs already passed through nitrification from the previous set, concentrations greater than 20 mg/L have not been achieved. Therefore, it is acceptable to use Monod equation, keeping the number of parameters to estimate as low as possible. And since there is no deficiency of dissolved oxygen, the growth of bacteria of the type *Nitrobacter* is always faster (the limiting dynamics is with the type *Nitrosomonas*), justifying the use of the homogeneous biofilm model.

5. Model implementation and results

The whole model was implemented, simulated, and fitted to the process data in the software EMSO [8] (Environment for Modeling, Simulation, and Optimization), maintained by a consortium of Brazilian universities and petrochemical industries. EMSO is a generic equation-oriented simulator for dynamic systems and its main applications have been to model equipments and processes of the chemical and petrochemical industry. Due to its dynamic principle, it can be used to simulate units on start-up and shutdown events, as well as changes on the operating point.

Since the set of RBCs is composed by 8 units, being 2 parallel series of 4 units, the final model is the series association of 4 instances of the model described before, with the equivalent volume of two real RBCs.

As we already stated, the first set of RBCs already nitrificates and so the affluent to this set of RBCs has considerable amount of nitrite and nitrate with no available data. Then, we can only compare the ammonium removal, as seen on Fig. 1.

The major difficulty on this implementation is with initial conditions for the RBC, as it is a continuous process with real dynamic conditions and the variable ε cannot be measured. Therefore all the initial values of the state variables need to be estimated, beside the kinetic parameters.

5.1. Results analysis

The model parameters were estimated using the maxim verisimilitude procedure, solved by IPOPT optimizer, a primal-dual interior point method, which is implemented on EMSO. The first set of data of Fig. 1 and validated with the second set, and their values are: μ_{max} = 0.0342 h^{-1}, b = 0.005 h^{-1}, k = 35.26 mg/L, $Y_{NH_4^+}$ = 1.78 x 10^{-6} g^{-1} and β = 1.3.

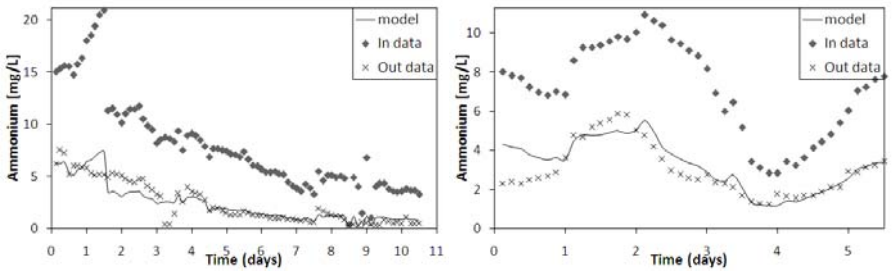

Fig. 1: Ammonium curves before and after the set of RBCs and the model prediction, on two different occasions, using the same kinetic parameters.

The model can predict well the system behavior, and the estimated parameters obey to what is expected from their meanings. The obtained values of ε are smaller than 0.5, which is considered a representative result, based on the experience with the process.

6. Conclusion

The proposed model for ammonia removal in RBCs allowed a better understanding of this process and can result on several improvements on the real process. In the studied industrial case, the analysis of the nitrification kinetics, from the process point of view, revealed the best way to operate it and explained why some actions did not work as expected before. The simplified model has shown that is capable to describe the process fairly well. Maybe a more detailed model would be desired, but it would need more data to estimate the additional parameters, which could be obtained from laboratorial analyses or pilot-scale experiments. A wider approach of the model is been developed and it will be used for operators training with the simulation of how to proceed in adverse conditions. Further on, it could be used as a virtual analyzer, for advanced control of the process.

Abstract

This paper considers the integration problem in the batch production mode of chemical industries, which contains a series of decisions such as the size and amount of batches, assignment of the batches on the units, sequence of the batches on each unit, making a timetable of batches production. For such integration problem, we develop a new solution approach, Heuristic Particle Swarm Optimization (HPSO) which combines some heuristics with PSO in order to obtain feasible solution in a simple method. Then two tactics are presented to speed up the algorithm. The performance of the new solution procedures for the integration problem is demonstrated by solving several instances of a case study from process industries. In contrast to the methods in the literature, HPSO can solve problem with sufficient accuracy in faster speed and principle simple. Moreover, HPSO can solve much larger practical problems.

Keywords: integration, HPSO, chemical industries.

1. Introduction

Integration of batching and scheduling in chemical industries has been the subject of extensive research since the early 1990s. Comparing with separate batching and scheduling, the integration can shorten the production time. The range of application areas for the theory goes beyond the chemical industries to include medicine, foodstuff, etc. The main focus is on the appropriate decision of batch size on units and efficient allocation of one or more resources to batches over time.

On the production environment, integration of batching and scheduling in chemical industries can be classified into two main groups such as singe stage and multiple stages. As for single-stage, Erdirik-Dogan and Grossmann (2007) present a multi-period mixed integer linear programming (MILP) formulation to deal with parallel units, which is effective for small size. They propose bi-level composition algorithm to decompose the problem into batching and scheduling sub-problems. The sub-problems were resulted corporately. Fleilschmann and Meyr (1997) present a local search algorithm to deal with one machine. As for multiple stages, there are three classes such as flowshop (FS), hybrid flowshop (HFS) and job shop (JS). Liu and Karimi (2005) present a MILP formulation which can deal with hybrid flowshop using a continuous-time representation with synchronous slots and a new idea of several balances such as time,

mass, resource. Janak and Floudas (2007) address a MILP formulation for job shop based on unit-specific event continuous-time approaches.

In the literature, most are based on MIP formulation. However, the proposed MIP models often have complex structures and large integrality gaps and are inefficient for solving practical problems. This paper employs another approach to do research, which is based on the mechanisms of problems. This approach has received very limited research attention and few papers can be found. Fleilschmann and Meyr (1997) has addressed on the problem of single stage. This paper studies integration of batching and scheduling in HFS, which is very useful as many practical production systems can be considered as HFS.

The remaining contents are organized as follow: Section 2 is problem description. Section 3 is Heuristic Particle Swarm Optimization (HPSO) algorithm. Section 4 is computational results. Finally, section 5 is conclusions.

2. Problem Description

In this paper, we consider integration problem of batching and scheduling a product in HFS with nonidentical machines and finite intermediate storage. Fig.1 shows the production process of the problem. The HFS has m stages with parallel machines. There are multiple products. The process of a product in a stage is defined as a task which is fulfilled in the batch mode. The relationship of the processing time and batch size is given. The objective is to minimize makespan.

The problem has most of the features in HFS, which is described as follows:

(1) Process consists of several stages. Raw material is transformed into intermediate and final products through some stages.

(2) There are several parallel units which are identical and non-identical in the each stage.

(3) Batches are produced on the units. Relationship of time and batch size is provided.

(4) Non-preemptive. Once a batch begins, batch can't stop until the whole batch is over. The batch is carried out without interruption.

(5) Finite intermediate storage should be considered between stages.

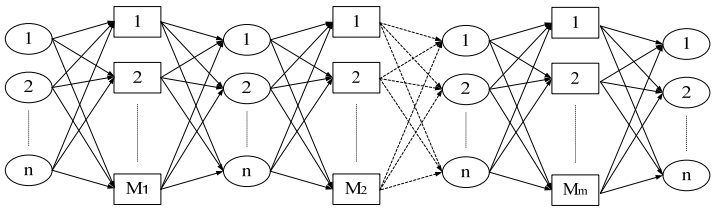

Fig.1 production Process of hybrid flowshop

3. HPSO Algorithm

PSO is a population based evolutionary meta-algorithm which is first presented by Kennedy and Eberhart. The swarm population is made of particles. A particle is correlated to a solution. The particle is composed of position and velocity. The positions are placed in the search space of some problem or function. And the velocity determines position's movement by combining information from its own and swarm. All particles improve their position and velocity in the mode of iteration. The swarm move close to an optimum of the fitness, like a flock of birds collectively foraging for food.

Integration of batching and scheduling is a complex problem. PSO is difficult to obtain feasible solution. Therefore, we propose hybrid PSO (HPSO) which combines some heuristics with PSO in order to obtain feasible solution in a simple method. Then we present two tactics to speed up the algorithm.

3.1. PSO

We use position value from the iterative formulation of standard PSO to denote the production quantity of units, which deals with the material balance between production levels.

$$y_{ijt} = \omega y_{ijt-1} + c_1 r_1 \left(xbest_{ij} - x_{ijt-1} \right) + c_2 r_2 \left(gbest_j - x_{ijt-1} \right) \quad (1) \qquad x_{ijt} = x_{ijt-1} + y_{ijt} \quad (2)$$

3.2. Some Heuristics

Based on the production quantity of units from PSO, we give some heuristics to obtain feasible solutions.

3.2.1. Batching

Based on the analysis of the problem, we found out that the less batches, the more possible to improve the results of minimized makespan. We develop heuristic algorithm to do batching as follow:

$$a = \frac{\text{Production quantity of unit}}{\text{maximal Limit of batches on the unit}} \quad (3) \qquad \text{Minimal batch quantity} = \lceil a \rceil \quad (4)$$

$$batchsize_i = \text{maximal Limit of batches on the unit} \qquad i = 1, \cdots, \lfloor a \rfloor \quad (5)$$

$$batchsize_i = \text{Production quantity of unit} - \sum_{j=1}^{\text{Minimal batch quantity}} batchsize_j \quad i = \lceil a \rceil \quad (6)$$

3.2.2. Precedent Relationship

Precedent relationship implies time relations between batches. Constrains such as material balance, storage limitation can be represented by precedent relationship. Problems with precedent relationship are similar to single machine problem and will be result in a simpler method. We provide Batch Splitting Mechanism (BSM) and Precedence Search Scheme (PSS) to describe precedent relationship with the ideas of RCPSP.

(1) BSM

This paper describes the problem as nonstandard RCPSP. In the literature, different algorithms have been suggested based on Schedule Generation Scheme (SGS) [1] for standard RCPSP. However there is no general scheme to result nonstandard RCPSP. We provide Batch Splitting Mechanism (BSM) to change nonstandard RCPSP to standard RCPSP.

1) Standard RCPSP

Precedence concept can be extended by so-called minimal time lags between the start times of two batches, implying $s_i + d_{ij}^{\min} \le s_j$.

2) Nonstandard RCPSP

Considering constrains of the finite intermediate storage between two stages. Some precedence relations between the start times of batches from the two stages have to be presented by the maximal time lags, implying $s_i + d_{ij}^{\max} \geq s_j$.

3) Change into Standard RCPSP

In order to make problems easy, we propose Batch Splitting Mechanism (BSM) to change nonstandard RCPSP into standard RCPSP. BSM is to split one batch into head and end activities in the project. The head activity implies the start processing the batch and the end activity implies off from processing machine. The limited intermediate storage constrains can be described by the minimal time lags between the start time of j in the later stage and the finish time of i in the former stage, implying $s_j + d_{ij}^{\min} \leq f_i$.

(2) PSS

We use the PSS to set up the network of precedent relationship which consists of node and line. The node implies the start and finish time points of batches and the line imply the span of time. After analysis we found out four kinds of relations in this problem that are shown as follow:

1) Relation in the same batch. The start and finish time points of the same batch should be linked.

2) Relation in the same task. There are two cases. One is that batches in a task have been assigned on the units. The other is that batches haven't been assigned. As for the first case, we should link finish time point and start point between the two batches. And as for the second case, we should link the start time points of the batches.

3) Relation to meet the supply of materials. To meet the supply of materials means that quantity of production in the former step should satisfy consumption in the next step. And among the point satisfying the conditions we choose the first.

4) Relation to meet storage constrain. With finite intermediate storage, some batch in the former step can't end until consumption in the next step free storage room.

3.2.3. Sequencing

Sequencing implies the sequence to schedule activities in the network of precedent relationship, which can guarantee our solutions feasible. The activities will be chosen one by one by the method as follow:

(1) Find out available set. A implies set that all its precedent activities have scheduled. B implies scheduled activities. C implies filtrated set. Filtrated set means once head activity of a batch happens, others in the same machine won't start until the end of the batch happen. $D = A - B - C$ Means set in which we can choose one to put into sequence this time.

(2) Sort activities. We choose an activity with large priory in D every time. The priory is given out by heuristic algorithm as follow: the number of the time points is given before we schedule the batches. Then the number is the priory of the time points.

(3)At last we gain a sequence satisfying precedence restrictions.

3.2.4. Timetable

Timetable implies to give a timetable to schedule the batches. The idea is to locate time for the activities in the sequence as early as possible. And at meantime, we complete machine assignment. We describe the method as follow:

(1) We use different way to calculate the start and finish time of batches. As for start time, it is the maximum of the machine released time and precedent point time. As for the finish time, it is the maximum of the machine released time, precedent point time and start time of the batch plus processing time.

(2) We propose heuristic algorithm to assign batches on parallel machine. Here we only consider the start time. And finish time should be assigned on the same machine as the start time.

The heuristic algorithm is as follow:

1) Calculate the time that the point is possible to start on the parallel machines.

2) Comparing these value and choose the minimum as the start time.

3.3. Two tactics

In order to speed up to find feasible solutions, we propose two tactics as follow.

3.3.1. No-wait

The tactic is to deal with no-wait relationship between the batches. In the network, it is possible that two activities are precedent one of each other, which implies the no-wait relation. To simple the problem, we only consider one side in the former. Then here, we deal with the other side, which is described as follow:

(1) Based on the former process, we can gain a time table.

(2) Mark the two point of no-wait.

(3) If the time of two points is not equal, move the front point to the time of back point.

3.3.2. Processing time

The tactic is to make the difference between the start and finish time of the same batch equal to the processing time. The method is described as follow:

(1) Check the start time point according to the sequence obtained above.

(2) Find out the first one that the difference between the start time and its corresponding finish time is not equal to the processing time.

(3) Move the start time point until the difference is equal to the processing time.

(4) Reschedule back points in the sequence.

(5) Repeat the above to make all the time spans of batches are equal to the processing time.

```
Initial HPSO parameters
for i=1 to n //each particle
    Initial HPSO variables
    Obtain production quantity of unit
    Obtain batch size
    Obtain precedent relationship
    Sequence the batches
    Compute fitness value
        Unit assignment and time allocation
        Simultaneity of no-wait relationship
        Make span of a batch equal to processing time
    Obtain the best solution of the particle
Obtain the best solution of the all particles
for j=1 to t//each iteration
    for i=1 to n //each particle
        Particle flies to new place
        Update production quantity of unit
        Update batch size
        Update precedent relationship
        Update sequence
        Compute fitness value
            Unit assignment and time allocation
            Simultaneity of no-wait relationship
            Make span of a batch equal to processing time
        Update the best solution of the particle
    Update the best solution of all particles
Output the optimization solution
```

Fig 2. Procedure of HPSO

4. Computational Studies

There are obvious difference between MIP formulation and HPSO. The HPSO is implemented with pure neighborhood search. To evaluate our algorithm, we compare it with that of S&K (Sundaramoorthy and Karimi, 2005) [2] using the same example. There are two demand values in the example such as 2000mu and 4000mu. The objective is to minimize the makespan. It is usual to measure the effectiveness of an algorithm by relative deviation of value of solution that is from the best know solution value. In the literature, the results of MIP formulation are 29.772h and 56.432h. Running the HPSO, results are 28.8h and 53.3h. HPSO improved 3.26% and 5.36%. From the computation analysis, we prove HPSO can obtain effective solution in limited time.

For give an indication of the consistency of HPSO in the larger size problem, we extend the demand value from 2000mu to 10000mu in the example. When evaluating HPSO, there is clearly a balance between the consumption of computation time and the quality of solution. To compare fairly, different methods should run in the same computation time. Otherwise it is difficult to draw firm conclusions. Then the run time is limited in 180 seconds. Table1 shows the results belong to S&K and HPSO for each instance. The results show that HPSO is efficient to deal with larger problems.

Table 1 Solution from S&K and Ours

	2000mu	3000mu	4000mu	5000mu	6000mu	7000mu	8000mu	9000mu	10000mu
S&K(h)	29.772	42.769	56.432	70.101	81.417	97.718	109.62	124.61	137.02
Our(h)	28.668	41.328	53.4644	66.6565	79.0458	90.7359	103.678	115.981	131.162

5. Conclusion

Integration problem of batching and scheduling multistage plants with nonidentical parallel machines and finite intermediate storage in chemical industries is a complicate problem. Methods in the literature are mostly based on MIP. In this paper, we develop HPSO which is based on the mechanisms of problems. HPSO combines some heuristics with PSO in order to obtain feasible solution in a simple method. Then two tactics are presented to speed up the algorithm. From computational studies, we can bring out conclusions as follow:

1) The proposed MIP formulations in the literature often have complex structures and large integrality gaps. Our HPSO is implemented with pure neighborhood search, which is simpler in finding a near-optimal solution. From the computation analysis, HPSO can obtain effective solution in limited time.

2) MIP formulations are often inefficient for solving practical problems. HPSO is a promising method to deal with very large and difficulty problem in the real world.

3) In the future, we should develop approaches to improve the qualities and decrease the computing time. Besides, more constrains such as arrival time and deadline should be considered.

Dynamic modeling of comminution using a general microscale breakage model

Rodrigo M. de Carvalho[a], Luís Marcelo Tavares[a]

[a]*Department of Metallurgical and Materials Engineering, COPPE – Universidade Federal do Rio de Janeiro, Rio de Janeiro – RJ, Brazil.*

Abstract

The traditional population balance model has been successfully used in the past to describe size reduction in industrial crushers and grinding mills, but presented limitations in scale-up from information obtained in the laboratory. The paper presents a general model that describes comminution of multi-component feeds in full-scale machines using a combination of information from breakage mechanisms, fundamental material characteristics, and the mechanical environment, allowing to overcome the limitations of traditional population balance model formulations. Since it is based on a detailed description of each stressing event, this model can be used to describe particle size reduction in different types of crushers and mills using the same fundamental material characteristics. In order to demonstrate its potential, the model has been applied to describe grinding in a ball mill, where the mechanical environment was predicted using the Discrete Element Method and breakage of particles was described using a model based on continuum damage mechanics. A good agreement was observed between measured and predicted results from a batch grinding test for a single-component feed. Simulations of the dynamics of grinding in a continuous mill demonstrated the effect of change in feed composition in both product size and fracture strength of particles discharged from the mill.

Keywords*:* microscale, breakage, comminution, grinding, modeling.

1. Introduction

There has been great success in the application of the population balance model (PBM) in the modelling of comminution machines (Herbst, 1979). By decoupling the contributions of selection, breakage and transport, size reduction in different types of crushers and mills has been successfully described quantitatively. While excellent in describing size reduction, the traditional PBM proved to be relatively weak as a predictive model. This is particularly critical, given the great demand for reliable tools for scale-up to industrial-sized machines from information obtained at a small scale in the laboratory. One of the reasons has been the dependence of both material and process on the functions used to describe breakage in the traditional PBM framework, which is obviously undesirable. It results in an additional limitation of the traditional PBM, in which functions determined for one particular type of equipment cannot be used to describe size reduction in another machine.

These and other limitations to the traditional PBM can be overcome with the development of a general microscale model of comminution. By combining a detailed description of the mechanical environment in the size reduction device, fundamental breakage characterization tests, which describe the response of the material to the

different breakage modes (body and surface) and stressing intensities, to a detailed description of the material transport, the proposed model allows to describe size reduction in different devices using a unified mathematical framework. While the mechanical environment and the transport in crushers and grinding mills may be precisely described using techniques such as the Discrete Element Method (DEM) and computational fluid dynamics (Mishra and Rajamani, 1992; Litcher et al., 2008; Cleary et al., 2006), experimental techniques and models are available which allow characterizing in detail the response of material to the different breakage models found in size reduction machines (Tavares, 2007).

The present paper proposes a general microscale model, which considers that the material contained in the feed is not homogeneous, but constituted by a number of components, each containing particles having a distribution of strengths (actually fracture energies). The model also considers that when particles suffer stresses that are insufficient to cause catastrophic (body) fracture, they will undergo surface breakage (abrasion/chipping) and may become progressively weaker. The application of the model has been demonstrated to batch grinding in a laboratory ball mill and also to investigate the dynamics of a continuously-operated ball mill, subject to disturbances in feed rate and composition of the feed material.

2. Model development

2.1. Generalized model

The generalized population balance for particles contained in size class i and component class l is

$$\frac{d\left[w_{il}(t)M(t)\right]}{dt} = w_{il}^{in}(t)W^{in}(t) + \omega\left[-D_{il,b} - D_{il,s} + A_{il,b} + A_{il,s}\right] - w_{il}^{out}(t)W^{out}(t) \qquad (1)$$

where $M(t)$ the mass of material at time t inside the mill, also called hold-up. $w_{il}(t)$, $w_{il}^{in}(t)$ and $w_{il}^{out}(t)$ are the mass fractions of particles contained in class i l in the mill, in the feed and in the discharge streams, respectively. W_{in} and W_{out} are the feed and discharge mass flowrates, respectively. ω is the frequency of stressing events in the comminution machine. Functions A and D represent the rate of appearance and disappearance of material in class i l due to fracture, being defined in Table 1, whereas subscripts b and s stand for body and surface breakage mechanisms.

Table 1. Definition of terms in Equation (1)

Breakage mode	Rate of appearance (A)	Rate of disappearance (D)
Body (b)	$\sum_{j=1}^{i-1} w_{jl}(t)\int_0^\infty m_j(E)p(E)\int_0^1 b_{ijl}(eE,t)F_{jl}(eE,t)p(e)de\,dE$	$w_{il}(t)\int_0^\infty m_i(E)p(E)\int_0^1\left[1-b_{iil}(eE,t)\right]F_{il}(eE,t)p(e)de\,dE$
Surface (s)	$\sum_{j=1}^{i-1} w_{jl}(t)\kappa_{jl}\int_0^\infty m_j(E)p(E)\int_0^1 a_{ijl}\left[1-F_{jl}(eE,t)\right]p(e)de\,dE$	$w_{il}(t)\kappa_{il}\int_0^\infty m_i(E)p(E)\int_0^1\left[1-F_{il}(eE,t)\right]p(e)de\,dE$

In the equations listed in Table 1, $p(E)$ is the distribution of stressing energies E in the comminution machine, m_j is the mass of particles contained in size class j captured in each stressing event and $p(e)$ is the energy split among these particles. a_{ij} and b_{ij} are the breakage functions in density form, corresponding to the mechanisms of surface and

body breakage, respectively, the later depending on stressing energy (Tavares and Carvalho, 2009). κ is the surface breakage rate.

Equation (1) should be solved simultaneously with the equations describing the overall mass transfer in the equipment and the other describing how the fracture probability distribution of each component varies with time, which may be calculated by

$$F_{il}(E,t+\Delta t)=\frac{G_{il}F^{*}_{il}(E,t+\Delta t)+(H_{il}+Q_{il})F_{il}(E,0)+I_{il}F_{il}(E,t)}{G_{il}+I_{il}+H_{il}+Q_{il}} \tag{2}$$

where the fracture probability distribution of the original material $F_{il}(E, 0)$ is well described using the upper-truncated lognormal distribution (Tavares and King, 2002), given by

$$F_{il}(E,0)=\frac{1}{2}\left[1+\operatorname{erf}\left(\frac{\ln E^{*}-\ln E_{50,il}}{\sqrt{2\sigma_{il}^{2}}}\right)\right] \tag{3}$$

where

$$E^{*}=\frac{E_{\max,il}\,E}{E_{\max,il}-E}\ \text{ and }\ E_{50,il}=E_{\infty}\left[1+\left(\frac{d_{ol}}{d_i}\right)^{\phi}\right]\overline{m}_{p,il} \tag{4}$$

where $E_{50,il}$ is the median particle fracture energy, σ_{il}^{2} is the variance, $E_{\max,il}$ is the upper truncation of the distribution, E_{∞}, d_{ol} and ϕ are material parameters and d_i and $\overline{m}_{p,i}$ are the mean size and weight of particles in class i, respectively.

$F_{il}(E, t)$ is the distribution of fracture energies of the material that did not suffer any impact event during the time interval and $F_{il}^{*}(E,t+\Delta t)$ is the distribution of fracture energies of the particles that suffered impact, but did not fracture, being given by

$$F_{il}^{*}(E,t+\Delta t)=\frac{\int_{0}^{E_i^{*}}p(E_k)\int_{0}^{1}\left[\frac{F_{il}\left[E/(1-D),t\right]-F_{il}(eE_k,t)}{1-F_{il}(eE_k,t)}\right]p(e)\,de\,dE_k}{\int_{0}^{E_i^{*}}p(E_k)\,dE_k} \tag{5}$$

and

$$D=\left[\frac{2\gamma(1-D)}{(2\gamma-5D+5)}\frac{eE_k}{E}\right]^{\frac{2\gamma}{5}} \tag{6}$$

where E_{il}^{*} is the maximum fracture energy of particles contained in class $i\ l$, which is equal to $E_{\max,il}$ in the first time interval and $F_{il}(E_{il}^{*})=1$ as comminution progresses (Tavares and Carvalho, 2009). D is the damage accumulation parameter, given by a model based on continuum damage mechanics (Tavares and King, 2002; Tavares, 2009), where γ is the only material-specific constant. The model is able to account for the fact that particles that are stressed but that do not fracture in a stressing event, may become progressively weaker. The various terms in Equation (2) are given by

$$G_{il}(t)=\frac{\omega\Delta t}{M(t)}w_{il}(t)(1-\kappa_{il})\int_{0}^{\infty}m_i(E)\,p(E)\int_{0}^{1}\left[1-F_{il}(eE,t)\right]p(e)de\,dE \tag{7}$$

which is the fraction of material in the class that has been damaged but remained in the original size range, and

$$H_{il} = \frac{\omega \Delta t}{M(t)} \left[\sum_{j=1}^{i} w_{jl}(t) \int_0^{\infty} m_j(E) p(E) \int_0^1 b_{ijl}(eE,t) F_{jl}(eE,t) p(e) de\, dE + A_{il,s} \right] \tag{8}$$

which is the fraction of material that appeared due to body and surface breakage, and

$$I_{il}(t) = \frac{w_{il}(t)}{M(t)} \left(M(t) - \omega \Delta t \int_0^{\infty} m_i(E) p(E) dE \right) \tag{9}$$

which is the fraction of material that was not captured in the time interval, and

$$Q_{il}(t) = \frac{w_{il}^{in}(t) W^{in}(t) \Delta t}{M(t)} \tag{10}$$

which is the mass fraction of material that enters the comminution equipment.

2.2. Batch grinding equation

In the case of a ball mill operating in batch mode, Equation (1) may be written as

$$\frac{dw_{il}(t)}{dt} = \frac{\omega}{M} \left[- D_{il,b}(t) - D_{il,s}(t) + A_{il,b}(t) + A_{il,s}(t) \right] \tag{11}$$

as the mill hold-up M remains constant and no material enters or leaves the mill.

Unfortunately, no generally well-accepted functions are available to calculate $m_i(E)$ and $p(e)$. The mass of material captured $m_i(E)$ in the active breakage zone in each collision event is probably influenced by contact geometry, size distribution of particles inside the mill and the friction coefficient between balls and particles (Schönert, 1979). This mass may be calculated by $m_i = N_{cap,i} \overline{m}_{p,i}$, where $N_{cap,i}$ is the number of particles captured in a stressing event, which may be estimated by considering that the finer the size of particles in comparison to balls, the larger their number. A relationship of this type is

$$N_{cap,i} = 1 + a (d_b / d_p)^b \tag{12}$$

where parameters a and b should be fitted to experimental data (Tavares and Carvalho, 2009). $p(e)$ allows to consider that particles involved in each collision inside a mill absorb different proportions of the stressing energy, according to their radial position. A simplifying assumption found to be reasonably valid (Tavares and Carvalho, 2009) is that the stressing energy is split equally among particles positioned within the active breakage zone in the mill. In this case the energy distribution function may be given by

$$p(e) = \delta \left(e - 1 / N_{cap,i} \right) \tag{13}$$

where δ is the Dirac delta function.

Parameters describing the material response to stressing have been determined using fundamental characterization tests, described elsewhere (Tavares, 2007).

3. Results and Discussion

The microscale model was verified by comparing batch grinding results to model predictions calculated using Equation (11). The complete list of material characterization parameters and the DEM collision energy distribution used in the simulations is given elsewhere (Tavares and Carvalho, 2009). Figure 1 shows that the model predicted fairly well the variation of the size distributions with time for grinding

of two different materials and initial sizes (copper ore -1.68 mm and granulite -4.75 mm), specially considering that it required no fitting to batch grinding data. Table 2 shows the parameters used in these simulations.

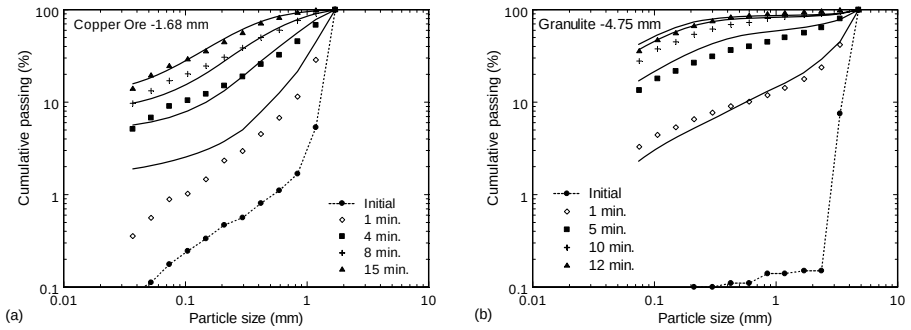

Figure 1. Comparison of measured and simulated results of batch grinding of -1.68 mm copper ore (a) and -4.75 mm granulite (b) in a 30x30 cm ball mill equipped with four lifters and running at 67% of critical speed at 30% mill filling and 100% voids filling.

The full dynamic version of the microscale model has been used to simulate a continuous laboratory ball mill operating with no internal classification. In this simulation, the mill is modelled as a perfect mixer and the relationship between the hold-up and the discharge rate is given by (Carvalho and Tavares, 2006)

$$W_{out}(t) = 0.015\left[M(t)/M*\right]^{1.5} \tag{14}$$

where $M*$ is a reference weight (1.0 kg) and W_{out} is given in kg/min.

The simulations consider that the feed is made up of two components, where component 2 has 50% lower fracture energies than component 1 and particles contained in a single size range (1.68-1.18 mm) are fed to the mill. After being initially fed exclusively by particles of component 1, the feed then becomes equally composed of particles of both components after 5 minutes of grinding. As expected, Figure 2 shows that the product size distribution, characterized by the 80% passing size increases continuously, given the lower average fracture strength of the material entering the mill. Figure 2 also shows that mean fracture energy of particles contained in the third size class increase as a result of the change in feed composition.

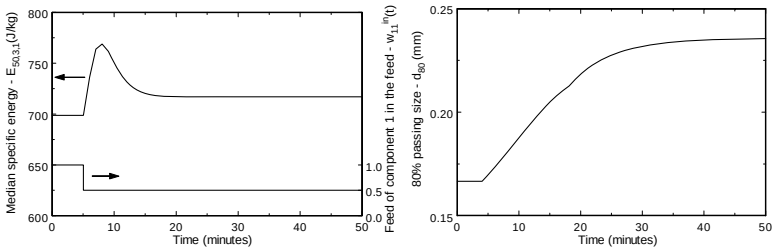

Figure 2. Variation of d_{80} and E_{50} as a function of time for a change in feed composition after 5 minutes of grinding (W_{in} = 0.18 kg/min, M = 5.24 kg)

Table 2. Model parameters used to simulate batch grinding data displayed in Figure 1a and 1b.

Material	Batch mill parameter	Material parameters						
	ω (impacts/s)	ρ (g/cm^3)	E_∞ (J/kg)	d_o (mm)	ϕ (-)	σ (-)	γ (-)	κ (%/s)
Granulite	230000	2.80	123.0	0.91	1.68	0.76	5.0	0.004
Copper ore		2.93	206.7	20.30	0.68	0.74	4.5	0.011

4. Conclusions

A general microscale breakage model that can be used to describe size reduction in different types of crushers and grinding mills was proposed. The model was applied to describe size reduction in ball mills operating both batch and continuously. The validity of the model has been demonstrated by the good correspondence between measured and simulated size distributions from grinding a copper ore in a batch laboratory ball mill.

Although the validation of the full dynamic approach of the proposed model is still a work in progress, which demands intensive experimental tests, this model formulation has been used to simulate a small laboratory ball mill subject to a step change in feed composition (fracture energy), and the results demonstrate that the mill product responds to this variation, in spite of a constant feed rate.

Provided that appropriate information exists that allows describing the milling environment under, for instance, different conditions, such as mill diameter, mill filling, ball size distribution and liner design, the model developed should enable predicting full-scale grinding exclusively using characterization data from small-scale breakage tests.

Abstract

The determination of the optimal coagulant dosage in the coagulation process of a water treatment plant (WTP) is very essential to produce satisfactory treated water quality and to maintain economic plant operation such as reducing manpower and expensive chemical costs. Failing to do this will also reduce the efficiency in sedimentation and filtration process in the treatment plant. Traditionally, jar test is used to determine the optimum coagulant dosage. However, this method is expensive, time-consuming and does not enable responses to changes in raw water quality in real time. Modeling such as neural network can be used to overcome these limitations. In this work, an inverse neural network model is developed to predict the optimum coagulant dosage in Segama WTP in Lahad Datu, Sabah, Malaysia. Real data from the WTP was obtained along with extensive data analysis and preparation, significant input-output selection and consideration of important raw and treated water lag parameters were carried out. The modeling results shown that the prediction capabilities are improving with the consideration of appropriate input parameters. Neural network models with different network architectures, including single and two hidden layers were developed and the optimum network architecture obtained was [11-27-9-1]. This model performed very well over the range of data used for training, with r-value of 0.95, mean square error (MSE) of 0.0019 and mean absolute error (MAE) of 0.024 mg/l when applied on the testing data set. Hence, the proposed techniques can significantly improve and have a great potential of replacing the conventional method of jar test due to its advantages; quick responsive tools, economical operating cost and its ability to be applied in real time process.

Keywords: Water treatment plant; Coagulant dosage; Artificial neural network; Inverse model.

1. Introduction

The water industry is working very hard to produce high quality of drinking water at a lower cost in order to meet the mandatory drinking water quality standard. The treatment of water involves physical, chemical and biological changes which will transform raw water into safe drinking water.

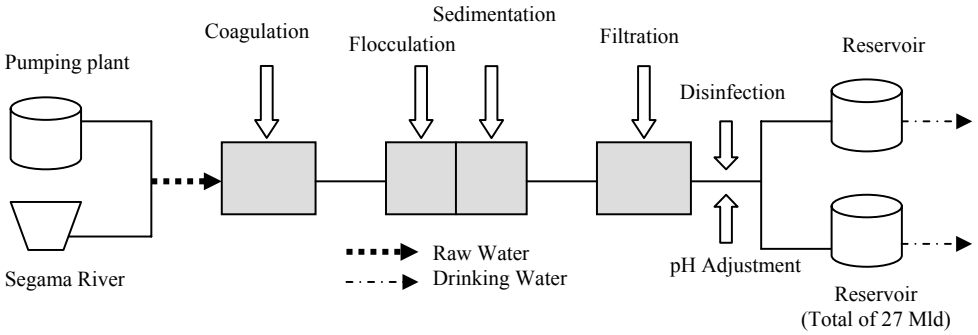

Figure 1: Segama WTP unit processes

A conventional water treatment process normally consists of coagulation, flocculation, sedimentation, filtration, pH adjustment and disinfection processes. The sequence of the treatment processes is shown in Figure 1. Among all processes involved in the treatment plant, coagulation process can be considered as the most important stages as it allows the removal of dirt and colloidal particles. Good coagulation control is very essential to produce satisfactory treated water qualities and to maintain economic plant operation. On the other hand, poor control of the same will cause wastage of chemicals, low water quality and failure in sedimentation and filtration processes.

Traditional method of controlling coagulant dosage relies very much on manual method called jar test (Baxter *et al.,* 1999; Joo *et al.,* 2000; Yu *et al.,* 2000). However, disadvantages associated with jar test are the necessity to rely on manual intervention and lack of adaptation to abrupt changes of raw water characteristics (Valentin *et al.,* 1999). Furthermore, conducting too often jar testing will consume a lot of chemicals for testing, contribute to higher electricity bills and also require an experienced manpower to obtain good results in determining the required coagulant dosage.

Since the coagulation process involve complex chemical and physical phenomena, therefore conventional process control used in chemical engineering is difficult to be applied (Mirsepassi *et al.,* 1995). The limitations of jar test for determining optimum alum dosages can be overcome by using artificial intelligence models such as Artificial Neural Network (ANN) (Yu *et al.,* 2000; Maier *et al.,* 2004).

2. Overview of Segama Water Treatment Plant

Operating data of Segama WTP, a plant which is managed by Lahad Datu Water Supply (LDWS) were used in this analysis. The treatment plant has the capacity of 27 million liters and operating on a 24 hour basis in order to serve a population of about 130,000 in the Lahad Datu District. The raw water comes from Sungai Segama; about 1 km away from the treatment plant area. A large proportion of the upstream watershed is uninhabited mountains and forest, palm oil plantations and mills, marbles factory and with little municipal or industrial development. The major source of upstream contamination is run-off from forested and agricultural lands.

3. Methodology

In order to predict the coagulant dosage required for any characteristic of incoming raw water into the treatment plant, thousands of potential data sets for the year 2005 was obtained. The available data sets were analyzed statistically using Microsoft Excel and

MINITAB 14 software to remove any major outliers and to select the appropriate input-outputs variables of the proposed model.

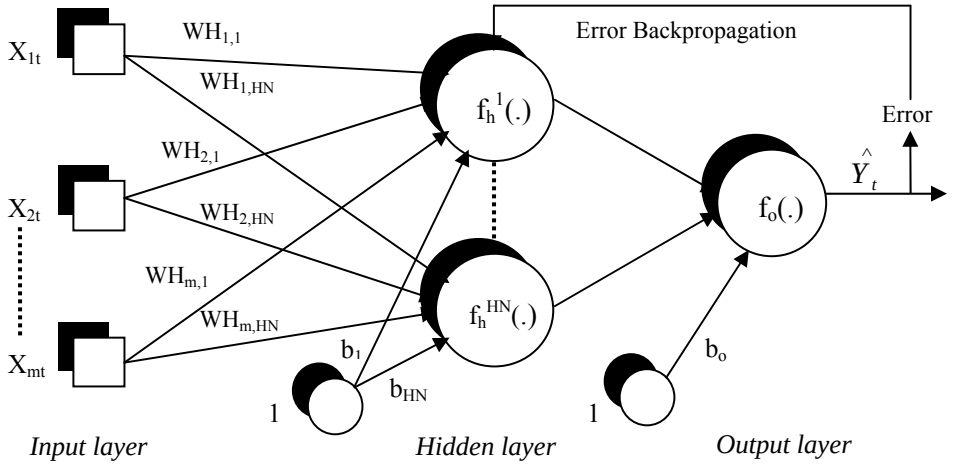

Figure 2: Architecture of multilayer feed forward neural network

All of the data were normalized linearly between 0.0 and 1.0 in order to overcome the significant minimum and maximum values used in the training process and to be commensurate with the limits of the log-sigmoid activation function in the hidden and output of neural network layers. Later, those preprocessed data were divided into training, validation and testing sets for modeling purposes. The neural network architecture which was used in this study is demonstrated in Figure 2, which consists of three layers; input, hidden and output layers. However, network with two hidden layers were also investigated. The hidden layer(s) also consist of PEs and carry out several calculations. The output, $\hat{Y}_t$ of the above neural network model, with one hidden layer and one output neural network is given by the following:-

$$\hat{Y}_t = f_o\left[\sum_{j=1}^{HN} WO_j \times f_h\left(\sum^{m} WH_{ij} \bullet X_{it} + b_j\right) + b_o\right] \tag{2.1}$$

where WH_{ij} is the weight of the link between the i^{th} input and the j^{th} hidden neuron, m is the number of input neurons, WO_j is the weights of the link between the j^{th} hidden neuron and the output neuron, f_h is the hidden neuron activation function, f_o is the output neuron activation function, b_j is the bias of the j^{th} hidden neurons, b_o is the bias of the output neuron, and HN is the number of hidden neurons. The equation of log-sigmoid function, which was used as the transfer function for both hidden and output layers;

$$f(x) = \frac{1}{1+e^{-x}} \tag{2.2}$$

The Matlab® R2006a package was used to develop the ANN process inverse model in a desktop computer with specification of Intel® Core(TM)2 CPU 1.86GHz and 1 GB of RAM. The ANN architecture used is supervised multilayer of feedforward network, and trained using Levenberg-Marquardt training function. In model training, the objective is

to find the appropriate weights and biases which will be further used in the model validation prior to testing phase. The best model architecture was found by cross validation technique, based on its error performances in term of mean square error (MSE), mean absolute error (MAE) and correlation coefficient of r-values between target and network output, all of which targeting the predetermined network goals. To reduce the network complexity, some of the less significant input variables were removed via backward elimination of stepwise regression analysis. Performance of the neural network model was compared among the model developed prior and after the inputs elimination.

4. Results and Discussion

4.1. Data Analysis and Preparation

Ranges of the available raw and treated water parameters as well as the coagulant dosage which covers and represent various operating conditions for the whole year of 2005 are shown in Table 1.

Table 1: Ranges of available data sets, 2005 (Robenson *et al.*, 2006)

	Raw Water					Treated Water						Coagulant Dosage
	pH	Turb (NTU)	Col (HU)	TDS	Alk (mg/l)	pH	Turb (NTU)	Col (HU)	TDS	Alk (mg/l)	Al res (mg/l)	Alum (mg/l)
Min	6.6	11	36	60	50	6.5	0.19	0	90	20	0.01	20
Max	7.9	3405	656	160	170	7.5	5.24	6	170	100	0.2	170

Notation: Turb = Turbidity, NTU = Nephelometric Turbidity Unit, Col = Color, HU = Hazen Unit, TDS = Total Dissolved Solids, Alk = Alkalinity, Al res= Aluminum residue

The quality of the raw water parameters is very uncertain due to natural perturbations and very much affected by the upstream activities of Segama River like palm oil plantations and its mills, marbles factory as well as logging activities. Three main parameters which give great effects in the determination of coagulant dosage i.e. pH, colour and turbidity (Zhang and Stanley, 1997) have shown unpredictable values and very uncertain throughout the calendar year.

The colour and turbidity values keep fluctuating over the year with values ranges from 11 to 3405 NTU and 36 to 656 HU respectively. Even though the plant operation manage to treat the water and producing acceptable drinking water qualities, fluctuations of raw water qualities give difficulties to the plant operators as they will only rely on conventional method of jar tests to determine the best coagulant dosage. Selection of significant input-output parameters was made based on the available literatures, priori knowledge and analytical studies of correlation coefficient.

Among the initial 18 inputs which were used to develope the model, 7 less significant input variables were eliminated based on the stepwise regression of forward and backward elimination. The remaining 11 significant inputs which were used in the model development are RW pH (t) and (t-1), RW Turbidity (t), (t-1) and (t-2), RW Colour (t) and (t-1), TW Turbidity, TW Colour, Alum Dosage (t-1) and (t-2).

4.2. Results of Process Inverse Model

The best network architecture found was [11-27-9-1] with MSE value of 0.0010. When applied to each of the data sets, the corresponding results were consistent with r-value of 0.95 for both the validation sets as well as the testing set. Similarly, the MAE for all data sets was quite small and ranged from 0.015 mg/l to 0.026 mg/l. This suggests that the model architecture is reliable and can be further applied in the real-time plant operation. The trained network was tested by comparing the simulated predictions to the measured values of coagulant dosage using the testing set and the results are presented graphically in Figure 3. The model follows the trends in the actual coagulant data quite well and accurate.

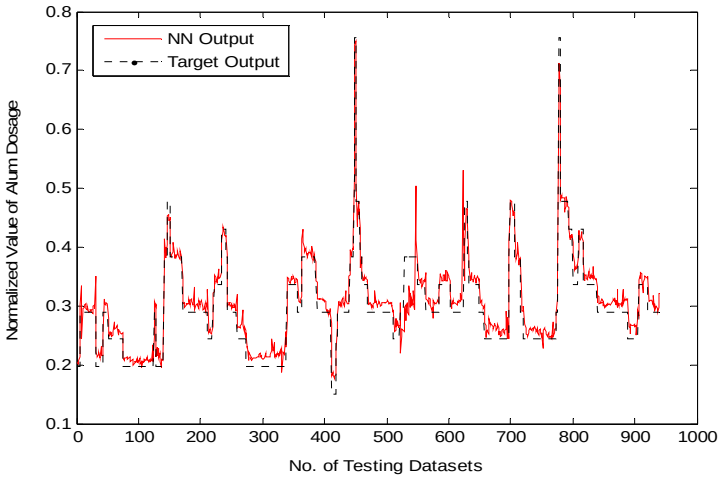

Figure 3: Comparison of actual & predicted coagulant dosage on testing set [11-27-9-1]

In order to ensure that there are no obvious trends in the model residuals, a plot of the residuals across all of the data patterns in the testing set is presented in Figure 4.

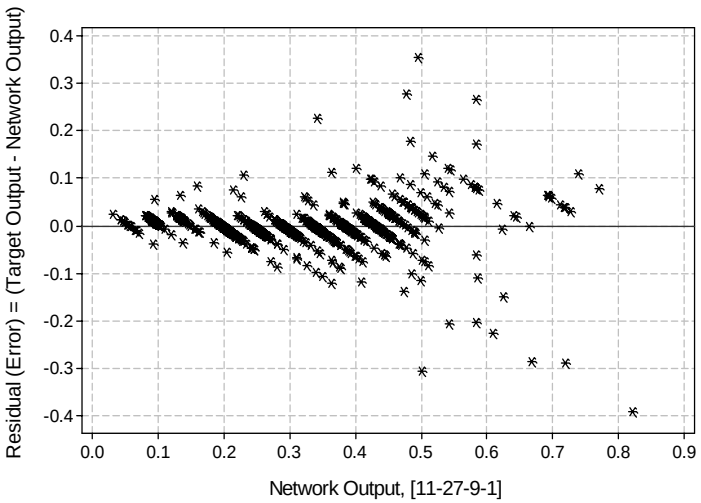

Figure 4: Residual plot of network output on [11-27-9-1]

The prediction capability is confirmed since almost all samples do not diverge from the range [-0.1 mg/l, 0.1 mg/l] of the residual plot. This result is better than the residual range obtained by Lamrini *et al.* (2005), which was [-0.3 mg/l, 0.3 mg/l]. The network with 11 inputs is performed better compared to the models with 18 inputs because those eliminated input parameters may have so many noises or outliers which make them less significant and contribute to poor generalization of the network. Furthermore, those noises will limit the accuracy of generalization that can be achieved no matter how extensive the training set is (Sarle, 2002).

5. Conclusion

Thousands of raw and treated water data sets from Segama Water Treatment Plant, Lahad Datu, Sabah have been used in the development of inverse neural network models, to predict the optimum coagulant dosage in the plant. The results obtained from the models indicate that it is capable of producing accurate predictions over the range of the data used in model training. With the application of such models in water treatment plant, difficulties associated with conventional method, jar test can be overcome due to its advantages; quick responsive tools, economical operating cost and its ability to be applied in real time process.

Abstract

A distillation column is a complex multivariable system and exhibits nonlinear dynamic behavior due to the nonlinear vapor-liquid equilibrium relationships, the complexity processing configurations and high product purities. In order to gain better product quality and lower the energy consumption of the distillation column, an effective nonlinear model based control system is needed in order to allow the process to be run over a large operating range. The availability of a suitable nonlinear model is crucial important in the development of a nonlinear model based control. Neural networks framework have been used extensively in nonlinear process model development. In this paper, the multiple-input multiple-output (MIMO) neural network model to predict the top and bottom product compositions of a methanol-water pilot plant distillation column was developed. The neural network approach was applied by previous researchers in the development of nonlinear model for continuous distillation column based on simulation data (Yu, 2003; Singh *et al*., 2005 and Singh *et al*., 2007). However, only a handful of works have been carried out to validate the model with real plant data. The validation of the model with real data was important in order to ensure the ability of the model to represent the real processes being considered. Therefore, experimental works was carried out to separate the methanol water mixture in a continuous pilot plant distillation column. The error between the model and the actual pilot plant data was observed.

Keywords: Pilot Plant Distillation column, Modeling, MIMO.

1. Introduction

Distillation columns are fairly complex units and exhibit nonlinear dynamic behavior due to their nonlinear vapor liquid equilibrium relationships, the complexity processing configurations (e.g., prefractionators, sidestreams and multiple feeds) and high product purities (Luyben, 1987).). The dynamics of the distillation column that is variations in time constants with the size and direction of an input change are caused by a mixture of very fast vapor flowrate changes, moderately fast liquid flowrate changes, slow temperature changes and very slow composition changes (Luyben, 2002).

Advanced control strategies such as model based control have been revealed as the better control systems to improve product yield, reduce energy consumption, increase capacity, improve product quality and consistency, increase responsiveness and improve process safety of distillation columns. Focusing on the distillation control problem, development of several advanced control schemes utilizing the neural network

model has been reported. Neural network technique is one of the most useful data driven model that can be utilized in nonlinear model based control system. The neural network provide powerful analysis properties such as complex processing of large input-output information arrays, representing complicated nonlinear associations among data and the ability to generalize.

The main aim of this paper is to develop a nonlinear model by using a neural network technique which is able to represent the continuous distillation column. This is based on the distinct capability of the model to capture the complex dynamic and static interactions of the input-output pattern of the distillation column. In this paper, the multiple-input multiple-output (MIMO) model is developed. The MIMO model consisted of 2 outputs; top and bottom product compositions. Reboiler heat duty, reflux flowrate and tray temperatures were selected as the inputs for the neural network model. The development of this MIMO model is focused on the selection of the input-output of the neural network and development of neural network models based on past and current input which are useful in light of the dynamic systems of the continuous distillation column. Validation with experimental data is carried out in order to determine the ability of the developed models to represent the distillation process.

2. Methodology

2.1. First principle model

The general first principle model for the distillation column which was developed consisted of a non-ideal column, a non-ideal mixture and a non-equimolal overflow (Luyben, 1989). The subroutine of the first principle model was developed in the Matlab® environment. The development of this general first principle model involved mass balance, component balance and enthalpy balance equations, the vapor-liquid phase equilibrium and liquid-hydraulic relationship resulting in 47 differential equations and sets of algebraic equations.

The nonideality of the distillation is performed using UNIFAC for activity coefficient and Peng-Robinson for fugacity coefficient. The system which was studied was a distillation column consisted of 15 trays, a reboiler and a condenser which separate methanol-water binary mixture.

2.2. Input-output selection

It is imperative to select variables that are relevant to the output so that possible model structures can be determined. Reflux rate, reboiler heat input and tray temperatures were selected as the inputs meanwhile top and bottom composition were selected as the output of the neural network model developed. These variables were chosen based on variables analysis of first principle model. Analysis results show that these variables play the prominent role in separation performance and have great effect on product quality.

2.3. Data collection

Different patterns of input variables were generated in order to provide sufficient information to identify the dynamic nonlinear behavior of the distillation column. Several reboiler heat input and reflux flowrate profiles were designated to excite the first principle model and the changes were made simultaneously for these two variables. The profiles considered were random, step change, staircase and pseudo random multilevel sequence. These profiles were selected because they provide a large range of

values. These characteristic is also important since strong input is needed for nonlinear system identification. Seven sets of data with different reflux flowrate and reboiler heat input profiles were generated from the simulation of the general first principle model. The reboiler heat input was varied from 11.25kW to 12.75kW and the reflux flowrate was varied from 0.54kmol/hr to 1.08kmol/hr. These sets of data were divided into three groups: training, validation and testing.

2.4. Neural network model development

Computational programs for designing the neural networks are implemented step by step in MATLAB® to find the suitable model for identification of distillation column. The toolbox, MATLAB®'s pre-defined functions is used to provide tools for design the neural networks model. One hidden layer feedforward neural network model was proposed in this study since two hidden layers rarely improve the model and may introduce a greater risk of converging to local minima. Sigmoid activation functions were used for the hidden and output layers.

The procedure to develop the optimum neural network model started with training process to select the structure of the neural network model. The Levenberg-Marquardt training algorithm is adopted to train the neural networks. The structure was determined by the number of neurons in each layer of the model which was determined by trial and error because this is the most widely used method for optimum topology selection (Miller *et al*., 2005) and the most efficient way has not be established yet. The structure was determined based on the performance of the model to predict behavior based on independent or validation data. The best topology was defined as the one that gives the largest correlation coefficient (R value) and the smallest sum squared error (SSE) value during the validation process. This method is known as the hold out method (Bishop, 1995).

2.5. Input-Output Scheme of the Neural Network Model

In this study, The inputs to the neural network models considered were the past value of the top and bottom compositions data, reflux rate (R) and reboiler heat input (QR) at two time instants, reboiler temperature (TB) and condenser temperature (TD) at three time instant and four tray temperatures; T2, T6, T10 and T14. The past values of the variables were included as model inputs. Using the current and one past (historical) sample of each variables permit for a limited degree of gradient information i.e. are given an idea of the recent rates of changes of each variable, will provide useful in light of dynamic systems, though it is not apparent that this particular choice is optimal (Kershenbaum and Magni, 2001).

The MIMO model can be presented as the following function respectively:

$$\left[xD(t), xB(t)\right] = f\begin{pmatrix} xD(t-1), xB(t-1), R(t), R(t-1), QR(t), QR(t-1), TD(t), TD(t-1), \\ TD(t-2), TB(t), TB(t-1), TB(t-2), T14(t), T10(t), T6(t), T2(t) \end{pmatrix}$$

3. Results and discussions

3.1. Training Performance

Table 1 tabulates the correlation coefficient, the R-value and the sum squared error, SSE between the validation data and the neural network output. These two characteristics

represent the performance of the model and were used in this paper for validation and testing of the MIMO model.

Due to the validation process which involved two sets of data, the performance of the network was determined based on the average of the R-value and the sum squared error for both sets of data. The numbers of hidden neurons considered were 10 to 21 because the neural network did not converge when the number of neurons was reduced to less than ten. Increasing the neurons to more than 21 did not improve learning; instead it increased the total training time.

From the results, it was found that the MIMO model with 18 neurons in the hidden layers was the optimum network architecture since it gave the highest average R-value of 0.983 and the smallest average SSE of 1.72×10^{-4}.

Table 1: R-value and SSE of MIMO model for different numbers of hidden neurons

Architecture	Average R-value	Average SSE
16-10-2	0.982	0.000181
16-11-2	0.945	0.000483
16-13-2	0.971	0.000525
16-14-2	0.912	0.000811
16-15-2	0.938	0.000657
16-16-2	0.982	0.000227
16-17-2	0.935	0.000836
16-18-2	0.983	0.000172
16-19-2	0.972	0.000888
16-20-2	0.975	0.0014
16-21-2	0.904	0.00131

3.2. Testing Results

In order to observe a better network generalization ability, the MIMO networks were tested with testing data which was independent of the training and validation data. This was carried out in order to confirm the performance of the network selected (Bishop, 1995).

The testing results for the MIMO models are summarized in Tables 2. The performance of the model during the testing process for the top and bottom product compositions estimation using the MIMO and models are illustrated in Figures 1. The figure shows the deviation of the current value of the top and bottom product compositions in the particular time instant from the steady state value for the testing data and the neural network output.

Table 2: Testing results for MIMO-1 model

Architecture	Architecture	R-value	SSE ($\times 10^{-4}$)
Top product composition	16-18-2	0.992	8.02
Bottom product composition		0.993	1.00

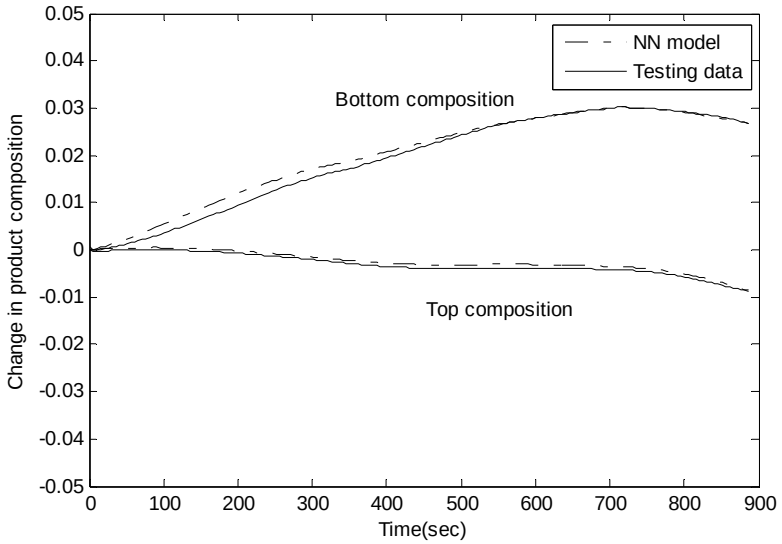

Figure 1 Testing performance of MIMO model

3.3. Comparison with Experimental Data

The comparison of the model with the experimental data was made by observation of changes in products compositions in changes of selected parameters within a certain period of time after the steady state condition as achieved. Figures 2 shows the deviation of the current value of the top and bottom product compositions in the particular time instant from the steady state value for the experimental data and the model output. Based on these figures, the trends in compositions obtained through the simulation of the neural network models were in good agreement with those found by experimental studies even though small deviations were observed. One possible reason for this mismatch is due to the choice of the number of historical data used.

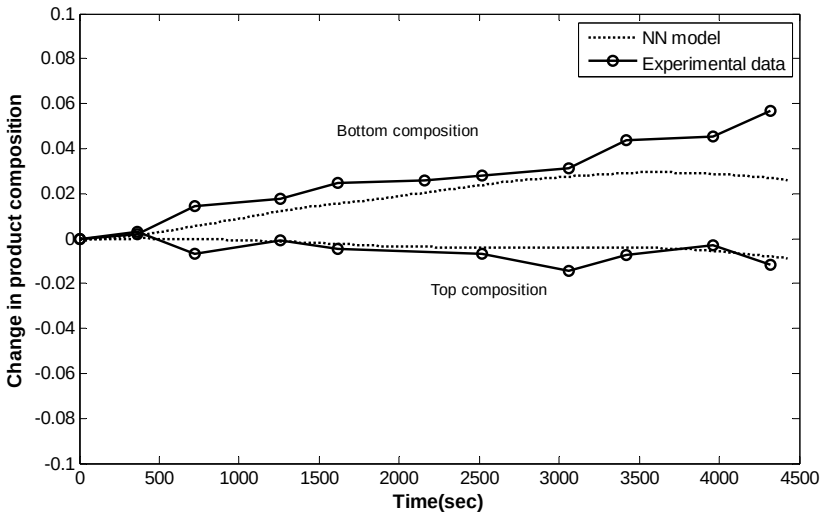

Figure 2 Comparison of the MIMO-1 model with experimental results

4. Conclusion

The MIMO model was found to be able to predict the top and bottom product composition precisely. From the results, it was observed that the model output closely followed the testing data trends. The R-value was 0.992 for the estimation of top product composition and the SSE was 8.02×10^{-4}. For the bottom product composition, the R-value and SSE were 0.993 and 1.00×10^{-4} respectively. The results showed that the MIMO models developed was in good agreement with the experimental data. The results obtained in this study proved that this neural network model could be used to represent the distillation process.

Abstract

The paper presents a case based reasoning (CBR) tool designed for the identification of crucial information for the modelling of pollutant transport in rivers. The developed CBR tool is using a case base comprising published information. This information regards pollutant transport modelling work carried out for different rivers. The models from the case base are designed for a specific river reach. For an unstudied reach it is possible to find a model for pollutant transport based on the comparison between the characteristics of that river reach with the characteristics of the already studied reaches, stored in the case base. The reaches of Somes River were compared against the reaches in the case base, and information for pollutant transport modelling was identified. The developed tool is also applicable in the case of other rivers were no detailed concentration measurements are available and the mathematical models for pollutant transport are needed.

Keywords: pollutant transport modelling, water quality modelling, case-based reasoning, Somes River.

1. Introduction

This work is motivated by environmental and as well economic issues encountered in the everyday environmental management. In this field the water quality assessment is essential, and the experience in solving problems related to river pollution shows that mathematical models for the evaluation of pollutant concentration along river are very important. The specific models for pollutant transport are needed for every studied river. However, the development of such models requires a lot of time and resources.

Our aim is to use the existing knowledge in order to identify the most suitable pollutant transport models for the Romanian Somes River. To achieve this goal the case based reasoning (CBR) approach is being used. The method is based on the idea that the similar problems have the similar solutions. According to the present literature, CBR is being applied in multiple engineering fields in order to find solutions for new problems using the past experience (Avramenko and Kraslawski, 2008; Botar-Jid, 2007).

In the field of water quality modelling Chau (2007) presents a prototype knowledge management system (KMS) useful for the selection of models and parameters for coastal hydraulic and transport processes. This KMS employs the principles of CBR to extract information from a knowledge base comprising 11 scenarios related to the water quality (e.g. flood forecast, water pollution and eutrophication). In the presented paper, the case base is much bigger and the CBR is going to rely on the similarity between the characteristics of river reaches in order to find suitable models for pollutant transport in

Somes River. According to our literature survey no similar CBR tools have been developed yet.

The Somes River, one of the most important rivers in Romania, covers an area inhabited by approximately 2 millions people. The river has to be subjected to an increased attention, due to the accidents which took place, and found the authorities in charge unprepared (Moldovan, 2006). Another reason is the continuous pollution taking place along the river branches due to the increasing industrialization and urbanization (Moldovan, 2006; Serban and Rosu; 2005). Consequently, a good model is needed for the assessment of the water quality. The literature search on Somes River reveals the existence of works aimed at the assessment of the water quality (Moldovan et al., 2007; Laszlo, 2006; Serban and Rosu; 2005; Ponta et al., 2003), but there are no studies focused on the modelling of pollutant transport.

The models for pollutant transport are very complex due to the large number of factors affecting the transport, the variable geometry of the channel along the river, and the multiple phenomena occurring simultaneously: convective-diffusive mass transport, physical processes, chemical and biochemical transformations (Socolofsky and Jirka, 2005). The model has to rely on field data in order to obtain the best estimates of the parameters and a high accuracy of the concentration prediction (Lee and Seo; 2007; Socolofsky and Jirka, 2005). This kind of data is obtained through high frequency monitoring of the concentrations along large river distances. Such approach requires time and resources and sometimes is difficult to carry out. The existing data for the Somes River consists of: (1) pollutant concentration data collected on a monthly basis in just 12 monitoring points along 421km; and (2) measurements of the channel features. This kind of data could be used to test a model, but not to build a reliable one.

Usually, the mathematical models for pollutant transport in the rivers rely on variables capturing the river channel characteristics as well. As the geometry of the channel could be similar from one river reach to another one, a solution to overcome the lack of data is to use the already validated models. For the case of Somes River, or any other case where data are missing, it is possible to implement the old, commonly-accepted models. These models will be identified and selected using CBR.

2. Method description

The identification of the models for pollutant transport in Somes River requires several research steps including (1) the division of the river length into five reaches; (2) building a case base; (3) the development of the CBR tool and (4) the comparison of the stored cases with the reaches of the Somes River in order to (5) identify the most similar cases and (6) retrieve the model description and related information from the sources.

The case base is built using information from the published literature and from existing databases about rivers. There are rivers which have been the subject of water quality modelling work, and can be used as old, solved cases in the present research. The information related to the problem statement and to the assigned solution for each case is stored in the case base. Our interest is focused on the details related to: the mathematical models for pollutant transport; models for the calculation of the transport parameters (water velocity, dispersion coefficients) and models for the transformations suffered by the pollutant during the transport.

Each stored case is characterised by the following variables corresponding to the investigated river reach: channel width, river bed slope, water depth, reach's length, width to depth ratio, mean water velocity, and longitudinal dispersion coefficient. The Somes River reaches are also assigned with values corresponding to these variables.

Further on each river reach from the case base is compared against the reaches of the examined river (in this work – Somes River), in order to find the most similar stored cases for each of the reaches. The similarity value between two river reaches (equation 1) is calculated as a weighted sum of similarity measures corresponding to the parameters of the reaches (a_i, b_i for A and B respectively):

$$SIM(A,B) = \sum_{i=1}^{k} w_i \cdot sim(a_i, b_i) / \sum_{i=1}^{k} w_i \quad (1)$$

where w_i is the weight of importance of parameter i; sim_i is the similarity function for the parameters; k is the number of parameters.
The similarity function for the parameters is based on the difference between the solved case and the new one. The smaller is the difference the bigger the similarity is. The similarity *sim* for two parameters *a* and *b* is defined as:

$$sim(A,B) = 1 - \frac{|a-b|}{range} \quad (2)$$

where *range* is the difference between maximum and minimum values in the overall set of parameters' values.
More details about the CBR approach and the development of the CBR tools are provided in Avramenko and Kraslawski (2008), Avramenko and Kraslawski (2006), and Botar-Jid (2007).
The solutions assigned to the cases with the highest similarity degree are further used in order to formulate the mathematical model for pollutant transport in the Somes River. After solving the problem of pollutant transport in the Somes River the five investigated reaches are going to be added to the case base, and further used in studies related to the modelling of pollutant transport in other rivers.

3. Results and discussions

3.1. The Somes River reaches

The measurements show that Somes River has a non-uniform channel geometry, which is causing the longitudinal variability of characteristic parameters of the pollutant transport and makes the modelling task more difficult. The approach to use in these complex cases, firstly suggested by Fischer and colleagues (1979), is to split the river into reaches, according to the characteristics of each river fragment.

Table 1 Normalized parameters of the reaches of Somes River

Reach number	Reach length [km]	Width	Depth	Slope	Width/ Depth	Flow rate -average-	Flow rate –min–	Flow rate -max-
1	90	0.16	0.19	1.00	0.82	0.11	0.138	0.053
2	80	0.42	0.51	0.18	0.82	0.19	0.290	0.118
3	8	0.58	0.83	0.09	0.70	0.43	0.489	0.401
4	59	0.78	1.00	0.10	0.78	0.70	0.715	0.723
5	113	1.00	1.00	0.07	1.00	1.00	1.000	1.000

Somes was preliminarily divided into five reaches of unequal length, as presented in Table 1. The CBR approach is used to find the suitable models for each reach.

3.2. The case base

The case base contains 147 cases regarding studies on the convective-diffusive pollutant transport. One river could be represented as different cases if it consists of multiple reaches studied on different occasions.

Most of the stored cases (90 cases) provide information about the estimation of dispersion coefficients. This knowledge can be used to formulate the models for parameter estimation which is included in the pollutant transport models. Other 26 cases are related to travel time studies, the velocity depending on the river morphology or tracer experiments. The most important stored cases (31 cases) are presenting details about pollutant transport modelling, including employed equations, initial and boundary conditions, pollutant transformation models and/or parameter estimation models.

The case base is implemented as Microsoft Excel workbook.

3.3. The CBR tool

The CBR tool is a single computer application with supplemented data files (e.g. the case base, the literature sources).

The tool is able to perform the following tasks: (1) to import the data from Excel documents or set of text files with parameters of the river reaches; (2) to compare the input (or import) parameters of a specific river reach against those in the case base; (3) to rank the cases according to the value of similarity to the case under consideration; (4) present the most similar cases; and (4) retrieve information from the data source (usually a PDF file).

3.4. The most similar cases and utility for the Somes River reaches

The CBR tool ranked all stored cases according to the similarity to the Somes River reaches. For each reach the three cases assigned with the highest similarity value are listed in Table 2. The first column contains the name of the river reach (as it was stored in the case base), the second column contains a synthesis of the available information, then the level of similarity is listed, and in the last column is mentioned at least one of the used references.

The results reveal that the models developed for the Swale, Rhine and Ebro rivers are the most appropriate to use in the modelling of the pollutant transport in Somes River. By analysing the similarity level two approaches could be proposed for the models allocation to the Somes River reaches. In the first approach the existing model for Swale 3 is used for reach #1; Swale 4 for reach #2; Rhine 4 for reach #3 and Ebro 2 for reaches #4 and #5. In the second approach the model for Swale 3 is used for reach #1, Rhine 4 for reaches #2 and #3 and Ebro 2 for reaches #4 and #5.

Since the order of the Somes reaches is in relation to distance from the spring it could be stated that the model from case Swale 3 is suitable to model the beginning of Somes River (reach #1), model from case Rhine 4 could be applied for the upper middle part of the river (reaches #2 and #3), and for the downstream end (reaches #4 and #5) the model from case Ebro 2 can be used.

4. Conclusions

The paper presents the development and application of a CBR tool for the identification of pollutant transport models for the reaches of Somes River. The results reveal that the prior developed models for the reaches of the rivers Swale, Rhine and Ebro could be applied to the reaches of the Somes River in further research studies. The developed CBR tool has general applicability with respect to river reaches, as it could be used to propose pollutant transport models also for other rivers than Somes.

Abstract

In order to develop optimization models for process industries, detailed hybrid modelling providing accurate descriptions of processes is required, where the simplest part of the model is represented explicitly in an equation-oriented environment whilst detailed calculations, e.g. enthalpies, kinetics, equilibrium and efficiencies, are programmed by external implicit functions. The two main objectives of our work have been: i) the development of such hybrid modelling environment, and ii) implementation of efficient solution strategies in an MINLP process synthesizer MIPSYN, the successor of PROSYN (Kravanja and Grossmann, 1994), which could make solving such complex industrial problems possible. The present study focuses on the catalytic distillation processes. Since the use of a multilevel MINLP approach reduces the effects of nonconvexities, better solutions were obtained by multilevel than by single level MINLP strategies.

Keywords: Reactive distillation, NLP, MINLP, MIPSYN.

1. Introduction

Catalytic Distillation (CD) is a multifunctional reactor concept which combines distillative separation with a chemical reaction catalyzed by a solid. The combination of distillation and chemical reaction may result in some advantages over the conventional process (reactor + distillation column), namely, investment cost reduction, higher conversion, improved selectivity, or heat integration.

The MINLP optimization of a CD column has already been studied by several authors (e.g. Ciric and Gu, 1994; Frey and Stichlmair, 2000; Cardoso et al., 2000; Poth et al., 2001; Jackson and Grossmann, 2001; Sand et al., 2004). Due to problem complexity, simplified models have mostly been used in the optimization so far, which might compromise the true optimality of the solutions. Only few attempts have been made in order to use more rigorous models. In 2003, Poth et al. proposed an extension of their previous works: the MINLP problem is solved using the general algebraic modelling systems (GAMS) in combination with external functions. Gomez et al. (2006) have proposed an optimization strategy to solve the Catalytic Distillation problem using a rate-based model and stochastic optimization algorithms.

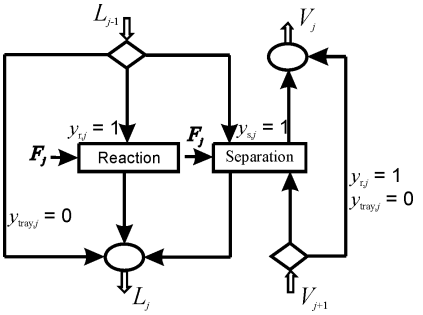
Although GAMS, as MIPSYN's interface, provides a powerful language for manipulating data and defining highly structured collections of variables and equations, there are situations when some parts of the model should be defined using FORTRAN,

C++ or some other language as user defined routines. This could be favourable because the size of the original optimization model could be significantly reduced if extensive calculations were accomplished outside the optimization model. Thus, the objective of the research has been to take advantage using such hybrid models through different advanced capabilities of MIPSYN. For example, MIPSYN allows the user to interfere and assist the optimization subiterations during the main iterations of the optimization algorithm, which significantly improves the robustness and the solution of the MINLP search. The hybrid distillation model consists of the equation-oriented part, defined by classical MESH equations, and the implicit part where rigorous sub-models are used to describe the thermodynamics, kinetics and hydrodynamics behaviour of the system, which are written in the external FORTRAN procedures, connected to MIPSYN.

2. Modelling of the tray superstructure of reactive distillation

The MINLP model of the reactive distillation column is based on the tray superstructure shown in Figure 1, where binary variables $y_{\text{tray},j}$, $y_{\text{r},j}$ and $y_{\text{s},j}$ are assigned to a tray j, a reaction stage j and a separation stage j, respectively. At every tray j, $i \in J$, three exclusive alternatives are available: a reaction stage ($y_{\text{r},j} = 1$), a separation stage ($y_{\text{s},j} = 1$), and a by-pass, ($y_{\text{tray},j} = 0$), which are combined with the following logical relation:

$$y_{\text{r},j} + y_{\text{s},j} = y_{\text{tray},j} \tag{1}$$



L ... liquid flowrate
V ... vapour flowrate
F ... feed flowrate

Figure 1: Superstructure for tray.

Many other logical constraints have to be applied as well in order to model such a tray. When separation is not selected, molar fractions for components i, $i \in C$, at a tray j in a vapour flow are the same as the ones below the tray:

$$x^{\text{v}}_{i,j} \le x^{\text{v}}_{i,j+1} + y_{\text{s},j} \quad \text{and} \quad x^{\text{v}}_{i,j} \ge x^{\text{v}}_{i,j+1} - y_{\text{s},j} \tag{2}$$

and similar constraints are given for tray temperatures, enthalpies and flow-rates. The same type of inequalities is applied also for a liquid flow when a by-pass is selected. In addition, the following constraints are applied when the reaction tray is selected:

$$r_{i.j} \le r^{\text{UP}}_{i,j}\, y_{\text{r},j} \quad \text{and} \quad r_{i.j} \ge r^{\text{LO}}_{i,j}\, y_{\text{r},j} \tag{3}$$

$$m_{\text{cat},j} \le m^{\text{UP}}_{\text{cat},j}\, y_{\text{r},j} \tag{4}$$

where r_{ij} and $m_{\text{cat},j}$ denote the reaction rate for a component i and the mass of the catalyst at tray j, respectively. There are also other logical equations, which prevent the structural multiplicity of the solutions:

$$y_{\text{tray},j} \ge y_{\text{tray},j+1} \tag{5}$$

and possibly the selection of two successive reaction trays:

$$y_{r,j} + y_{\mathrm{r},j+1} \le 1 . \tag{6}$$

The MESH equations for reaction trays are different from the ones for separation trays because there is no vapor-liquid interface, and the vapour characteristics of the tray are the same as below the tray. Therefore, some terms in the MESH equations are subtracted and, furthermore, the mass of catalyst has to be considered, e.g. as in the partial material balance:

$$L_{j-1}x_{i,j-1} - L_j x_{i,j} + m_{\mathrm{cat},j} r_{i,j} + F^{l}_{i,j} = 0 \tag{7}$$

An objective function, given below, is a cost function taken from Gomez et al. (2006) where C_i is the cost for raw materials, C_{cat} for the catalyst, C_{reb} and C_{con} for the utilities, and C_{T} and C_{SH} are the investment costs for the trays and shell, and C_{prd} for a product, respectively:

$$\min \left(\begin{array}{l} C_0 + \sum_i C_i \sum_{j=\mathrm{feed}} x_{i,j} L_j + A_{\mathrm{F}} \cdot C_{\mathrm{cat}} \cdot m_{\mathrm{cat}} + C_{\mathrm{reb}} Q_{\mathrm{reb}} + C_{\mathrm{con}} Q_{\mathrm{con}} + C_{\mathrm{T}} D^{1.55} \cdot \\ N\left(h_{\mathrm{tray}} + 1.27 \frac{W}{D^2} \right) + C_{\mathrm{SH}} D \left(h_0 + N\left(h_{\mathrm{tray}} + 1.27 \frac{W}{D^2} \right) \right)^{0.802} - C_{\mathrm{prd}} \cdot L_{n+1} \end{array} \right) \tag{8}$$

3. Connection between MIPSYN and FORTRAN

As rigorous sub-models are too complex to be represented explicitly, they are written in FORTRAN as external implicit functions. On the other hand, the conventional MESH equations are modelled in the GAMS language and represent the explicit part of the resulting hybrid model. In this way, constraints in the problem (MINLP) are decomposed into equation-oriented (EO) constraints used in GAMS, e.g. ($h_u(x_u, x_v, y) = 0$), and constraints represented in the external program, e.g. ($h_v(x_v, x_u, y) = 0$), where the suffix u is used for EO and v for the external part of the model. Similarly, the vector of continuous variables $\boldsymbol{x}$ is decomposed into $\boldsymbol{x}_u$ and $\boldsymbol{x}_v$, and the dimensionality n into n_u and n_v. When $\boldsymbol{x}_v$ is substituted by implicit functions $\Phi_v(x_u, y)$ through external procedures, the hybrid (MINLP-H) problem is defined.

$$\begin{array}{ll} \min Z = c^{\mathrm{T}} y + f(x_u, x_v) & \\ \text{s.t.} & \text{(MINLP)} \\ \quad h_u(x_u, x_v, y) = 0 & \\ \quad h_v(x_u, x_v, y) = 0 & \\ \quad g_u(x_u, x_v, y) \le 0 & \\ \quad g_v(x_u, x_v, y) \le 0 & \\ \quad x = [x_u, x_v] \in X \in R^n & \\ \quad X = X_v \cup X_u & \\ \quad x_u \in X_u \in R^{n_u}, x_v \in X_v \in R^{n_v} & \\ \quad y \in [0,1]^m & \end{array}$$

$$\begin{array}{ll} \min Z = c^{\mathrm{T}} y + f[x_u, \Phi_v(x_u, y)] & \\ \text{s.t.} & \text{(MINLP-H)} \\ \quad h_u[x_u, \Phi_v(x_u, y), y] = 0 & \\ \quad g_u[x_u, \Phi_v(x_u, y), y] \le 0 & \\ \quad x_u \in X_u \in R^{n-n_v} & \\ \quad y \in [0,1]^m & \end{array}$$

4. Strategies for MINLP synthesis of reactive distillation in MIPSYN

In our earlier attempts to solve the hybrid model for reactive distillation we were able to obtain feasible solutions only for NLPs at fixed structures with a moderate number of

trays (up to 20) applying the GAMS solver CONOPT3. Due to a variety of severe numeric problems, we could not solved the entire problem (MINLP-H), using the solver DICOPT.

In order to overcome the drawbacks, MIPSYN's outer-approximation (OA) algorithm was upgraded for the use of external routines in combination with disjunctive programming and convex hull formulation of the problem where subproblems $(NLP)^k$ are solved only for selected trays and not for the entire superstructure. This substantially reduces the effects of nonconvexities and singularities. In addition, since MIPSYN allows the user to interfere and assist the MINLP optimization, the robustness and hence chances of achieving the convergence of the MINLP search significantly increase. If the desired product purity increases, more trays have to be included in the model and the chances of obtaining the optimal solutions significantly decrease. Powerful strategies have to be implemented in MIPSYN in order to facilitate the solution procedure. They consist of different options that can easily be accommodated in the synthesizer MIPSYN:

- Interactive and automated mode of operation where the interactive one is perhaps the most important option since it enables the user to dynamically adjust the course of the optimization.
- A capability to perform the mentioned disjunctive programming with execution of only the "existing" part of the model.
- The use of different extensions of the OA algorithm with a possibility to use convexity test and the validation of the outer approximation, in order to reduce the size of the MILP master problem and reduce the undesirable effects of the nonconvexities.
- The possibility to solve feasibility problems with an augmented penalty function in the NLP and MILP master problems.
- Using different NLP and MILP solvers in sequence with different option files for the better tuning of solvers' parameters.
- Different multilevel MINLP can be implemented in the synthesizer, e.g. in our problem it consists of the execution of several sequences of MINLP iterations, each level restarting from an optimal solution obtained at the previous level.
- Additional constrained integer-cuts can also be imposed in order to limit the search to a narrower space of topological solutions.

5. Illustrative example

The illustrative example presented in this contribution is the cost minimization of ETBE production as main product. A minimum 95% molar purity of the ETBE is required. The significance of this reaction resides in the worldwide consumption of ETBE. We only consider the main reaction:

$$(CH_2)C{=}CH_2 + C_2H_5OH \leftrightarrow (CH_3)_3COC_2H_5 \tag{9}$$

The Vapour/Liquid equilibrium constant of component *i* at stage *j* $K_{i,j}$, present in the MESH equation is evaluated by an external procedure, as a function of the optimization variables (temperature, vapor and liquid composition, at a given total pressure, *P*).

$$K_{i,j} = \frac{\gamma_{i,j} P_i^{\text{sat}} \phi_i^{\text{sat}}}{\hat{\phi}_{i,j} P} \tag{10}$$

The vapour pressure (P_i^{sat}) is estimated using the Antoine equation. The activity coefficient ($\gamma_{i,j}$) is calculated using the modified UNIFAC (Dortmund) model. The

Soave, Redlich and Kwong equation of state is used in order to compute the fugacity coefficients of pure component *i* at vapor pressure (ϕ_i^{sat}) and the fugacity coefficients of the vapor mixture ($\hat{\phi}_{i,j}$). The effect of pressure on the liquid mixture is neglected.

The liquid and vapour molar enthalpies are also evaluated using external FORTRAN procedures. Specific heat capacities are given by the polynomial expression as a function of the temperature. The excess enthalpy is assumed to be zero. The reaction term arising in the MESH equations (mass balances) is a pseudo homogeneous kinetics based on the model proposed by Langmuir, Hinshelwood, Hougen and Watson (Jensen and Datta, 1995). The liquid phase is strongly nonideal and has to be taken into consideration by using activities instead of molar fractions.

The minimum column diameter recommended to avoid entrainment flooding is calculated using the correlations of Kister and Hass (Perry and Green, 1997; Gomez et al., 2006).

6. Results and discussion

The objective was to minimize the annual cost and identify an optimal column configuration: optimal location of two feeds, optimal number and location of reaction and separation trays, and optimal values of operating and design parameters. Three different strategies were applied: a 1-level MINLP with multiple restarts, a multiple level MINLP, and a multiple level MINLP with constrained integer cuts. It should be noted that in both multilevel MINLPs each level restarts from an optimal solution obtained at the previous level. The procedure continues to the next level until there is no better solution obtained at the current level. Table 1 shows the results. The optimal solution of the 1-level MINLP (8.970 k$/year) was taken as a starting point at the 2nd level MINLP. In both multilevel cases this gave rise to better solutions with 8.809 and 8.571 k$/year, respectively. Since the solutions at the 3rd level were not improved, the procedure was stopped. Thus, the best solution with 8.571 k$/year was obtained by the third strategy where constrained integer-cuts were applied in the multilevel MINLP. It should be noted that without the initialization of each NLP subproblem any feasible solution could hardly ever be obtained.

Table 1: Solution for three different strategies.

Process parameters	1-level MINLP with multiple restarts	Multiple level MINLP (2nd level)	Multiple level MINLP with constrained integer-cuts (2nd level)
Position of the feeds	8, 36	8, 37	10, 37
Position of reaction trays	3, 5, 7, 9, 11, 13, 15, 18, 36	2, 4, 6, 10, 14, 23, 25, 32, 38, 40	3, 5, 7, 10, 12, 14, 16, 21, 34, 37, 39, 41
Number of separation trays	37	36	35
Flow of distillate, mol/s	0.0648	0.0646	0.0642
Flow of product, mol/s	0.0281	0.0282	0.0284
Reboiler duty, W	4 024	3 687	3 377
Condenser duty, W	4 230	3 895	3 586
Isobutylene conversion, %	99.36	99.44	99.71
Annual cost, k$/year	8.926	8.809	8.571

In all three cases different trade-offs were obtained than the one by Gomez et al. (2006) using the same equilibrium model in stochastic optimization (annual cost of 8.970 k$/year, conversion of 99.77 %, reboiler duty of 6473 W, 44 separation and 11 reaction trays). It is interesting to note that although the conversions are now somewhat smaller, the annual costs are lower because of significant reduction in the reboiler duties and the number of separation trays (up to 48 % and 20 %). Note also that a hybrid model of distillation collumn with approximately 40 separation and 10 reactive trays typically comprises up to 3000 constraints and 1500 variables, one tenth of them being binary. About 500 equations and almost all variables were part of external procedures.

7. Conclusions

One of the main ideas of our research was to upgrade the process synthesis package MIPSYN for the use of implicit models using GAMS's external functions capabilities, since the convergence was not achieved when we tried to solve the complex hybrid reactive distillation model by DICOPT. To achieve sufficient purity of the final product in the MINLP synthesis of reactive distillation more trays had to be added to the superstructure. Consequently, the probability for obtaining an optimal solution significantly decreased. In order to solve problems with high product purities and hence a large number of trays, the main objective of our recent work has been to develop strategies by which it is now possible to solve such complex MINLP problems within the MINLP synthesizer MIPSYN. Since MIPSYN allows an interactive mode of optimization, different strategies have been implemented in the synthesizer. With the combination of multiple restarts, the convexity test at the first level of multilevel MINLP, and additional constrained integer-cuts without convexity test at the second level, the best solution was obtained.

Exergoeconomic Analysis Applied in the Optimization of Refrigeration System in Ethylene and Propylene Production Process

Francine M. Fábrega[a], Jakeline S. Rossi[a] and José V. H. d'Angelo[a]

[a]*DESQ - Department of Chemical Systems Engineering – University of Campinas, UNICAMP, Chemical Engineering School, Campinas-SP, CP 6066, 13083-970, Brazil*

Abstract

The expectation of economic growth for the next years concerns the industrial sectors with a possible shortage in the supply of electric energy. The inevitable exhaustion of fossil fuels has also been a constant source of concern. The use of fuels that emit large amounts of CO_2 and CO is becoming increasingly environmentally unacceptable. All these reasons led the most developed countries to optimize their production processes in order to reduce energy consumption and one way to do this is to perform an exergetic and exergoeconomic analyses of the processes. In this context, for ethylene and propylene production process, exergoeconomic costs were determined based on Exergetic Cost Theory from Lozano and Valero making use of software MatLab version 7 to solve the matrices of this method.

Keywords: exergoeconomic, refrigeration, ethylene, propylene

1. Introduction

The increasing consumption of energy to support the growth of chemical industries demands that processes must be operated in an optimized, making rational use of energy. Some actions in this direction are accessible and may be technical and economical feasible, leading to energy rationalization programs that with low costs when they are properly planned.

In Brazil, according to the National Energetic Balance of 2008 (MME, 2009), the chemical sector was responsible for 25.7% of the total industrial electrical energy consumed, which is equivalent to 4.8% of the total electrical energy consumed in the entire country.

In thermodynamics, the exergy of a system is defined as the maximum work possible during a process that brings the system into equilibrium with its surroundings. So, the exergy is the potential of a system to cause a change as it achieves equilibrium with its environment. Exergy is then the energy that is available to be used. After the system and surroundings reach equilibrium, its exergy is zero (Kotas, 1995).

The exergoeconomic analysis is defined as the union of exergetic analysis with economic concepts, which the main objective is to assign a cost to the exergetic content of a system or a stream of the system and when applied, this analysis provides a function of appropriate cost for that system (Valero *et al*., 1996).

The exergoeconomic analysis can be performed by applying the Theory of the Exergetic Cost (Lozano and Valero, 1993) which enables the determination of costs associated with the destruction (dissipation) of exergy, to evaluate the costs of production of each

product in order to: make possible studies of optimization and improvement of the process; help in decisions about actions for the operation, maintenance and resources allocation; compare alternatives techniques and exergoeconomic evaluation of each component.
In order to reduce the energy consumption of the process, exergoeconomic analysis has been used in many works (d'Accadia and Rossi, 1998a; Sahoo, 2008) and with this analysis it is possible to have a reference how the cost of exergy increases as the quality of energy is deteriorated during the process.
In this context, the exergoeconomic costs were calculated to the Refrigeration Systems in the Ethylene and Propylene Production Process.

2. Thermoeconomic analysis and optimization metodology

2.1. Refrigeration Systems in the Ethylene and Propylene Production Process

The simulation of the ethylene and propylene production process in this work was performed based in the production process of Quattor petrochemicals (former Petroquímica União S.A. – São Paulo). The simulation was done with the objective to obtain the thermal charges in the condensers of the distillation columns, which were validated comparing with industrial data and so they were used to simulate the refrigeration cycles required to provide cold utilities to the process. This simulation was performed using commercial simulator HYSYS© version 2.2 from Aspen Technology and the fluid package used in the determination of thermodynamic properties was Peng-Robinson equation of state, which is appropriated for systems consisting of hydrocarbons.
The simulated refrigeration cycles of each column were based in the Carnot cycle. Their configurations are detailed in Rossi *et al.* (2007) and are described below:

- in the demethanizer column three integrated cycles were used operating with the following refrigerants: methane, ethylene and propylene;
- in both deethanizer column and ethylene-ethane splitter, one cycle with propylene as refrigerant was used;
- in the propylene-propane splitter one cycle was used with ethane as refrigerant.

It is important to comment that in the simulation of these cycles were used the pressures given by Table 1.

Table 01 – Operational conditions of the refrigeration cycles in the Ethylene and Propylene Production Process.

Column		High Pressure (kPa)	Low Pressure (kPa)
Demethanizer	Cycle 1	2250	135
	Cycle 2	2000	50
	Cycle 3	1300	150
Deetanizer		1500	150
Ethylene-Ethane Splitter		1300	240
Propylene-Propane Splitter		4000	800

The values of the variables in Table 01 were obtained after adjusting the simulations of the refrigeration cycles and they were combined in order to perform exergetic analysis of all systems, after this the Theory of the Exergetic Cost proposed by Lozano and Valero (1993) was used to estimate exergoeconomic costs of the streams, using software MatLab version 7.1 to solve the matrix built from the equations of this theory. The reference state used in this work is T_o = 298.15 K e P_o = 101.325 kPa.

2.2. Calculation of exergoeconomic costs

In order to obtain the exergonomic costs of the process streams a model for the exergetic and exergoeconomic balance was developed, based on the Carnot cycle proposed by d'Accadia and Rossi (1998). This balance can be represented by Figure 1 and it is used to obtain the exergetic and exergoeconomic costs.

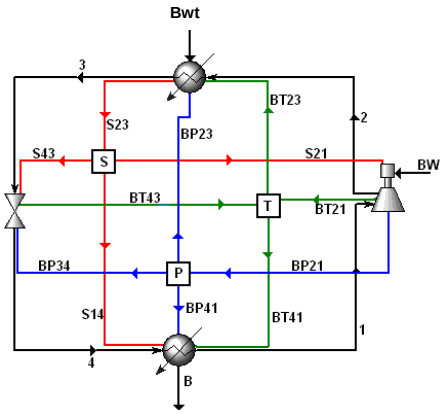

Figure 1 – Exergetic and exergoeconomic balance of a Carnot cycle.

As shown in Figure 1, there are three fictitious points that represent each of the thermodynamic variables in this study. There is an increase in the entropy of the refrigerant stream when it passes through the compressor, the expansion valve and evaporator. In the condenser it is necessary to reduce the entropy of the refrigerant. This is the reason for exergetic flow out of the condenser which is distributed to the others components of the cycle (red lines of Figure 1). Considering the exergetic flow referring to pressure (blue lines), it leaves the compressor and splits into three streams that represent the pressure drop in the heat exchangers and in the expansion valve. Finally, the exergetic flow related to temperature (green lines) leaves the compressor and the expansion valve and goes to heat exchangers.

In the balance showed in Figure 1 BT is the physical exergy of the thermal component which means that it is calculated using only the reference temperature (T_o) for each stream. BP is the physical exergy of the pressure component and it is calculated using only the reference pressure (P_o) for each stream. S is a component of the exergy related to the irreversibilities, and it is obtained by multiplying the entropy variation by the reference temperature. BW is the component realated to the work, Bwt is the component related to the exergy variation of the heat flow of condenser (cold water stream) and B is the exergy variation that the refrigeration cycle, or in order words, the final stream-product of the cycle.

Using this model and the balance equations proposed by Lozano and Valero (1993), d'Accadia and Rossi (1998) have developed a methodology to determine the exergonomic cost of each stream represented in Figure 1. The same procedure was used in this work, quantifying investment costs, operation and maintenance related to each one of the equipments present in the refrigeration cycles of the ethylene and propylene process, which are: expansion valves, compressors and heat exchangers, and also the cost of refrigeration water and electricity.

The values for the investment costs were defined according to the equations proposed by d'Accadia and Rossi (1998):

$$C_{comp} = 12000 \times \left(\frac{BP21 + BT21}{100} \right) \times \left(\frac{\eta}{0,9 - \eta} \right)^{\eta} \quad (\$) \quad (1)$$

$$C_{cond} = 450 \times \left(\frac{-\ln(1 - \varepsilon_{co}) \times S23}{U_{co} \times A_{co}} \right) \quad (\$) \quad (2)$$

$$C_{evap} = 1140 \times \left(\frac{-\ln(1 - \varepsilon_{ev}) \times B}{U_{ev} \times A_{ev}} \right) \quad (\$) \quad (3)$$

$$C_{valv} = 37 \times BT43 \quad (\$) \quad (4)$$

In Equation (1), η is the efficiency of the compressor chosen as 80 %. In Equation (2), ε_{co} is the condenser effectiveness used as 70 %, U_{co} is the unit thermal condutance, adopted as being 0.15 kW/(m^2·K) and A_{co} is the reference area, adopted as 100 m^2. In Equation (3), ε_{ev} is the evaporator effectiveness, adopted as 70 %, U_{ev} is the unit thermal condutance, adopted as 0.20 kW/m^2·K and A_{ev} is the reference area, adopted as 100 m^2. These values are the same ones used by d'Accadia and Rossi (1998), which also considered the cost of utility water as $0.25.10^{-3}$ \$/kg and the value of electricity as \$10/GJ. It was done an estimation of the operation and maintenance costs, amortizing the general cost of the equipment. In this estimation the following factors were considered: the maintenance cost of each equipment (as a percentage of its investment cost - %C.I.); the useful life for each equipment (V.U.) and the annual time of operation (T.O.). The equipment cost is defined as:

$$Z = \left(1 + \frac{\%C.I.}{100} \right) \times \frac{\text{initial cost}}{V.U.} \times \frac{\text{lano}}{T.O.} \quad (5)$$

where %C.I. = 6%, V.U. = 15 years and T.O. = 8000 hours (Kwak *et al*, 2003).

From the exergetic balance devoleped and from the derived equations proposed by Lozano and Valero (1993), it was determined the exergoeconomic costs matrix presented in Figure 2.

3. Results and Discussion

The calculations of exergoeconomic costs were performed for the refrigeration cycles in the ethylene an propylene production process and the results are presented in Tables 2 and 3.

Initially, it is important to do some observations about de matrix A (represented by Figure 2) and in the solution of the linear system **A**.**x = b**. In this work it was observed that matrix $\mathbf{A} \in \Re^{nxn}$ is not singular, therefore it admits inverse and it has complete rank (rank = 15). The augmented matrix $\mathbf{[A,b]} \in \Re^{nxn+1}$ has the same rank of matrix **A**, therefore the system **A**.**x = b** is consistent and it has an unique solution. This solution is obtained directly by solving the system, without requiring an approximation of results.

The lowest unit exergoeconomic cost for the stream-product B (Figure 1) was for cycle 01 of the demethanizer column and the one for the propylene-propene splitter was the greatest of all.

For the other streams of the cycle (*S, BP, BT* – Figure 1), the exergoeconomic costs were in the same range. It can also be observed, from Tables 2 and 3, that the integrated cycle of the demethanizer column is the most expensive, this happens because methane is the refrigerant, with the lowest temperatures and it is one that has the highest costs. The second more expensive is the cycle of ethylene-ethane splitter column, showing that both are the most indicated to attempt optimization procedures.

Table 2 – Exergoeconomic costs (C), unit (C_{un}) and costs rate (Z) for each equipment of the demethanizer colum refrigeration cycles.

4. Conclusions

In this present work the exergoeconomic costs of the refrigeration cycles in the ethylene and propylene production process were determined.

The computational tool (HYSYS©) and the methodology used in this work have shown to be adequate for estimating exergoeconomic costs of the cycles.

It was observed that the integrated cycle of the demethanizer column is the most expensive, followed by the cycle of the ethylene-ethane splitter column, showing that both are the most indicated cycles for optimization procedures.

Determining Reaction Networks

Samantha C. Burnham[a] and Mark J. Willis[b]

Abstract

This work introduces a method to identify chemical reaction networks through the analysis of process data obtained in a laboratory environment (batch reactors operating away from steady state), assuming no *a priori* information about reaction stoichiometries or species structures. This is a three stage process achieved through: a) the determination of conservation relations, number of linearly independent reactions b) the partitioning of the matrices of conservation relations, thus reaction stoichiometry to reduce the parameter identification problem c) screening for a unique chemical reaction network. A case study is used to demonstrate the method.

Keywords: reaction networks, mathematical modelling, stoichiometry.

1. Introduction

Aris and Mah[1] were the first to demonstrate that by calculating the rank of a matrix of the process data it is possible to infer the actual number of reactions. More recently a number of contributions have attempted to infer stoichiometric information from process data. Hamer[6] and Bonvin and Rippin[2] demonstrated that the number of reactions and observed stoichiometry may be obtained from a singular value decomposition (SVD) analysis[7] of the matrix of molar change of chemical species. Bonvin and Rippin[2] also incorporated the chemometric method target factor analysis (TFA), to check if a proposed (target) stoichiometry was consistent with the measured data. Fotopoulos *et. al.*[4] and Georgakis and Lin[5] propose and use structured target factor analysis (STFA) to systematically check a pre-defined set of structured, sparse vectors against the observed stoichiometry. The procedure introduced in this paper compliments these earlier techniques and is consistent with the work completed in biochemical systems theory (e.g. see Palsson, 2006[10]).

2. Background

Assuming constant density, the material balance expression for a (homogeneous phase) well mixed, batch reactor that is operating isothermally, may be written as (1)

$$\frac{d[x_i]}{dt} = f_i \quad i = 1,...,n \tag{1}$$

where $[x_i]$ is the molar concentration of species i at time t. (1) is a set of coupled ordinary differential equations (ODEs) that describe the dynamic behaviour of the reactive species due to chemical reactions, as represented by the n reaction fluxes f_i.
The flux terms f_i are directly linked to the stoichiometries of the N_R reactions taking place and the kinetic rate terms of these reactions. The (n x N_R) stoichiometric matrix $\mathbf{V}$ describes the topology of a chemical reaction network. The stoichiometries of the

chemical species in the reactions, which make up the network, provide the entries of the stoichiometric matrix. For a network with n species and N_R chemical reactions, the stoichiometric relationships, which are assumed to be time invariant, are given by (2).
Where $v_{i,l}$, $i = 1, \ldots, n$, $l = 1, \ldots, N_R$, are the stoichiometric coefficients for the i^{th} species in the l^{th} reaction. By convention, $v_{i,l} < 0$ for a species that undergoes net consumption in a reaction, $v_{,il} > 0$ for a species that undergoes net production and $v_{i,l} = 0$ for a species that is either not involved in the l^{th} reaction or has no net change in it.
The component balances may now be expressed in terms of **V** and the N_R individual reaction rates; in matrix-vector form, (3).

$$\mathbf{V} = \begin{bmatrix} v_{1,1} & \cdots & v_{1,N_R} \\ \vdots & & \vdots \\ v_{n,1} & \cdots & v_{n,N_R} \end{bmatrix} \qquad (2) \qquad \frac{d\mathbf{x}}{dt} = \mathbf{V}\mathbf{r} \qquad (3)$$

Where **r** is the ($N_R \times 1$) dimensional vector of reaction rates and **x** is the ($n \times 1$) dimensional vector of species concentrations $[x_1],\ldots,[x_n]$ at time t. The N_R reaction rates constituting **r** are, in general, non linear functions of the concentrations **x**. If elementary reactions are assumed then the form of the N_R rate terms in **r** is determined uniquely by the reactants in each of the N_R elementary reactions.
The law of mass action kinetics states that the rate of an elementary reaction may be assumed to be directly proportional to the product of the reactant concentrations. Consider the chemical reaction (4): a molecules of species x_1 and b molecules of species x_2 form c molecules of species x_3 and d molecules of species x_4, with rate coefficient k.

$$ax_1 + bx_2 \xrightarrow{k} cx_3 + dx_4 \qquad (4)$$

The rate r of this reaction at any time, according to the law of mass action, is (5).

$$r = k[x_1]^a[x_2]^b \qquad (5)$$

Thus, given that the correct stoichiometric matrix **V** may be determined it is possible to generate the structure of the vector of reaction rates. Leaving the kinetic rate constants to be identified (possible by standard kinetic fitting).

3. Case Study

3.1. Data Generation
For example, consider the following chemical reaction network comprising five reactive species involved in three elementary reactions with rate coefficients k_1 and k_2 and k_3

$$(CH_3CO)_2O + H_2O \xrightarrow{k_1} 2CH_3COOH \qquad CH_3COOH + CH_3OH \underset{k_3}{\overset{k_2}{\leftrightarrow}} C_3H_6O_2 + H_2O \qquad (6)$$

In the first reaction acetic anhydride reacts with water to produce acetic acid. In the second (reversible) reaction acetic acid reacts with methanol to produce methyl acetate and water. The matrix **V** and vector **r** for this network are given by, (7).

$$\mathbf{V} = \begin{bmatrix} -1 & 0 & 0 \\ -1 & 1 & -1 \\ 2 & -1 & 1 \\ 0 & -1 & 1 \\ 0 & 1 & -1 \end{bmatrix} 1 \qquad \mathbf{r} = \begin{bmatrix} k_1[(CH_3CO)_2O][H_2O] \\ k_2[CH_3COOH][CH_3OH] \\ k_3[C_3H_6O_2][H_2O] \end{bmatrix} \qquad (7)$$

Hence the n ODEs, for known species initial conditions can be used to describe the temporal evolution of the species concentrations, (8).

$$\frac{d\mathbf{x}}{dt} = \mathbf{V}\mathbf{r} = \begin{bmatrix} -k_1[(CH_3CO)_2O][H_2O] \\ -k_1[(CH_3CO)_2O][H_2O] + k_2[CH_3COOH][CH_3OH] \\ \quad -k_3[C_3H_6O_2][H_2O] \\ 2k_1[(CH_3CO)_2O][H_2O] - k_2[CH_3COOH][CH_3OH] \\ \quad +k_3[C_3H_6O_2][H_2O] \\ -k_2[CH_3COOH][CH_3OH] + k_3[C_3H_6O_2][H_2O] \\ k_2[CH_3COOH][CH_3OH] - k_3[C_3H_6O_2][H_2O] \end{bmatrix} \quad (8)$$

For reaction scheme (6), it was assumed that only initial concentrations of acetic anhydride, methanol and water were present. A simulated batch experiment was performed, with each of the initial concentrations specified as 0.10moldm^{-3}. Note that the volume of the batch is specified as 1 litre and that the reaction takes place in an inert solvent. The kinetic rate constants were specified as k_1 = 0.10, k_2 = 0.15 and k_3 = 0.05 min^{-1}mol^{-1}dm^3. Eleven concentration measurements of each species were generated by numerical integration of the true system ODEs, (8), using the initial reactant concentrations specified above. The total simulation period was specified as 1200 mins and measurements of all species were recorded every 120 mins, therefore the number of time points, *N*, is eleven. In this case no simulated measurement error was added to the signals. The generated data is depicted in figure 1. Curves were fitted to the process data (also figure 1 – using MATLAB ® v.7.1 curve fitting toolbox) for the purpose of estimating the rate of change of species concentrations (figure 2 – calculated from derivatives of the fitted curves). The actual derivatives are also shown in figure 2, where the mean squared errors for the respective approximations are less than 3.840x10^{-6}.

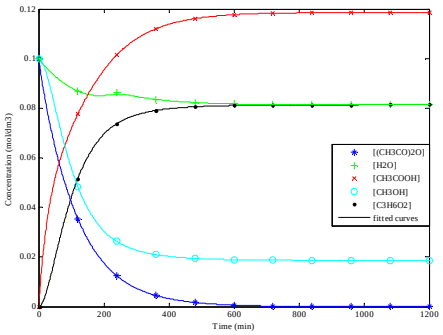

Figure 1: Measured concentration values and fitted curves

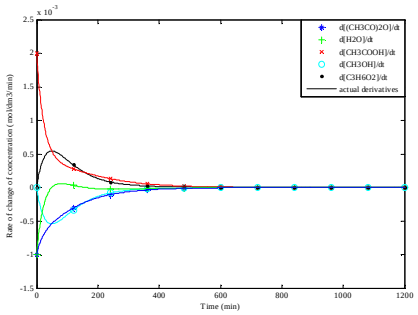

Figure 2: Approximate and accurate derivative values for the concentration data in figure 1.

3.2. Stage a) - Conservation Relations

3.2.1. Moiety Conservation

The term conserved moieties[11] defines molecular subgroups that are conserved during the evolution of a chemical reaction network. A conserved moiety is time invariant and is solely determined by the initial conditions imposed on the system, in a batch reactor by the initial concentrations of the species. A practical reason why conservation relations should be identified as a preliminary step in chemical reaction network analysis is that they allow the set of species, S_S, to be divided into independent and dependent species, S_I and S_D, respectively. The concentrations of the S_D can be calculated from the concentrations of the S_I. Thus the conserved moieties represent dependencies which can be removed to reduce a system's dimensionality. It should be noted that for each individual reaction one species involved in that reaction (not already in the set of independent species) must be included in the set of independent species.

3.2.2. Determining conservation relations from process data

The data in figure 2 was compiled to give the matrix $\dot{\mathbf{X}}$ (N x n) which represents rate of change of concentration of all species (each column) at all measured time points (each row). It is documented[10], that the conservation relation matrix, **C** (N_C x n), lies in the left null space of the stoichiometric matrix, **V**. Given that the transpose of the data matrix ($\dot{\mathbf{X}}'$) lies in the same vector space as **V**, it follows that **C** may be estimated from the (right) null space of $\dot{\mathbf{X}}$ and is estimated to be (9)[i].

Note that there are N_C conservation relations, equal the estimated number of reactions, $\hat{N}_R$, in this case two. The actual number of reactions is three (6), but only two are detected as the second and third reactions are fully correlated.

Note: given that **C** lies in the left null space of **V**; it is also true that **V** lies in the null space of **C**. Therefore by calculating the null space of **C** it is possible to gain an estimate of **V**; this will be referred to as an observed stoichiometry, $\mathbf{V_o}$, (10) – see footnote i.

$$\mathbf{C} = \begin{bmatrix} 1 & 1 & 1 & 0 & 0 \\ -1 & 1 & 0 & 1 & 0 \\ 1 & -1 & 0 & 0 & 1 \end{bmatrix}^{\mathbf{T}} \qquad (9) \qquad \mathbf{V_o} = \begin{bmatrix} -0.5 & -0.5 & 1 & 0 & 0 \\ -0.5 & 0.5 & 0 & -1 & 1 \end{bmatrix}^{\mathbf{T}} \qquad (10)$$

3.3. Stage b) – Reduction of the parameter identification problem

3.3.1. MatrixPartitioning

Given that $\dot{\mathbf{X}}$ is ordered so that the first $\hat{N}_R$ = *rank*($\dot{\mathbf{X}}$) columns ($\dot{\mathbf{X}}_\mathbf{I}$) correspond to $\hat{N}_R$ independent species (S_I) and, the remaining $N_c = n - \hat{N}_R = n$ - *rank*($\dot{\mathbf{X}}$) columns ($\dot{\mathbf{X}}_\mathbf{D}$) correspond to the dependent species (S_D), $\dot{\mathbf{X}}$ is partitioned as $\dot{\mathbf{X}}$ = [$\dot{\mathbf{X}}_\mathbf{I}$ ¦ $\dot{\mathbf{X}}_\mathbf{D}$].

By partitioning $\dot{\mathbf{X}}$ it is true that **C** is also partitioned as $[-\mathbf{L_0} \,¦\, \mathbf{I}]^\mathbf{T}$, where $\mathbf{L_0}$ is a link-zero matrix ($\hat{N}_R$ x N_C), given that $N_C = n - N_R$, and **I** is an identity matrix (N_C x N_C). Further the stoichiometric matrix **V** may be partitioned to $[\mathbf{V_I} \,¦\, \mathbf{V_D}]^\mathbf{T}$ where $\mathbf{V_I}$ is a ($\hat{N}_R$ x $\hat{N}_R$) matrix representing the stoichiometries of the independent species and $\mathbf{V_D}$ is a (N_C x $\hat{N}_R$) matrix representing the stoichiometries of the dependent species. $\mathbf{V_D}$ can be calculated by (11)[9].

$$\mathbf{V_D} = \mathbf{L_0 V_I} \qquad (11)$$

Therefore the parameter estimation problem is reduced from determining a (n x N_R) stoichiometric matrix **V** to determining a ($\hat{N}_R$ x $\hat{N}_R$) matrix, $\mathbf{V_I}$, representing the stoichiometries of the independent species.

3.3.2. Defining a set of possible stoichiometric vectors

Assumption 1: reactants and products are restricted to be either unimolecular or bimolecular with a maximum of two reactants and products[ii].

Given assumption 1, the stoichiometric coefficients of the vectors within $\mathbf{V_I}$ belong to the set, S_C = {-2, -1, 0, 1, 2}. Given the choice of independent species, this integer representation is simply a description of the reactants (negative integers), products

[i] In this work the null spaces are calculated in MATLAB using the reduced row echelon form as a basis. The resulting matrices that this procedure produces are not unique. Applying a different basis will lead to different, but equally valid matrices.

[ii] This representation could be easily modified to include reaction types of greater or lesser complexity.

(positive integers) or species not involved (zeros) in each reaction. For $\hat{N}_R$ = 2, the set of all (uncorrelated) vectors, S_{VI}[iii], is (12).

$$\begin{matrix} 0 & 1 & 1 & 1 & 2 & 1 \\ 1 & -2 & -1 & 1 & -1 & 0 \end{matrix} \quad (12)$$

Given **C**, (9), $\mathbf{L_0}$ may be defined as [-1, 1, -1; -1 -1 1]. Therefore, given $\mathbf{L_0}$ and S_{VI}, the respective stoichiometries for the dependent species, S_{VD}, may be calculated from (11). Combining these with S_{VI} with S_{VD} a set of target stoichiometries is produced (13). Applying assumption 1, a number of these vectors can be discounted – highlighted by a shaded background. Leaving three feasible vectors – but as these vectors may be in the opposite direction they represent six possible reactions (14).

0	1	1	1	2	1
1	-2	-1	1	-1	0
-1	1	0	-2	-1	-1
-1	3	2	0	3	1
1	-3	-2	0	-3	-1

(13)

$$CH_3COOH + CH_3OH \leftrightarrow H_2O + C_3H_6O_2$$
$$2CH_3COOH \leftrightarrow (CH_3CO)_2O + H_2O \qquad CH_3COOH + C_3H_6O_2 \leftrightarrow (CH_3CO)_2O + CH_3OH \quad (14)$$

3.4. Stage c) – Screening for a Coupled System

3.4.1. Best Subsets Regression

From (14) there are six possible reactions, whose rate vectors may be identified, with unknown rate constants (15).

$$r_i = \{k_a[CH_3COOH][CH_3OH] \quad k_b[H_2O][C_3H_6O_2] \quad k_c[CH_3COOH]^2 \quad k_d[(CH_3CO)_2O][H_2O] \quad k_e[CH_3COOH][C_3H_6O_2] \quad k_f[(CH_3CO)_2O][CH_3OH]\} \quad (15)$$

Given that the data in figure 1 was compiled to give the matrix **X** (*N* x *n*), concentration of all species at all measured time points, then the values of r_i/k_i in (15), for *i* = a:f, at the measured time points may be calculated.

Given that the correct r_i/k_i terms will be proportional to the respective columns of $\dot{\mathbf{X}}$ (8), with proportional constants of the rate coefficients, k_i, it is possible to use regression analysis to determine the relevant r_i terms. Best subsets regression allows a number of models containing different predictors and different numbers of predictors to be compared. As $\hat{N}_R$ was estimated to be two, we know that N_R is a minimum of two (uncorrelated reactions) and a maximum of four (including the reverse reactions of the two uncorrelated ones). Hence, it is possible to compare the models comprised of all possible combinations of two, three or four terms from the set of rate terms in (15), when regressed against the rate of change of CH_3COOH (chosen as it is present in all six possible reactions)[iv].

It is usually not feasible to model each combination of predictors individually; alternatively, a statistical algorithm is used to produce summary statistics for the

[iii] The set of all possible (N_R x 1) vectors were generated using the set of stoichiometric coefficients, $\boldsymbol{S_C}$. The set were then reduced by removing any that implied reactions that were not unimolecular or bimolecular. All sets of correlated vectors were identified and the minimum norm solution was retained within the set, $\boldsymbol{S_V}$.

[iv] In other examples it may be necessary to perform regression against the rate of change of concentration of more than one species, given that one species may not appear in all possible reactions. Also it may be performed against the rate of change of all species to confirm any results.

possible combinations of predictors.
Performing best subsets regression the following rate terms were identified to produce the best model $k_a[CH_3COOH][CH_3OH]$, $k_b[H_2O][C_3H_6O_2]$ and $k_d[(CH_3CO)O][H_2O]$ with an adjusted R^2 value of 100% and Mallows' *C-p* statistic[8] of 2.5. Thus the reactions are correctly identified as (16) – *cf* (6). It would then be possible to use standard regression or standard kinetic fitting techniques to determine the values of kinetic rate coefficients[3].

$$CH_3COOH + CH_3OH \underset{k_b}{\overset{k_a}{\leftrightarrow}} C_3H_6O_2 + H_2O \qquad (CH_3CO)_2O + H_2O \overset{k_d}{\rightarrow} 2CH_3COOH \tag{16}$$

4. Discussions, Conclusions and Future Work

This paper proposes a method for the determination of chemical reaction networks. The procedure is demonstrated to be successful, through a worked example, consisting of five chemical species and three reaction steps. The presented analyses are relatively simple from a mathematical viewpoint and use concepts and tools that will be familiar to most researchers and engineers, for example curve fitting and regression analysis. The majority of methods from the literature are based on system perturbations around stationary states, thus do not lend themselves to the type of experimentation performed in most chemical laboratory contexts. In comparison the techniques proposed here, are based solely on the analysis of process data obtained from batch reactors. There are a number of potential limitations to the approach in its current form. For example, in accordance with other approaches in this area, and in the field of system identification in general, adequate experimental data (i.e. data from a system with sufficient excitation and appropriate data collection) is a pre-requisite to the success of the presented approach. Currently, however, the approach lacks diagnostic tools to systematically evaluate whether the acquired data is sufficient, in terms of information content, for successful network identification.

A Comparison of Functional Modeling Techniques for Autonomous Systems Development

José Luis de la Mata[a] and Manuel Rodríguez[b]

[a,b]*Autonomou System Laboratory-Technical University of Madrid, José Gutiérrez Abascal, Madrid 28006, Spain*
[a]*joseluis.delamata@upm.es*
[b]*manuel.rodriguezh@upm.es*

Abstract

When developing autonomous systems one important step is to have integrated different views of the system modelled. One essential view of the system behavior is the functional view, so the first step is to choose a functional modeling technique. In order to be able to have an integrated model an open, neutral, domain and platform independent language is needed. The Systems Modeling Language (SysML) complies with these requirements. The SysML is a subset and an extension of the well-known Unified Modeling Language (UML).

Keywords: Functional modeling, autonomous systems.

1. Autonomous Systems Development

Etymologically autonomy means “giving itself its own laws” (Greek auto-self and nomos-law). That meaning, translated to technical language, can be read as the system decides about the control strategies to follow. Being autonomous seems to be at the very central objectives of most engineers. The model-driven approach, a generalization of formal development methods, is the current engineering trend trying to tackle the autonomy problem [1].
When developing autonomous systems, a very important aspect is that the system has “knowledge” about itself, i.e., its structure, behavior, etc. For this reason, a model-driven approach is used. A complete model will require integrated different views of the system. One essential view of the system behavior is the functional view, given by a functional model. Models are the core around which everything is developed.
This paper has been realized in the framework of the ASys project of the Autonomous Systems Laboratory research group. ASys is a long-term research project focused in the development of technology for the construction of autonomous systems.

2. Functional Modeling

A model is a simplified representation of the reality. It may have as many views as reality has. The question is to define the more interesting (useful) views to be included in a model. It seems that two philosophically fundamental views are mostly important and have to be considered: functional and structural. A functional model is a structured representation of the functions, activities or processes within the modeled system [2].

2.1. Multilevel Flow Modeling (MFM)

Multilevel Flow Models (MFM) are graphical models of technical processes [3]. The goals describe the purposes of a system and its subsystems, and the functions describe

the system's abilities in terms of flows of mass, energy and information. MFM also describes the relations between the goals and the functions that achieve those goals, and between functions and the subgoals that provide conditions for these functions. Mass and energy flow structures are used to model the functions of the plant and activity and information flow structures are used to model the functions of the operator and control systems. Using these concepts it is possible to represent knowledge of complex process plants. The basic MFM functions were presented by Lind [3], the use of information functions was introduced by Larsson [4], finally, Petersen [5] presented causality considerations between functions. Later, in [6] some extensions were proposed in order to perform control system reconfiguration.

2.2. Goal Tree – Success Tree (GTST)

The GTST is a functional decomposition framework for modeling complex physical systems. It is a functional hierarchy of a system organized in levels beginning with an objective at the top. The objective describes the main purpose of the system in an unambiguous term [7]. The relations in hierarchies represent a connection between different nodes of a hierarchy or between nodes of two correlative hierarchies. The type of relations in the GTST technique can be tagged as logical, physical or fuzzy [8].

The lowest level of the GTST models explains how system parts interact with each other to achieve higher level functions. In order to present the success logic of a very complex interacting system in a compact and transparent way, the Master Logic Diagram (MLD) is used. The MLD is such a model to represent the relationship between the main and support functions [8].

3. Functional Modeling Techniques Comparison

A. Jalashgar in [9] provides an overview of both methods but no comparison is made. According to the differences presented and their different performance, it is possible to compare both techniques.

Although both techniques are functional goal oriented techniques, there are several differences between them. While MFM provides a good general view (even of very complex systems), GTST doesn't, essentially because MFM models are not restricted to hierarchical structures. Relations between different hierarchical levels and different parts of the model are allowed and can be represented explicitly i.e., hierarchy does not constrain the model.

GTST represents all kinds of knowledge of the technical system and it has got textual appearance. This could be an advantage because it simplifies the implementation of the model, but it can also be a disadvantage because it makes complicated the identification of similarities between the parts of the model and between different models.

On the other hand, MFM represents in an explicit way the objectives and the system functions as well as their relations. A MFM model captures the functions and the goals of a system but there is a lack of homogeneous semantics because there are different ways of representing the same system and different levels of abstraction can be considered.

But the most important feature of MFM is that it is a *flow ontology*. Mass, energy and information flows are responsible for causal interactions in chemical plants. Safety, productivity and economy are managed by administrating these flows. The concepts of mass and energy flows can be applied on multiple levels of physical aggregation and to a wide variety of physical processes. According to the previous paragraphs, MFM seems to be the most suitable functional modeling technique for the implementation of the functional view of a chemical plant.

4. SysML

The Systems Modeling Language is a domain-specific modeling language for systems engineering that is defined as a dialect (Profile) of UML 2 [10]. The language provides graphical representations with a semantic foundation for modeling system requirements, behavior, structure, and parametrics, which is used to integrate with other engineering Modeling Language [11]. The block is the basic unit of structure in SysML and can be used to represent hardware, software, facilities, personnel, or any other system element [12]. The four pillars of SysML are:

1. *Structure*. Block definition diagrams and internal block diagrams represent the system structure.
2. *Behavior*. Use case diagram, activity diagram, sequence diagram, and state machine diagram.
3. *Requirements*. Provides a bridge between the typical requirements management tools and the system models.
4. *Parametrics*. Represents constraints on system property values as a mean to integrate the specification and design models with engineering analysis models.

As aforementioned, the block is the basic unit of structure in SysML and the basic units of MFM models are goals, structures and flow functions. A SysML block will model each flow concept of MFM. For example, a transport function will be a block with a flow input, a flow output and a condition port. Its behavior can be modeled with the SysML state diagram. In the same fashion, a structure can be modeled by a block with various achieve ports, an achieve-by-control port, a control port and various condition ports. The internal structure of a MFM structure is represented in the SysML internal block diagram.

5. Industrial process

5.1. MMAN production

MMAN is an explosive obtained from the reaction of nitric acid and monomethylamine (MMA) in a stirred tank reactor. The reaction is exothermic and it must be kept under 60ºC by the cooling jacket which is fed with water. MMA is stored as liquefied gas so it is vaporized before being fed to the reactor. To avoid crystallizations and product decomposition, MMAN has to be kept above 55ºC and below 70ºC. A P&I diagram of the process is shown in Fig. 1.

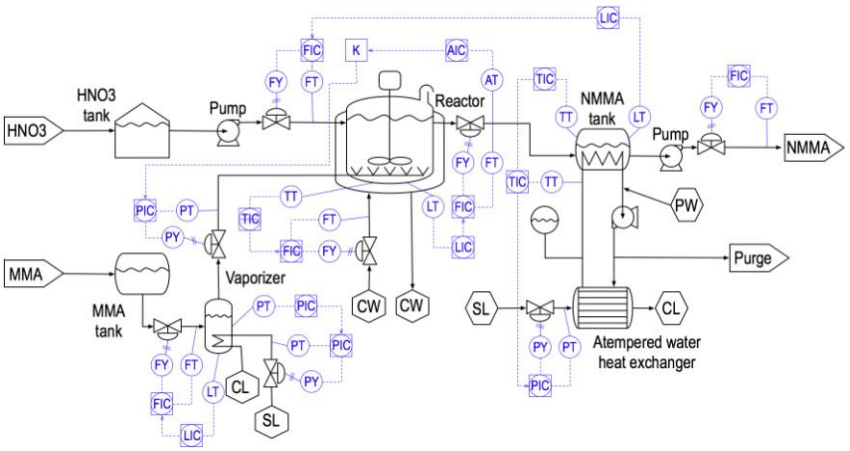

Fig. 1. MMAN process P&I diagram.

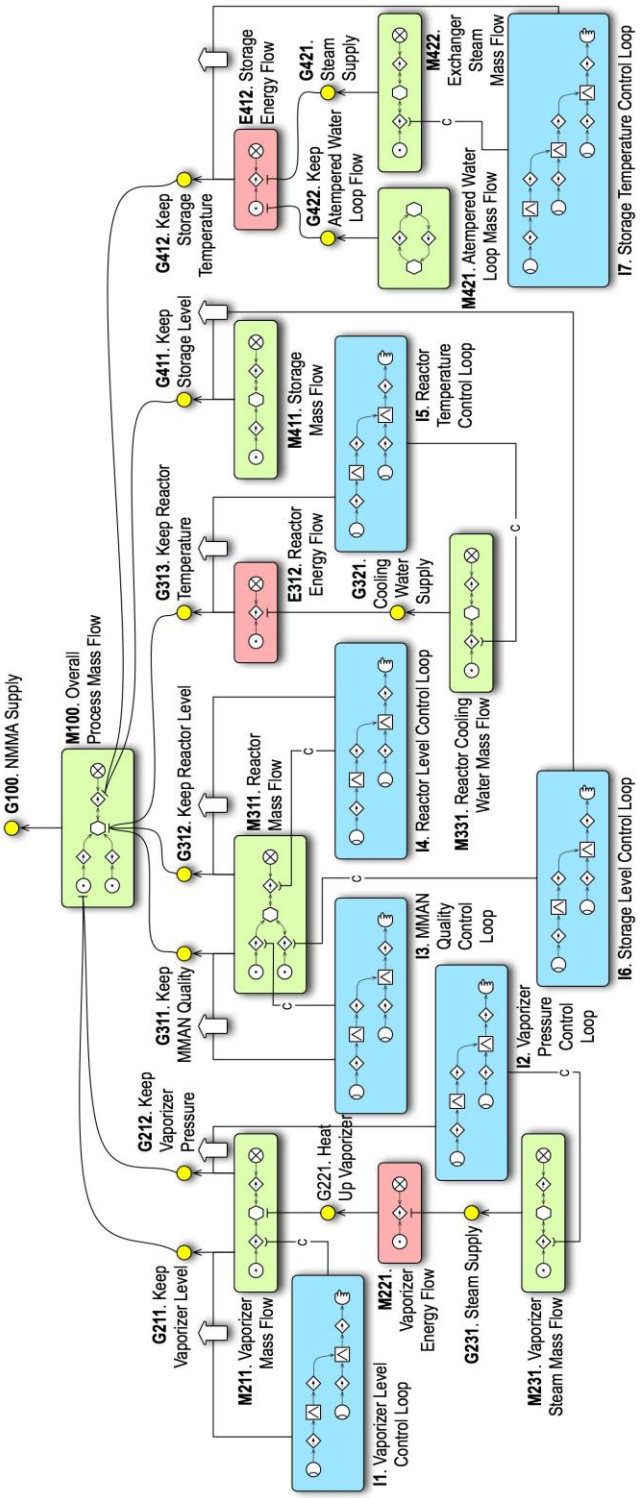

Fig 2. MMNA process MFM model.

A set of goals and subgoals has been identified in order to guarantee a good plant behavior. The main goal is to "supply MMAN" (G100), this goal is achieved in a mass structure (M100) which is conditioned by lower level goals. There are eight mass structures, three energy structures and seven information structures. Related to these structures there are thirteen goals and more than one hundred flow functions. All the relations between structures, goals and flow functions are collected in Fig. 2.

5.2. SysML Block Diagram

The MMAN MFM model is too big to represent it fully in a SysML block diagram, so only a part of it will be analyzed. The block diagram shown in Fig. 3 has been developed considering goal G313 (Keep Reactor Temperature) in Fig. 2 and its related structures and goals (E312, M331, I5 and G321). Keeping the reactor temperature is achieved in energy structure E312 which is conditioned by goal G321 (Cooling water supply). This goal is achieved in structure M331 which is controlled by the information structure I5. The goal G312 is achieved by control in structure I5. These concepts are represented in the block diagram shown in Fig. 3.

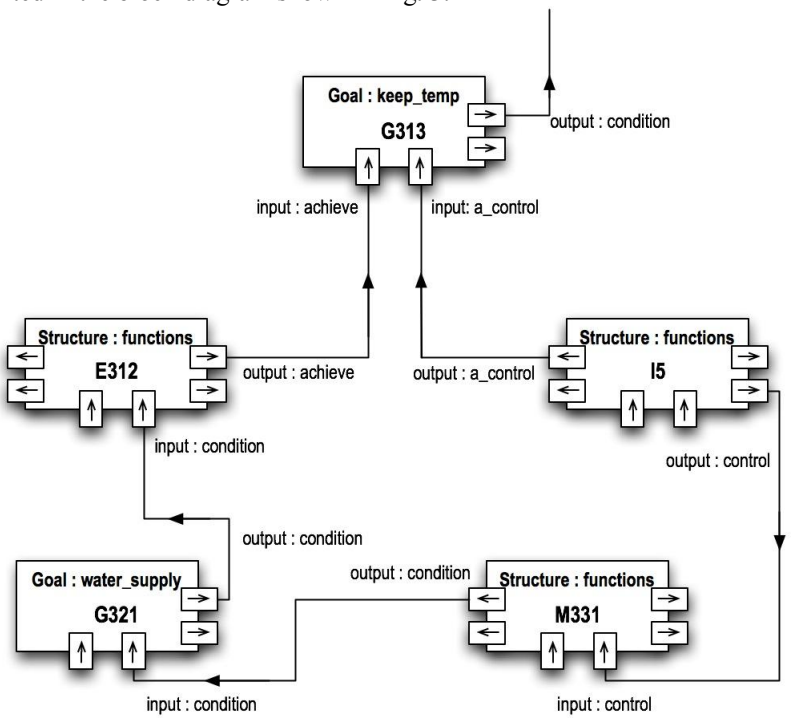

Fig. 3. SysML Block Diagram

In Fig. 4 the Internal Block Diagram of the energy structure is depicted. The structure consists of a source function, a transport function and a sink function, which are represented by the related blocks. There are different flows in both diagrams (figures 3 and 4): mass, energy, information, condition, control, achieve and achieve-by-control.
The MFM vertical relations are modeled as SysML connections, in fact, flow connections in the block diagram. The block diagram captures the main structure and relations of MFM models.

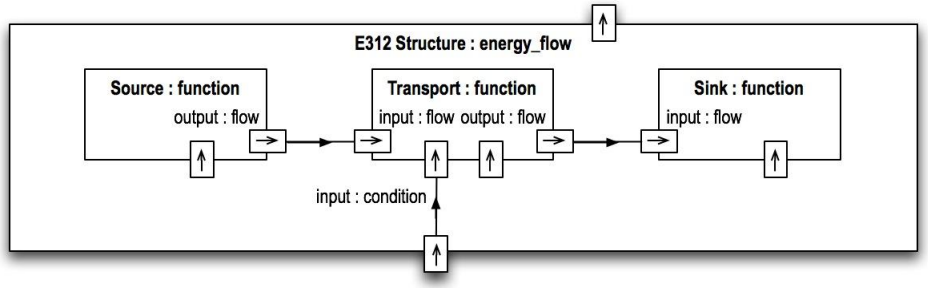

Fig. 4. SysML Internal Block Diagram of structure E312.

6. Conclusions and Further Work

In this paper a comparison between functional modeling techniques (MFM and GTST) has been made. Both techniques provide modeling features that are useful for developing the functional view of process plants but the flow ontology feature makes MFM more suitable for process systems.

An MFM model of the MMAN production process has been implemented. This model also has been developed in SysML using blocks to model MFM concepts and connections to model MFM relations.

MFM models implement the functional view of a system. These models can be used for multiple purposes such as risk analysis, fault diagnosis and control system reconfiguration. Further work includes the development of these features in SysML along with quantitative information integration.

Development of integrated functional-structural models

Manuel Rodriguez[a], Ricardo Sanz[a]

[a] *Autonomous System Laboratory- Technical University of Madrid, Jose Gutierrez Abascal, Madrid 28006, Spain*

Abstract

Chemical processes are usually large complex systems. Models concerning the topology and structure have existed for decades and more recently functional models have appeared as a complementary way to describe these systems. In this paper a new modeling formalism to capture structure as well as functionality of a system is presented. Based on the visual formalism higraphs, it has been adapted and extended to be applicable to process systems description. Although it can be used for several applications, this paper focuses on its use in risk analysis.

Keywords: Higraphs, functional modeling, complex systems.

1. Introduction

General systems theory (as introduced in [1], [2]) can be seen as a universal framework for abstract modeling, the philosophy of this theory can be summarized as pointed out by Le Moigne:

"*an object with a set of goals, in a well defined environment, exerts an activity (function) and at the same time experiences how its internal structure evolves through time keeping its identity*".[3]

This idea will be kept in the remaining of the paper along with the idea of model based systems engineering methodology. An extension of the higraph formalism is presented and it will be applied to the development of models that capture the functional (activity) as well as the structural (ontologic) aspects of a process. The inclusion and need of evolutionary (genetic) aspects in a model is not treated in this paper although it could, a priori, be represented using this same formalism.

The methodology described complete some of the existing techniques used for functional analysis (as Multilevel Flow Modeling [4] or Goal Tree Success Tree [5]), and although it is not conceived to be an alternative to the classical modeling environments, a simple translation could be made from one to the other.

The paper is organized as follows: section two explains the higraphs formalism and its extension for process systems, section three applies the proposed methodology to a benchmark process, section four deals with implementation issues and finally section five draws conclusions on the presented work.

2. Integration of functional-structural models

2.1. Higraphs

Higraphs were first presented by Harel in [6]. They are an extension and combination of conventional graphs and Venn diagrams. They constitute a visual formalism of topological nature that can represent set enclosure, exclusion and intersection and the Cartesian product. Higraphs consist of two elements: blobs and edges. Blobs are represented as rounded-corner rectangular shapes. They represent mutual exclusive sets, they may intersect and be arranged in an inclusion hierarchy. Blobs of different levels in the hierarchy may be connected. Edges, represented as arrowed lines, are used to connect blobs. Higraphs can be defined as the result of:

graphs + depth (hierarchy) + orthogonality (Cartesian product). [7]

This visual formalism is well suited for the behavioral specification and design of complex concurrent systems. Another formalism, statecharts, derived from higraphs has been widely used on this purpose for discrete-event systems. In statecharts, blobs represent system states and edges represent the transitions between the states.

Figure 1. illustrates higraphs components and features. It represents the `stopwatch` state of a watch [8].

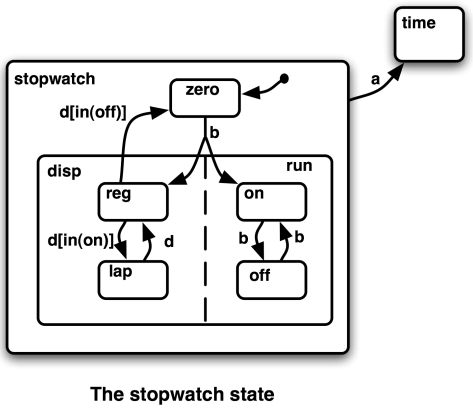

Fig 1. Statechart diagram representing the stopwatch state of a watch.

The `stopwatch` blob (state) has two states, the `zero` state and the `disp/run` state. These states are OR components. The `disp/run` state has a `disp` state and a run state, these are AND states, so both happen at the same time. The `run` state has the `on` and `off` states (which, again, are OR states). Transitions between states are labeled and they can contain a condition. The transition from `reg` to `lap` happens in the event of d, and when the condition (in `on` state) is true.

2.2. D-Higraphs: An extension for process systems

Classic higraphs or statecharts are not useful to specify functional models of process systems because they provide depth in states. When describing the functionality, depth is required for functions (in order to have functional dependency) and system states enable these functions. So, in order to use higraphs for process systems they will have to

be used in a dual way as they are used in statecharts. Blobs will represent now transitions and edges will represent states.

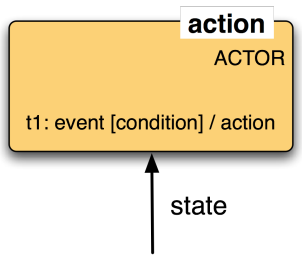

Fig. 2. Basic blob (action), performed by ACTOR when state (event) is enabled and condition is true.

The name of the function will appear in the border of the blob, and the actor (usually equipment) that performs or allows that function will be indicated inside the blob. Transitions are enabled when the state (incoming arrow) is achieved and, as in statecharts, transitions can contain conditions. Firing the transition causes new states, represented by the edges coming out from the blob. Edges represent flow of material (solid line), or energy (dashed line) or information (dotted line). Figure 2 shows the basic components of the D-higraph. Being dual to statecharts, blobs included in a blob are AND blobs, so all the functions have to happen in order for the more global function to happen. Usually OR blobs are not necessary but if needed they would be represented separated by a dashed line. For the edges, an additional representation is added. When the occurrence of a state is necessary for the function, the edge arrow must be solid black, when the event to fire the transition (function) is one of several states (OR condition) the edge arrow is empty. For more complex combinations a black solid bar is added before connecting to the blob. Figure 3 exemplifies some cases.

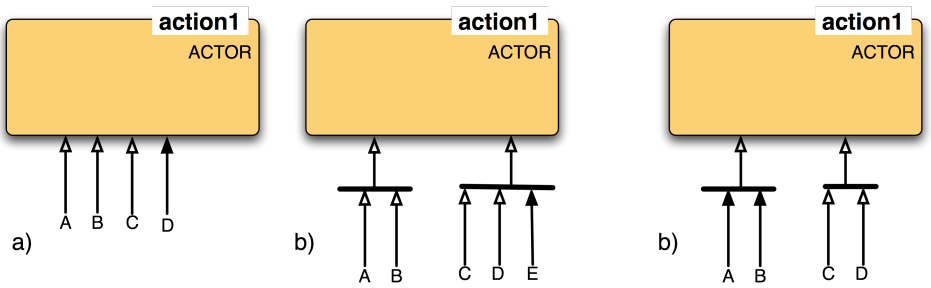

Fig 3. Case a) A or B or C and D must be true to fire action1. Case b) A OR B OR (C OR D AND E) must be true to fire action1. Case c) A AND B or C OR D must be true to fire action1.

A simple example (fig. 4) illustrates what has been explained so far. In this case a Jacketed Continuous Stirred Tank Reactor with two feeds is represented. The overall goal is to produce in operating conditions, this goal is decomposed in `produce` and `remove_heat`. `Produce` (in this kind of reactor) has another function in it, `stir`. As all the arrows are solid, it means that all the states have to be true before the transition is fired. In the case of the CSTR, the `produce` transition will happen if reactants A and B are flowing into the reactor.

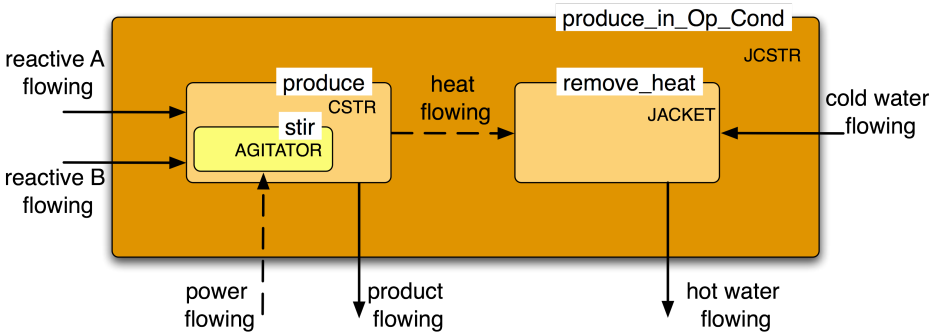

Fig 4. D-Higraph simple example. A Jacketed continuous stirred tank reactor.

3. Application

The Tennessee Eastman Process consists of a reactor, condenser, separator, compressor and stripper with a gas recycle stream, a more detailed description can be found in [9]. This process was initially developed as an industrial plantwide control test problem. In the control structure considered, (on-demand product) we assume that the flowrate of the product stream leaving the base of the stripper is set by a downstream customer as in [10]. Control loops selected are production rate, product quality, reactor temperature, pressure, liquid inventories and two compositions. A ratio is used to feed G and H reactants accordingly to the desired production.

Considering the process description a set of goals and subgoals have been identified in order to guarantee a good plant behavior. All these goals are related with the mentioned control objectives and with guaranteeing plant safety, being the overall goal to produce in safety conditions and with the desired quality. Figure 5 represents the Eastman process using the D-higraph formalism.

It can be observed that control loops are represented in a straightforward way including advanced configurations as cascade control or ratio control. In this case, both configurations are present in the feed to the reactor. The process can be followed without difficulty even without having the classic flowsheet representation.

Risk analysis can be easily performed. For example, if `heat transmission` state from the reactor to the jacket fails, then it causes the `remove heat` function to fail and, consequently, the `react in op. conditions` does fail which implies that, finally, the overall goal `produce safely and with desired quality` is not accomplished. Notice that the failure of the `heat transmission` does not affect the `produce G,H` function of the reactor as this state is not an input to that blob and therefore it is not a necessary condition to fire it. In the other hand, in the cases of the heat exchanger and the vaporizer `heat transmission` affects both functions (`vaporize` and `heat` and `cold` and `heat`) as showed with the double arrowed line.

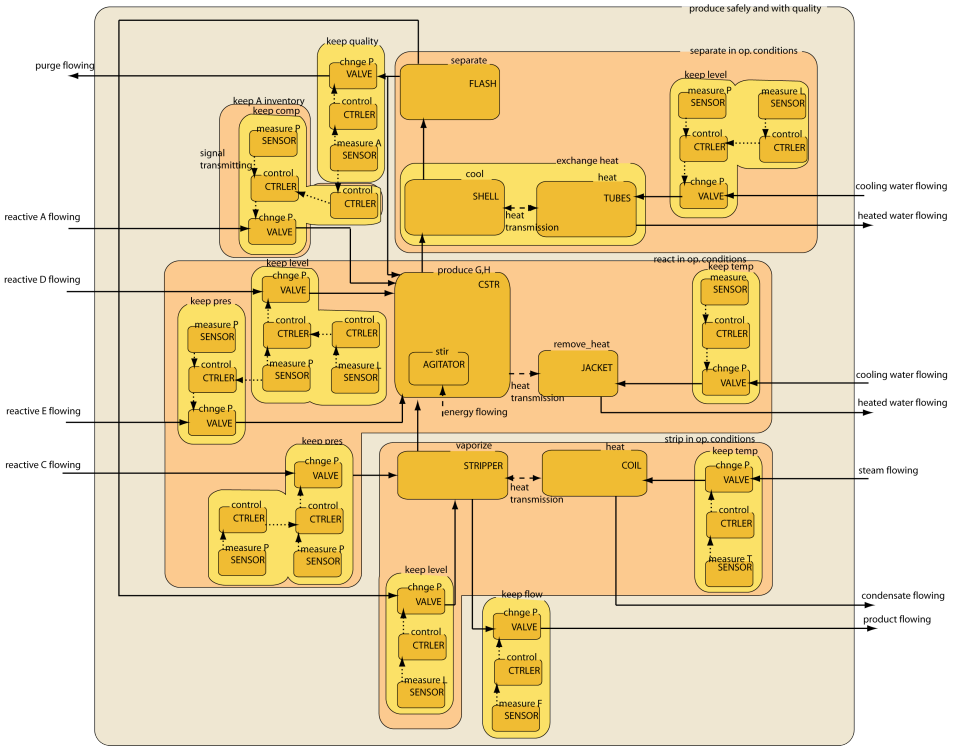

Fig 5. D-Higraph diagram of the Tennesse Eastman process.

4. Implementation

The implementation will be based on a model driven approach for systems engineering. of the visual formalism D_Higraphs. To support this model based design and implementation, sysML (Systems Modeling Language) will be used as it is suited for modeling different aspects (functional/behavioral, structural, operational) of large scale engineering projects. SysML is an extension of the Unified Modeling Language (UML) and it is specified in [11]. SysML models can be transformed into models used by simulation languages.

Figure 6 shows the implementation diagram. Model development will be based on existing ontologies, namely a domain -structural- ontology (as can be ONTOCAPE [12] for the process systems domain) and a functional ontology. The built (D-higraph) model can be mapped to a sysML model (with different views) that can be itself transformed to a model for many (simulation) languages. For example an interface definition language model (.idl extension) can be generated from the sysML description and this can be embedded in a simulator as a Cape Open component. A direct mapping from the D-higraph model to a commercial modeling environment is as well possible.

Following the systems engineering approach a product will be generated from the requirements specification using the commented components.

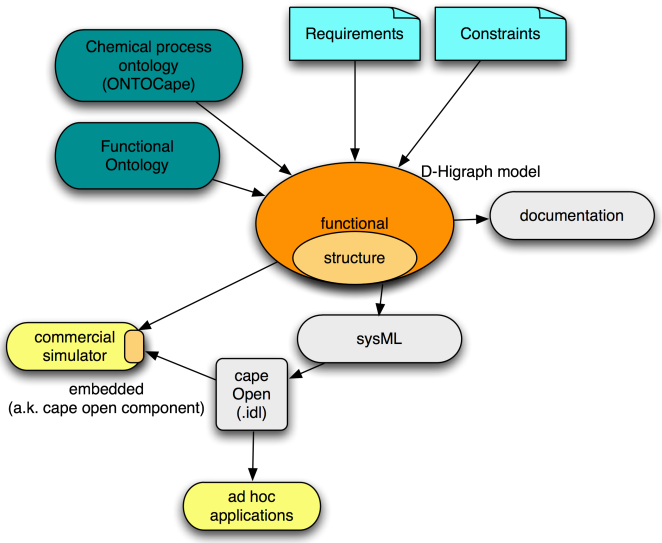

Fig 6. Implementation diagram. Model based engineering.

5. Conclusions

In this paper a new formalism has been described, based on higraphs it extends and adapts them to be used for process systems description. Structure and functionality are captured by the resulting diagram, which can be understood without many additional explanations. Not only process information but control information as well is displayed in the diagram. The diagram can be used for multiple purposes from fault diagnosis or risk analysis, to process documentation although only risk analysis have been outlined in this paper. Being a layered diagram, different views can be displayed, allowing for more abstract or specific views, or for just a functional or structural view. Further work includes representing (in a similar fashion as in existing commercial simulators) quantitative models, mapping ontologies to models and integrating the components in a single architecture with additional features, mainly cognitive.

A Fast and Systematic Procedure to Develop Dynamic Models of Bioprocesses – Application to Microalgae Cultures

Johan Mailier and Alain Vande Wouwer

Control Department, Polytechnic Faculty - University of Mons
31 Boulevard Dolez, 7000 Mons, Belgium.

Abstract

The purpose of this paper is to report on the development of a procedure for inferring black-box, yet biologically interpretable, dynamic models of bioprocesses based on sets of measurements of a few external components (biomass, substrates, products of interest). The procedure has three main steps: (a) the determination of the number of macroscopic biological reactions linking the measured components, (b) the estimation of a first reaction scheme, which has interesting mathematical properties, but might lack a biological interpretation, and (c) the "projection" (or transformation) of this reaction scheme onto a biologically-consistent scheme. The advantage of the method is that it allows the fast prototyping of models for the culture of micro-organisms that are not well documented. The good performance of the third step of the method is demonstrated on an application example of vegetal cell culture.

Keywords: reaction networks, mathematical modeling, parameter estimation, bioprocesses

1. Introduction

The increasing demand in process monitoring, control, and optimization encourages the development of various techniques for modeling bioprocesses. Among these techniques, the one exposed by Bastin and Dochain [1990] relies on the concept of macroscopic reaction schemes. These schemes consist of a set of reactions that represent simple relations between key-components like substrates, biomass, and products of the process. The general form of a macroscopic reaction scheme is

$$\sum_{i\in\mathcal{R}_k}(-\nu_{ik})\xi_i \xrightarrow{\varphi_k} \sum_{i\in\mathcal{P}_k}\nu_{jk}\xi_j, \quad k\in[1,M], \tag{1.1}$$

where $\mathcal{R}_k$ and $\mathcal{P}_k$ are respectively the sets of reactants and products of reaction k, φ_k is the k^{th} reaction rate expressed as a function of the reacting species concentrations, and ν_{*k} are the yield (or pseudo-stoichiometric) coefficients of reaction k. This simple formulation provides a dynamic model of the process that requires no knowledge on its metabolic pathways, yet preserving some biological meaning. In the absence of gaseous outflow, a mass balance applied to (1.1) gives

$$d\xi(t)/dt = K\varphi(\xi) - D(t)\xi(t) + Fe(t), \tag{1.2}$$

where $\xi(t) \in \mathbb{R}^N$ is the vector of species concentrations, $K \in \mathbb{R}^{M \times N}$ the pseudo-stoichiometric matrix, $\varphi(t) \in \mathbb{R}^M$ the reaction rate vector, $D(t) \in \mathbb{R}$ the input dilution rate, and $Fe(t) \in \mathbb{R}^N$ the external feed rates.
The considered problem is to use the measurements of $\xi(t)$ in order to identify the elements ϑ_K of the pseudo-stoichiometric matrix K, and the parameters ϑ_φ of the kinetic function $\varphi(\xi)$, the structure of which is assumed to be known as soon as the number of reactions M is known.

2. Robust Methodology of identification

In this study, the assumption is made that the whole vector $\xi(t)$ is measured at discrete times. A continuous version of the measurements can be obtained through simple filtering and interpolation.

2.1. Number of Reactions

As described by Bernard and Bastin [2005a, 2005b], the number of reactions M needed by the model to reproduce the dynamic observations is successfully estimated by principal component analysis (PCA) applied to the measurements, possibly filtered and interpolated. In the sequel, this first stage is assumed to be completed, so that the number of reactions M is known.

2.2. Identification of C-Identifiable Schemes

A systematic data-driven method has been suggested by Hulhoven et al. [2005] to identify those reaction schemes that satisfy the mathematical property known as C-identifiability. This procedure relies on a state transformation, operated via the partitioning of the pseudo-stoichiometric matrix K into matrices $K_a \in \mathbb{R}^{M \times M}$ and $K_b \in \mathbb{R}^{(N-M) \times M}$. The dynamics of the transformed state vector $z = CK_a + K_b$ (with matrix $C \in \mathbb{R}^{(N-M) \times M}$ chosen so that $CK_a + K_b = 0$) is independent of the reaction rates $\varphi(\xi)$. Moreover, the dynamics of z involves C, which can then be estimated from the measurements, independently of the kinetics. Those reaction schemes whose matrix K uniquely derives from the knowledge of C, are called C-identifiable (Chen and Bastin [1996]).

The procedure of Hulhoven et al. [2005] forces the C-identifiability of the identified model, by testing specific values of K_a, and selecting the one that gives the lowest cost function after identification of the matrix C. Matrix K is then simply derived from K_a and C.

However, the majority of the real bioprocesses are not C-identifiable, so that there is little interest in determining an "optimal" K_a, which anyway would lead to a reaction scheme lacking biological interpretability. Therefore the present approach simply sets K_a equal to the identity matrix I_M for identifying the matrix C independently of the kinetics (Bogaerts et al., 2008). In the sequel, it is assumed that C has been identified, so that the model now writes

$$d\xi(t)/dt = \begin{pmatrix} I_M & -C^T \end{pmatrix}^T \varphi_C - D(t)\xi(t) + Fe(t), \tag{2.1}$$

where φ_C is a reaction rate vector which may not be biologically consistent (for instance it could be negative). However, it can be estimated from measurements. The introduction of biological consistence into the model is left to the next stage of the

procedure, which does so by identifying the matrix K_a that projects the model (2.1) onto the following biologically consistent model, i.e. this model satisfies biological constraints on its pseudo-stoichiometric and kinetic parameters:

$$d\xi(t)/dt = \begin{pmatrix} K_a^T & -K_a^T C^T \end{pmatrix}^T (K_a^{-1}\varphi_C) - D(t)\xi(t) + Fe(t). \tag{2.2}$$

Note that following Delcoux et al. [2001], (2.1) and (2.2) are equivalent models because they describe the same time-evolution of the state vector $\xi(t)$.

2.3. Identification of Biologically Relevant Schemes

This last stage, to which the main contribution of the present study is devoted, can itself be decomposed into two intermediate steps: a quick estimation step, followed by a refining step that consists of a classical maximum-likelihood identification of all the parameters, starting from the values obtained by the quick estimation. Only the first step is described in this paper, since it is precisely the contribution of this work.

The purpose is to find K_a together with the kinetic parameters ϑ_φ, so that the projected reaction rates have a relevant biological structure: $K_a^{-1}\varphi_C = \varphi(\xi, \vartheta_\varphi)$. To do so quickly, (2.2) is rearranged by grouping the measured signals (i.e. $d\xi/dt + D\xi - Fe$, possibly filtered and interpolated) column-wise in the left-hand side. Doing so for the other signals in the right-hand side gives the following matrix equation:

$$U = \begin{pmatrix} I_M & -C^T \end{pmatrix}^T K_a(\vartheta_K)\Phi(\vartheta_\varphi), \tag{2.3}$$

from which a least-square estimator of K_a is built as a function of ϑ_φ (via Φ):

$$\widehat{K}_a = (I_M + C^T C)^{-1}(\mathrm{I}_M \quad -C^T)\Phi^T(\Phi\Phi^T)^{-1}. \tag{2.4}$$

Biological constraints on ϑ_K can also be added, using a classical constrained linear optimization for the estimation of $K_{\hat{a}}$

The quick estimation step then consists of a (constrained) nonlinear optimization of ϑ_φ that aims at minimizing the following cost function built from (2.3) and (2.4):

$$\mathcal{J} = \sum_i \sum_j \left(U - (I_M \quad -C)\widehat{K}_a\Phi \right)_{i,j}^2. \tag{2.5}$$

3. Simulation Example

The continuous cultivation of microalgae in a photobioreactor is considered, where growth is limited by a single nutrient. Attention is focused on the third stage of the identification procedure (consisting of a quick parameter estimation without integration of the model equations, and of a final global nonlinear identification) and its comparison with a standard identification of all the parameters in a single step.

3.1. Macroscopic Model

Plant cells generally behave differently from animal cells. Indeed, rather than directly depending on the external substrate concentrations, their growth rate is bound to the quantity of stored nutrients. The concept of nutrient quota, i.e. the quantity of nutrient per biomass unit, has therefore been widely used in algal growth models, like the well-

known Droop model. However, these quotas do not fit well in the formalism of the general dynamic model, which rather uses absolute quantities. Therefore, algal growth should be modeled in terms of total amount of stored nutrients, i.e. multiplying quotas by the biomass.

The considered model has been developed by Lemesle and Mailleret [2008], as a mechanistic reformulation of the Droop model. The first reaction is the storage of extracellular substrate *S* into the cell, and the second is the metabolism of stored nutrients *R* to produce biomass *X* and metabolized nutrients *B*:

$$\begin{aligned} &1S \xrightarrow{\varphi_1} 1R && \text{(substrate storage)},\\ &0.5R \xrightarrow{\varphi_2} 0.5B + 1X && \text{(biomass growth)}. \end{aligned} \tag{3.1}$$

with the reaction rates $\varphi_1 = S/(S+15)\,X$ and $\varphi_2 = (R/X)/(1+R/X)X$. A simple mass balance on (3.1) gives the following matrix system of differential equations:

$$\begin{pmatrix} dS/dt \\ dR/dt \\ dB/dt \\ dX/dt \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \\ -1 & -1 \\ -2 & -2 \end{pmatrix} \begin{pmatrix} \vartheta^*_{K_{1,1}} & \vartheta^*_{K_{2,1}} \\ \vartheta^*_{K_{1,2}} & \vartheta^*_{K_{2,2}} \end{pmatrix} \begin{pmatrix} \dfrac{S}{S+\vartheta^*_{\varphi_1}} X \\ \dfrac{R/X}{\vartheta^*_{\varphi_2}+R/X} \end{pmatrix} - D \begin{pmatrix} S \\ R \\ B \\ X \end{pmatrix} + D \begin{pmatrix} S_{in} \\ 0 \\ 0 \\ 0 \end{pmatrix}, \tag{3.2}$$

with $\begin{pmatrix} \vartheta^*_{\varphi_1} & \vartheta^*_{\varphi_2} & \vartheta^*_{K_{1,1}} & \vartheta^*_{K_{2,1}} & \vartheta^*_{K_{1,2}} & \vartheta^*_{K_{2,2}} \end{pmatrix}^T = (15 \;\; 1 \;\; -1 \;\; 1 \;\; 0 \;\; -0.5)^T$.

3.2. Simulated Experimental Data

Four experiments are made, with a constant dilution rate $D = 0.1$, starting from the following measured initial conditions: $\xi_{0,1} = (2 \;\; 0.75 \;\; 5.9 \;\; 3)^T$, $\xi_{0,2} = (30 \;\; 0.25 \;\; 5.3 \;\; 2.6)^T$, $\xi_{0,3} = (10 \;\; 0.5 \;\; 2.6 \;\; 1.3)^T$, and $\xi_{0,4} = (4 \;\; 1 \;\; 2.2 \;\; 1)^T$.

Sixty equally-spaced measurements of $\xi(t)$ are made for each experiment, from $t = 0$ to $t = 60$. Gaussian noise is then added, with a constant relative standard deviation $\sigma = 0.05^{1/2}$. Interpolation is performed by the Matlab function *csaps*, with a smoothing parameter $p = 0.9$, while filtering is achieved by a moving average filter with a five-measurement moving window.

3.3. Identification Results

Fifty initial guesses (ten for each value of $\Delta\vartheta$) are generated using the formula $\vartheta_0 = \vartheta^*(1+\Delta\vartheta.\alpha)$, where α is a standard normally distributed random vector. The first step of the optimization is carried out by a Fletcher version of the Levenberg-Maquardt algorithm (Fletcher [1971]), while direct one-step optimizations use the Nelder-Mead simplex method (Matlab function *fminsearch*).

Figure 1 illustrates the repartition of the relative distances between the estimates and their corresponding optimum values, for ϑ_{φ_1} (left column) and ϑ_{φ_2} (right column). Compared to direct identification, excellent performances are obtained with the new method, since the estimates are always close to their optimum value. In this specific example, the second step of the new algorithm does not improve the estimation provided by the first step, due to the limited information content of the measurements.

Because there is no numerical solution of the model equations, the quick estimation step of the new method takes only a few seconds, which is much faster than the few minutes of the direct identification. Figure 2 illustrates these observations.

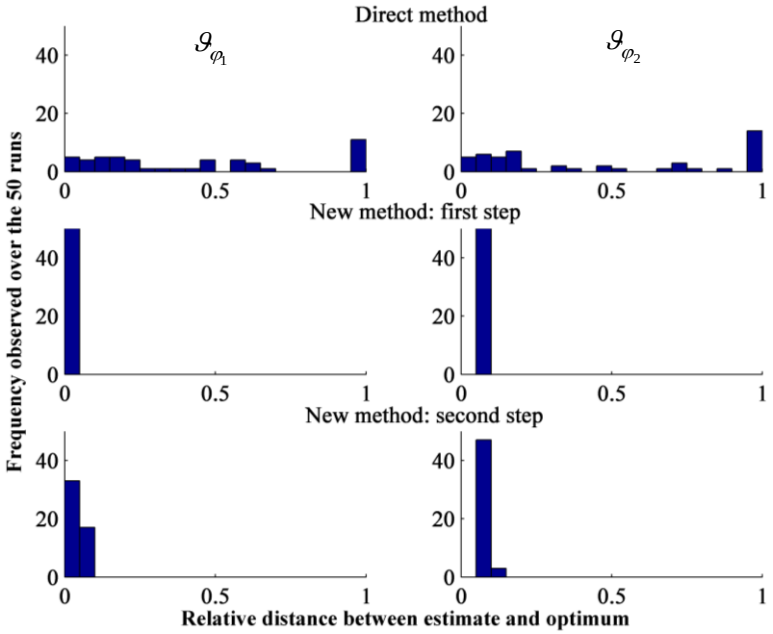

Figure 1. Histogram of the relative distance between estimates and their corresponding optimal values, after direct identification (top), quick estimation (middle), and final identification (bottom)

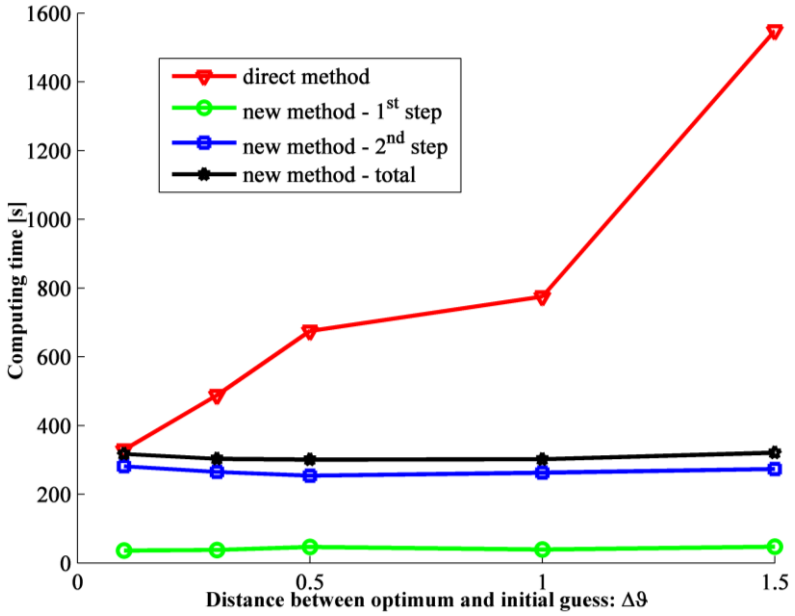

Figure 2. Mean computing time as a function of the distance $\Delta\vartheta$ between the initial guesses and the optimum parameters.

4. Conclusions

The systematic identification procedure developed in this paper uses and extends previous research results to the projection of C-identifiable schemes onto biologically consistent schemes. The strong point of the new approach mainly lies in the quick estimation step of the projection stage. Indeed, it has a low computation time because it integrates no differential equation, and also because it operates on a limited number of parameters, i.e. the set of kinetic parameters. Moreover, a simulation example of continuous microalgae culture has shown that the new method is more robust than direct global identification with regard to uncertainties on initial guesses.

Reliability vs. efficiency when solving multiphase equilibrium problems with hybrid optimization codes

Paula B. Staudt and Rafael de P. Soares

Department of Chemical Engineering, Federal University of Rio Grande do Sul – UFRGS, Rua Engenheiro Luis Englert, s/n, CEP 90040-040, Porto Alegre - Brasil

Abstract

Computation of phase equilibrium is a very important and frequently encountered problem in process systems engineering. Accurate and robust flash routines are at the core of the major part of chemical engineering design applications, ranging from pipelines to distillation columns, chemical reactors, and oil and gas production. The multiphase equilibrium calculation by the direct minimization of the Gibbs free energy has some potential advantages over classical methods, mainly because the equality of chemical potentials is a necessary but not a sufficient condition for equilibrium. Recent developments in global optimization and the availability of very fast computers have stimulated the research on the direct minimization approach. In this work, a hybrid method (genetic algorithm for the global search and interior point for refinement) was implemented and the efficiency/reliability relation was studied. For some systems the global minimum can be found in a NFE compatible with the methods currently available in process simulators. But, it was also found that, for some systems, there is an asymptotic behavior. Apparently, a reliability of 100 %, when using global search algorithms with some random nature, would be found only for an infinite number of function evaluations.

Keywords: Global optimization, Gibbs minimization, multiphase equilibrium.

1. Introduction

Phase equilibrium calculations and phase stability problems have to be solved a very large number of times in the design and analysis of chemical processes. For a system with specified components, composition, temperature and pressure, a phase equilibrium problem involves the calculation of number of moles of each phase and its composition at equilibrium whereas phase stability analysis determines the stability of the system (Srinivas and Rangaiah, 2007).

Today, the availability of fast computers has stimulated the research of reliable but efficient methods for resolving phase equilibrium calculations. Methods for solving phase equilibrium problems can be classified into two main categories: equation-solving and direct minimization of the Gibbs free energy. A minimum in the Gibbs free energy implies that chemical potential, activity, and fugacity of each component must be equal in all phases of the system. In the equation-solving approach this isoactivity (or fugacity matching) conditions coupled with mass balances and mole fraction summations for an assumed number of phases are solved numerically (Teh and Rangaiah, 2002). Even though, equation solving approach seems to be faster and simple, the solution obtained by this method may not correspond to the true minimum of Gibbs free energy function.

A major drawback is that the equality of chemical potentials represents only the stationary point conditions for the minimum. Any method based on these conditions may fail to find the global minimum, being attracted by local minima. Also, it needs *a priori* knowledge of phases coexisting at equilibrium (Srinivas and Rangaiah, 2007). Then it is usual to combine equation-solving and phase stability algorithms to determine the number of existing phases and their composition.

A second approach, which has gained much attention recently, is the treatment of the phase equilibrium problem by the direct minimization of Gibbs free energy (Nichita et al., 2002). This optimization problem consists in the minimization of the overall system Gibbs free energy:

$$\frac{G(n)}{RT} = \sum_{k=1}^{N_p} \sum_{i=1}^{N_c} n_i^k \, ln f_i^k \tag{1}$$

satisfying the appropriate material balance constraints:

$$\sum_{k=1}^{np} n_i^k = n_i \qquad i = 1,2,3, \dots, N_c \tag{2}$$

and bound constraints:

$$0 \leq n_i^k \leq n_i \quad i = 1,2, \dots, N_c \quad k = 1,2, \dots, N_p \tag{3}$$

where n_i is the overall (or feed) number of moles of the component i, n_i^k and f_i^k are the number of moles and the fugacity of the component i in the phase k, respectively. The decision variables for minimizing the free energy are n_i^k. The maximum number of phases at equilibrium N_p is considered to be known. If N_p is greater than the actual number of phases at equilibrium, the solution will contain empty phases (all n_i^k zero for a phase k) or identical phases (phases with nonzero n_i^k values but identical composition). Identical phases need to be identified and agglutinated into a unique phase in a post processing step.

The constrained minimization problem (Equations 1-3) can be simplified to a bound-constrained problem replacing the decision variables n_i^k by β_i^k (for $i=1,2,\dots,N_c$; $k=1,2,\dots,N_p-1$). The new variables, β_i^k are bounded between 0 and 1 and are related to n_i^k by:

$$n_i^1 = \beta_i^1 n_i \tag{4}$$

$$n_i^k = \beta_i^k \left(n_i - \sum_{j=1}^{k-1} n_i^j \right) \quad i = 1,2, \dots, N_c \quad k = 2, \dots, N_p - 1 \tag{5}$$

The equality constraints are eliminated and the number of decision variables is reduced from N_c by N_p to N_c by N_p-1. The optimization problem (Equation 1) with the decision variables β_i^k is a bound-constrained problem. This problem is much more suited for the solution using stochastic methods than the constrained optimization problem (Equations 1-3). Regardless the formulation (constrained or bound-constrained), the difficulty of phase equilibrium calculations using the direct optimization approach comes from the highly nonlinear and non-convex form of the objective function (the fugacity coefficients in Equation 1) that gives no guarantee that the global minimum will be found.

In this work, the solution of multi-phase equilibrium problem by the minimization of the bound-constrained optimization problem by a hybrid algorithm (global + local) is studied. Our objective is to obtain an optimum balance between global and local search reducing the number of function evaluations in the global search step as much as possible without sacrificing the reliability.

2. Robustness and Reliability

In order to solve a multi-phase equilibrium calculation by direct minimization of the Gibbs free energy, an optimization problem needs to be solved. The objective function of this optimization problem is highly nonlinear and non-convex. The complexity of the problem increases near critical points and phase boundaries. In order to reach the global minimum a global optimization strategy is necessary, but it is common sense that global optimizers are very computationally expensive.

In many practical applications, heuristic stochastic methods have been successfully used. These algorithms do not use any gradient information and are usually initialized with random values. Examples are: genetic algorithms, tabu-search, simulated annealing, tunneling and differential evolution. This class of methods has the property to descend the objective function value very fast at the beginning, but as they lose diversity information of the space, they tend to be extremely slow to actually get the global solution (Nichita et al., 2002). As a consequence, the global minimization tends to be very computationally intensive. Because of this, the use of hybrid procedures is becoming more frequent in literature (Teh and Rangaiah, 2003; Balogh et al., 2003; Srinivas and Rangaiah, 2007).

In this work, we solve the optimization problem in two steps. A genetic algorithm (GA) *evolves* a *population* of fixed size (randomly initialized) for a fixed number of evolutions. The *individual* with the best objective function is used as the starting point for an interior point algorithm which does the local optimization. The GA implementation used was the open-source package JGAP (http://jgap.sourceforge.net). For the local search the interior point open-source optimization package IPOPT from Wächter and Biegler (2006) was used. The first-order derivatives of the objective function required by the local minimizer were obtained analytically.

GA implementations usually do not have a convergence criteria, the user just select a *population* size and a number of *evolutions* to be executed. In our approach, the GA *fittest individual* (the best point found) is the starting point to the local optimization method (that uses gradient information). The objective is to refine the solution of the global optimization in few extra function evaluations.

The most important aspect of this kind of approach is how it balances global *vs*. local searches. Emphasis on global search increases the number of function evaluations significantly. While emphasis on local search can decrease the total number of function evaluations, it usually decreases the reliability in finding the global solution (Saber and Shaw, 2008). When using GA the emphasis on the global search is mainly controlled by the population size and the number of evolutions.

In order to discover the reliability/efficiency relation for our hybrid implementation several experiments varying the population size and number of evolutions were executed for the Problem 1 (Table 1). The reliability (RE) is the rate of success in finding the true global minimum of the problem and it is obtained by running the same problem a certain number of times. The term efficiency is measured as the inverse of the number of function evaluations (NFE) required for the solution (including both steps global and local). The Problem 1 is known to have a global minimum very difficult to

find. To compute the reliability, 2500 independent optimizations were executed for each pair of population and evolutions. The results can be seen in Figure 1.

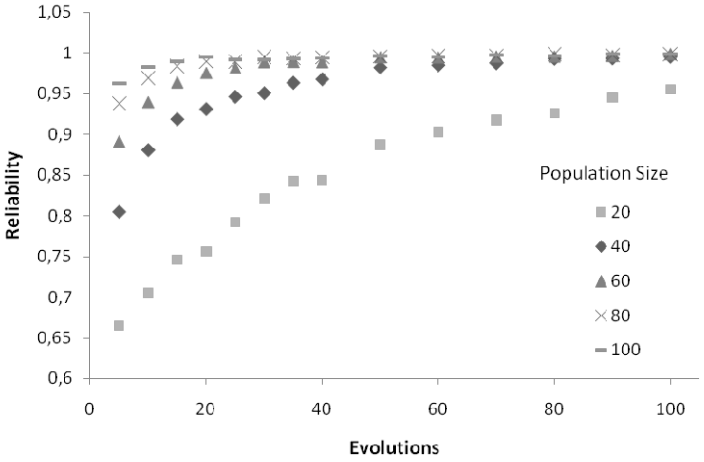

Figure 1: Variation of reliability with number of evolutions and population for Problem 1

The different curves illustrate the variation of the number of evolutions for a fixed population. As expected, large population sizes and large number of evolutions produces larger reliabilities but an asymptotic behavior is noticed (no experiment in Figure 1 actually reached reliability equals 1). This indicates that no matter how big is the population size or the number of evolutions, there will always be a small probability of missing the true global minimum.

In Figure 2 we can observe the relation between NFE and reliability. As can be seen, there is room for a great improvement in reliability when the NFE is small. But in the vicinity of 100% reliable, better results can be obtained only by a great increase in the NFE.

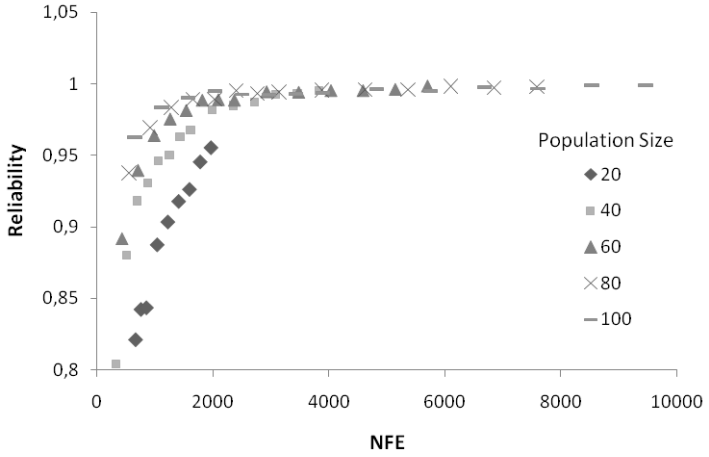

Figure 2: Reliability vs. NFE for Problem 1, including all tests of Figure 1.

This means a great additional effort for a very small gain, because no matter how large is the NFE, there will always be a small probability of failure in finding the true global minimum. Large population sizes and number of generations are very often in the literature, for instance in Teh and Rangaiah (2003), they are set to 200 and 100,

respectively. From the results in Figure 2, we can conclude that this is a conservative set of parameters. Still, according to the Figure 2, we can see that in the low reliability region, a bigger population size offers a better reliability in less NFE. This relation is not clearly observed when reliability around 100 %. Thus, we decided to set the population size as 50 and the number of evolutions as 30 for solving the benchmark problems in Section 3.

3. Results with Benchmark Problems

Using the optimum set for the population size and number of evaluations obtained in the previous section, the performance of our hybrid implementation was tested using benchmark problems drawn from the literature.

Table 1: Benchmark problems used to test the implementation.

	Mixture	**Model**	**Eq.**	**Reference**
1	Toluene, water, aniline	NRTL	LLE	McDonald and Floudas (1995)
2	Hydrogen sulfide, methane	SRK	VLE	Hua et al. (1998)
3	N-butyl acetate, water	NRTL	LLE	McDonald and Floudas (1996)
4	Nine hydrocarbons	SRK	VLE	Rangaiah (2001)
5	Nitrogen, methane, ethane	PR	LLE	Hua et al. (1998)
6	Benzene, acetonitrile, water	NRTL	VLLE	McDonald and Floudas (1995)

The efficiency of our implementation was evaluated through the NFE necessary to achieve the solution of the minimization problem. The NFE of each example above were compared to those found by Teh and Rangaiah (2003) with GA and Tabu search for global search and a quasi-Newton method for local refinement, referred as GAQN and TSQN, respectively. Also, a comparison was made with the differential evolution (DE) approach in Srinivas and Rangaiah (2007) and simulated annealing (SA) results from Rangaiah (2001). In Teh and Rangaiah (2003), the number of generations used was 100 and the population size equal to 200. The reliability number was found running only 25 times each example. In this work the reliability was computed running 100 times each problem.

Table 2: Efficiency comparison with other algorithms.

	This work		***GAQN***		***TSQN***		***DE***		***SA***	
	NFE	**RE**	**NFE**	**RE**	**NFE**	**RE**	**NFE**	**RE**	**NFE**	**RE**
1	**1493**	**99%**	20069	96%[a]	1719	96%[a]	-	-	-	-
2	**1320**	**99%[b]**	20024	80%	1187	96%[a]	-	-	-	-
3	1336	73%	20018	96%[a]	**1425**	**96%[a]**	7600	99%[b]	34563	99%[b]
4	**2855**	**82%**	20515	96%[a]	10040	96%[a]	-	-	134767	99%[b]
5	1449	87%	20238	96%[a]	**1777**	**96%[a]**	-	-	-	-
6	**1991**	**99%[b]**	20212	96%[a]	5615	96%[a]	-	-	-	-

[a] 100% in 25 runs [b] 100% in 100 runs

The NFE shown is the total number of function evaluations to solve the problem, including both global and local search steps. As can be seen in Table 2, our implementation presents a very good reliability in much less function evaluations for most problems. Even for a bigger problem like the example 4, with nine components, the NFE was much smaller than the other implementations. Reliability larger than 82 % can be achieved for this problem if the population size or number of evolutions is

increased, this can be done without much performance penalty. For Problems 3 and 5 Tabu search shown a better reliability with NFE only slightly greater.

4. Conclusions

The correct prediction of multi-phase equilibrium problems is a very important task. The minimization of Gibbs free energy is a promising approach to solve this class of problems. There are many methods to solve the problem and hybrid algorithms have a great advantage because they merge global search and local search becoming more efficient and robust. These two aspects, efficiency and robustness, are closely connected and have to be analyzed together. The reliability of a method is inversely proportional to the efficiency, thus a balance is necessary to get the better performance.

When a stochastic method is used, like genetic algorithm, the reliability analysis requires some attention. Because of the random character of the method, two independent optimization runs can lead to different solutions. Even if a first execution succeeded to find the global minimum, there is no guarantee that the next independent run will. This effect is more evident if a complicated problem is solved. Analyzing the results of a phase equilibrium problem with a very difficult to find global minimum, it was found that a reliability of 100 % would require an infinite number of function evaluations. Besides, after a certain number of function evaluations (which is problem dependent) an increase in the size of the optimization problem (populations and evolutions) does not guarantee a better reliability; just make the approach less efficient.

Abstract

Fouling is a complex problem which affects thermal equipment. The deposits over the heat exchanger surface diminish the thermal effectiveness and increase flow resistances. The consequences of fouling are related to important economic penalties, such as, more expensive equipment with larger thermal surfaces, higher energy consumption costs (heat/power), shutdown costs for exchanger cleaning, fluid treatment costs, etc. Despite the considerable research efforts about this subject, the engineering practice is still based on traditional approaches, e.g., fouling factors. Several recent papers have been focused on the schedule optimization of heat exchanger cleaning during a certain time horizon. In this case, optimization algorithms demand the availability of a heat exchanger network model in order to predict the network behavior. Aiming to this important problem, this paper presents the modeling and simulation of heat exchanger networks subjected to fouling. A fundamental aspect of the proposed simulation scheme involves the capacity to represent the network behavior considering heat transfer and fluid flow aspects simultaneously. For a given set of fouling models, it is possible to predict the temperature and flow rate along a heat exchanger network during a certain time span in the future. The model is represented by a set of matrix equations, where the network structure is parameterized using graph theory concepts. The potentiality of the proposed simulation scheme is illustrated through a typical example of an industrial heat exchanger network.

Keywords: fouling, heat exchangers, simulation.

1. Introduction

The modern concern of the society with the rational use of fossil fuel energy is not only with respect to environmental laws, but mainly because the costs are increasing every year. In process plants, an important issue about energy efficiency involves fouling management. Fouling is the accumulation of deposits on the surface of heat exchange equipment; as a consequence, this phenomenon imposes higher energy consumption to reach the required process temperatures. The traditional design of heat

exchangers take into account a factor for fouling, but due to the complexity of predicting its behaviour, often occurs unnecessary oversizing of equipment. Other important economic impacts due to fouling involve heat exchanger cleaning costs, shutdown costs, necessity of treatment of certain streams, etc.

Besides the fouling aspects related to heat transfer, fouling also brings problems to fluid flow. In this context, this paper discuss a heat exchanger network algorithm involving heat transfer equations coupled to fluid flow equations in order to predict the network behavior. The model is represented by a set of matrix equations, where the network structure is parameterized using graph theory concepts, allowing an expansion of the purely thermal approach of Oliveira Filho et al., 2007.

2. Model of network elements

The main network elements considered in this analysis are heat exchanger, pipe sections and flow machines (e.g. centrifugal pumps). The following subsections discuss the model employed for the description of the behaviour of each element. Since, the network model will be employed for optimization and time series analysis, unnecessary complex models were discarded for the representation of each element.

2.1. Heat Exchangers

The heat transfer in heat exchangers can be modeled by linear equations in relation to inlet and outlet temperatures. This linear structure can be built employing the ε-NTU method.

In this context, the equations can assume the following form (Oliveira Filho et al., 2007):

$$\begin{bmatrix} \varepsilon + (y-1) & -(y-1) & y-\varepsilon & -y \\ C_R(y-1)+y & -C_R(y-1)-y & C_R y+(y-1) & -C_R y-(y-1) \end{bmatrix} \underline{T} = \underline{0} \qquad (1)$$

where the parameter y is equal to 1, if the minimum fluid is the hot stream (i.e. the heat capacity flow rate of the cold stream is larger than the hot stream one), otherwise it is equal to 0, C_R is the ratio between maximum and minimum heat capacity flow rates and $\underline{T}$ is a vector of heat exchanger temperatures, $\underline{T}^T = [\ T_{c,i}\ \ T_{c,o}\ \ T_{h,i}\ \ T_{h,o}\ ]$ (c and h represent cold and hot streams, i and o represent equipment inlet and outlet.

The film coefficients of each stream in the heat exchanger is calculated using the equation below, with a base case and a correction factor to account for the variation of the stream flow rates:

$$h = h_{base}(m \,/\, m_{base})^n \qquad (2)$$

where h is the film coefficient, m is the mass flow rate and the exponent n is 0.8 for tube side flow and 0.6 for shell side flow, considering turbulent regime.

The hydraulic equation for heat exchangers is also built employing a base case correction:

$$P_i - P_o = \Delta P_{base}(m \,/\, m_{base})^n \qquad (3)$$

where P is the stream pressure and n is equal to 1.8 for tube side and shell side flow, in turbulent regime.

2.2 Flow machines

Flow machine model corresponds to the representation of a characteristic curve, e.g., centrifugal pumps/compressors:

$$P_i - P_o = -\rho g \sum a_i (m/\rho)^i \tag{4}$$

where a_i are coefficients of the polynomial equation of the characteristic curve. Eventual thermal effects during fluid flow along the machines are not considered

2.3. Pipe sections

The model equation for a pipe section corresponds to the Bernoulli equation, with the head loss described by the Darcy equation:

$$P_i - P_o - [(8L)/(\rho \pi^2 D^5)]m^2 + \rho g(z_i - z_o) = 0 \tag{5}$$

where L is the pipe length, D is the inner pipe diameter and z is the elevation. Head losses due to fittings can be included using the concept of equivalent length.

3. Network representation

The network flowsheet is described through a digraph, where the network connectivity is parameterized by an incidence matrix. In the flowsheet digraph, pipe sections and flow machines correspond to the edges and heat exchangers correspond to the vertices. The flowsheet digraph is employed to model energy balances along the network together with heat exchanger equations (ε-NTU). Figure 1 illustrates the process digraph related to the example discussed later in the Results section.

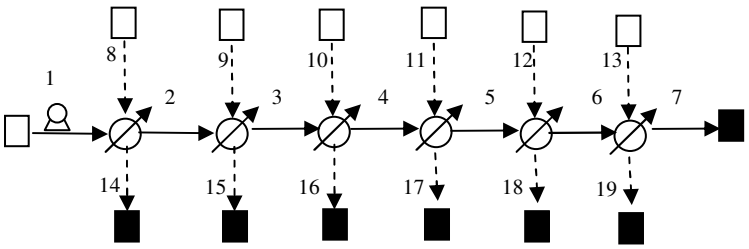

Figure 1. Process flowsheet digraph – Cold streams: continuous lines – Hot streams: dashed lines – Supply units: white squares – Demand units: black squares

However, the hydraulic model of the network, demands a different representation, where the heat exchangers become edges instead of vertices. Using an adequate reorganization algorithm of the incidence matrix, the hydraulic digraphs can be generated automatically. In this process each heat exchanger vertex is transformed in two new edges connected to four new terminal vertices. Figure 2 presents the corresponding digraphs originated from the flowsheet digraph of Figure 1.

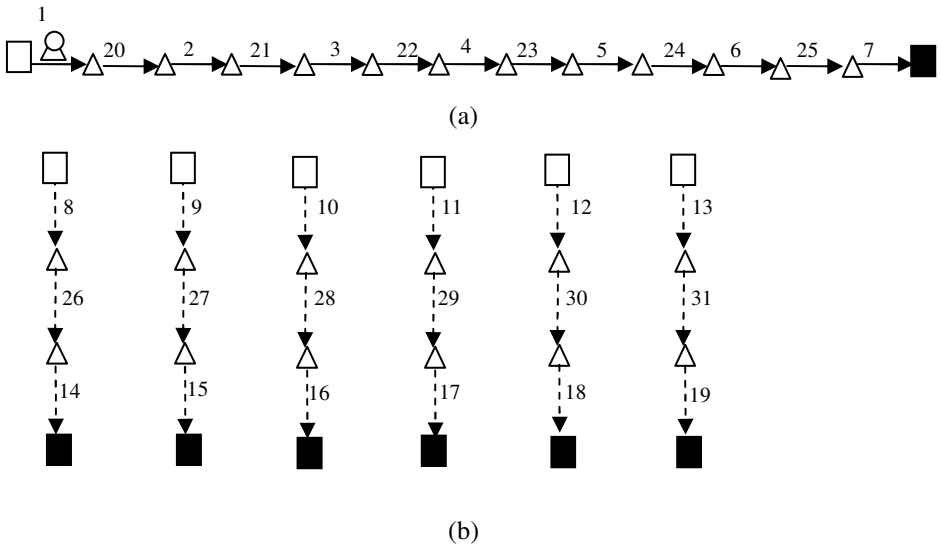

Figure 2. Hydraulic digraphs – Cold streams (a) and Hot streams (b) – Supply units: white squares – Demand units: black squares – Triangles: modified vertices

4. Network modeling and simulation

The models of the network elements are interconnected using a matrix structure based on the corresponding digraphs. The set of equations are organized in two systems: a hydraulic model, composed by a system of nonlinear algebraic equations and a thermal model, composed by a linear system.

The network simulation is conducted in two steps, the flow rates and pressures along the network are determined by the resolution of the hydraulic model through a Newton-Raphson algorithm and, then, the network temperatures are evaluated by the solution of the linear system of the thermal model.

4.1. Fouling

Since fouling is much slower than the temporal behavior of the process variables, the dynamic simulation of a fouled network can be executed using a pseudo-stationary approach. Thus, a time series of the network behavior due to fouling can be generated through a sequence of steady-state simulations, where fouling factors are updated after each individual run. The equation below presents a typical linear model for fouling growth, after a temporal discretization:

$$R_f \Big|_{t+1} = R_f \Big|_t + c\Delta t \tag{6}$$

For a given thermal conductivity of the deposits (k), the fouling thickness (δ) can be given by:

$$\delta = 0{,}5[D_{t,i} - D_{t,i}\exp(-2R_f k / D_{t,i}) \tag{7}$$

where $D_{t,i}$ is the tube inner diameter. Since, the fouling thickness is known; a correction of the tube diameter of the heat exchanger allows the simulation of the respective increase of the pressure drop (Ishiyama et al., 2008).

5. Results

The network example investigated is illustrated by the flowsheet in Figure 1. This structure is typical from a preheat train in petroleum refineries.

The thermal surface of the heat exchangers are presented in Table 1, organized in a countercurrent configuration. The inlet temperature of the cold stream is 30 ºC and the hot stream ones are 90 ºC, 140 ºC, 175 ºC, 220 ºC, 255 ºC and 276 ºC. The cold streams flow inside the tubes with a diameter of 3/4 in. The base conditions of pressure loss and flow rates in the heat exchangers are 0.5 bar and 80 kg/s for hot streams and 0.5 bar and 210 kg/s for cold streams. All heat exchangers are interconnected by pipes with a diameter of 6 in and an equivalent length of 50 m.

The supply and demand points of the cold streams are associated to a pressure of 2 bar and 3 bar, respectively. The specifications of the hydraulic circuit of the hot streams correspond to a pressure of 6 bar at the supply node and the following set of flow rates at the demand point: 40 kg/s, 30 kg/s, 30 kg/s, 80 kg/s, 120 kg/s, 100 kg/s, according to the exchanger ordering. The coefficients of the characteristic curve of the pump are a_0 = 429 m, a_1 = -331 s/m^2 and a_2 = -257 s^2/m^5 (Eq. 6). Fouling growth involves a linear model with $c = 1\cdot10^{-10}$ m^2/K·J (Eq. 8) and deposit thermal conductivity of 0.5 W/m^{2}K.

Table 1. Heat exchanger data

Heat Exchanger	1	2	3	4	5	6
Surface Area (m^2)	681	683	229	281	406	407
Overall coefficient (W/m^{2}K)	1000	3000	2500	3200	2600	4100

For the described problem, two simulations were conducted for a period of 36 months: a traditional thermal simulation and the proposed thermohydraulic simulation.

The cold stream flow rate calculated by the thermal simulation does not change, maintaining a constant value of 479 kg/s during the whole simulation period. Differently, the thermohydraulic model is able to predict the impact of fouling on the head loss, implying the reduction of the flow rate at the end of the simulation from 479 kg/s to 465 kg/s. Additionally, Figure 3 compares the results of both approaches in relation to the final cold stream temperature. As can be seen, there is a considerable difference between the profiles (a smaller cold stream flow rate reaches a higher temperature).

It is important to stress that the traditional thermal simulation does not predict any of these mentioned effects.

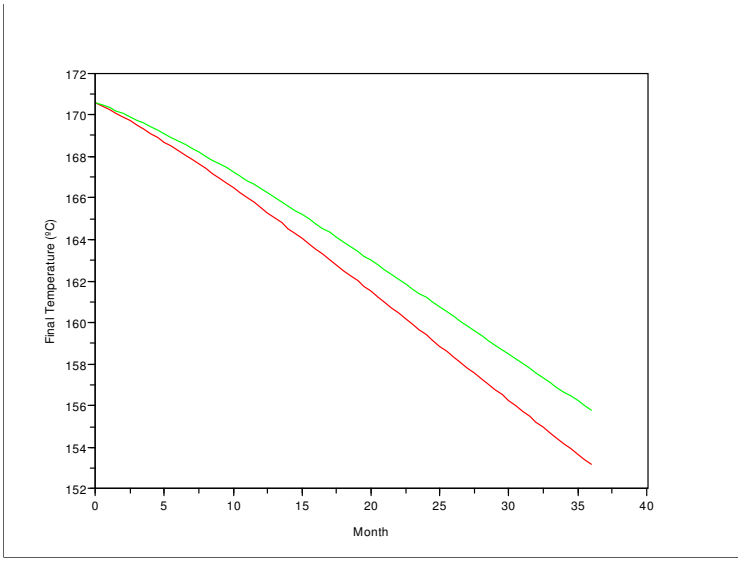

Figure 3. Final temperature of the cold stream
(green – thermohydraulic simulation, red – thermal simulation)

6. Conclusions

This paper presents a thermohydraulic model for heat exchanger network simulation. The proposed algorithm is explored seeking to predict the behavior of fouled networks. A numerical example shows a significant difference of simulation results between a traditional thermal model and the thermohydraulic proposal. This gap illustrates the importance of this approach for an accurate investigation of fouling in networks, especially when there is pump power limitations.

Abstract

The interest in renewable fuels such as bioethanol has significantly increased in the last years all over the world. In this work, a decision-support tool based on a mixed integer linear model for the design of sugarcane supply chains (SC) is developed. The approach considers the minimization of the total SC costs and environmental impact, which is determined according to the Life-Cycle Assessment principles. The solution is a set of Pareto optimal alternatives, i.e. SC configurations with associated strategic planning decisions. The capabilities of the proposed framework are illustrated through a case-study designed on the basis of the current situation in Argentina.

Keywords: bioethanol supply chain, Life-Cycle Assessment.

1. Introduction

Following the global trend, Argentina approved the National Act 26 093 to foment the production of bio-ethanol for fuel blending in 2010. However, given the fiscal-technical uncertainty generated by this measure, it is crucial that the industry turns flexible to satisfy the market, using proper energetic and environmental policies (Borrero et al., 2003; von Blottnitz and Curran, 2007).

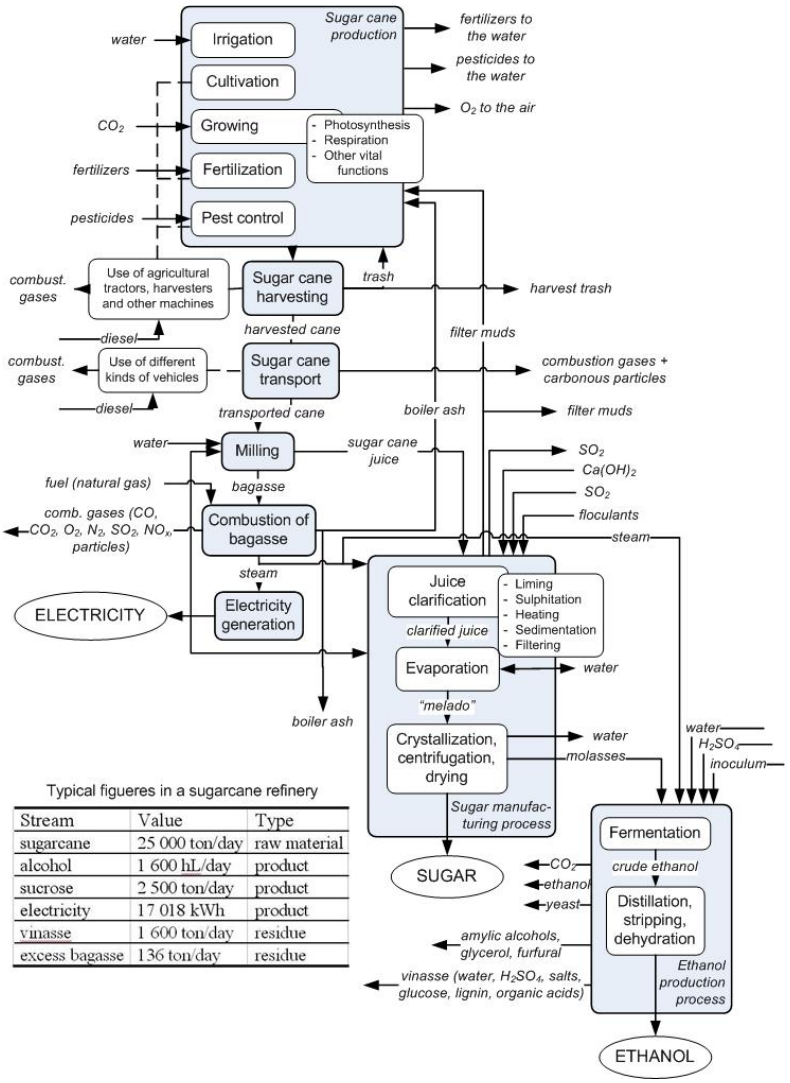
Ethanol production from sugar cane has a clearly positive energy balance which can mitigate global warming, but the fast expansion of the ethanol production/consumption has affected the global market of sugar, whose production is closely linked.

A key issue that still remains open in this area is how to address the design of efficient supply chains (SC) capable of fulfilling the sugar and bioethanol demand in the growing markets. This is not a trivial task, since it requires the understanding of the temporal and capacity interdependencies among the different entities of the network. The problem complexity is further increased by the fluctuating nature of the sugar/alcohol demand in the markets, and the need to consider different conflicting criteria at the design stage (Buddadee et al., 2008).

The aim of this work is to develop a quantitative decision-support tool based on mathematical programming for tackling this last issue, the design of SCs for sugar and bioethanol production. The solution obtained for such a problem will be a set of Pareto optimal alternatives, each of which entailing a particular SC configuration and associated strategic planning decisions (i.e., number, location, type and capacity of the production and storage facilities; sugar and alcohol production at each location; average inventory levels; and type and capacity of the transportation units).

2. Motivating Case Study

The optimization model has been inspired in the sugarcane industry of the NW of Argentina. The area occupied by the sugarcane SC has been divided into sectors, which must be provided as input data to the model. This SC includes a number of plants producing or storing sugar and bio-ethanol; and transportation links between sectors. It is assumed that sugar and alcohol are produced from sugarcane cultivated in the vicinity of the factories by using the current regional technologies. Sugar is elaborated in two different types: white and raw sugar. Ethanol is also made in two qualities: anhydrous (for fuel blending) and azeotropic.



Typical figueres in a sugarcane refinery

Stream	Value	Type
sugarcane	25 000 ton/day	raw material
alcohol	1 600 hL/day	product
sucrose	2 500 ton/day	product
electricity	17 018 kWh	product
vinasse	1 600 ton/day	residue
excess bagasse	136 ton/day	residue

Figure 1. System boundaries for the LCA-based environmental impact assessment

The SC of interest includes (I) a number of plants that produce sugar and bio-ethanol, (II) a set of warehouses where these products are stored before being delivered to the

markets and (III) a set of transportation links that connect the SC entities. The model is used to find different configurations that satisfy the customers' requirements along a time horizon divided into periods. Decisions to be made include the number, type and capacity of the storage and production facilities, the sugar and ethanol production rates and inventory levels at each facility, and the transportation flows. Since this industry combines continuous and batch processes, the periods have been taken large enough so that the operations can be considered to be continuous. Most of the parameters used have been taken from industry, whereas missing data has been supplied from the literature (Hugot, 1982).

The standard production scheme of sugar and ethanol considered is showed in Figure 1. For sugar production, it includes milling, clarification, evaporation (vacuumed quadruple effect tanks), crystallization (three cooked masses), centrifugation and drying. For ethanol production, the process includes: substratum preparation, fermentation, centrifugation, distillation, rectification and dehydration. To obtain ethanol, different combinations (blending) of the sugar production process streams are allowed (sugarcane syrup, molasses A, B or C).

3. Mathematical model

The approach relies on assuming a superstructure that embeds all possible logistic alternatives to the SC design problem. This mathematical representation is then converted into a bi-objective MILP problem that is solved via standard branch and bound techniques. To construct such a superstructure, the overall region of interest (i.e., NW of Argentina) is first divided into a set of sectors, each featured by a specific demand of sucrose and ethanol. The production plants and storage facilities can be established in any of these sectors, and may be expanded in capacity over time in order to follow a specific demand pattern. The model includes three main sets of equations: mass balances, capacity constraints and objective function calculations. A brief outline of each of these blocks of equations is next given.

3.1. Mass Balance Constraints

A total mass balance must be written to relate inputs and outputs of a particular region, in a given period *t*. The current inventory level in a region *f* (S^T_{isft}) is equal to the sum of the total flow rate of each product entering region ($Q_{ilf'ft}$), plus the amount of raw materials purchased PU_{ift}, plus the total production rate of the same region (P^T_{ift}), and the inventory level in the previous time interval ($S^T_{isf,t-1}$), minus the total flow rate leaving this region ($Q_{ilff't}$), the flow of wastes produced W_{irt}, and the total demand required by region r itself (D^T_{irt}). The following equation expresses this balance:

$$\sum_s S^T_{ift} = \sum_s S^T_{if,t-1} + P^T_{ift} + RM_{ift} + \sum_{f' \neq f} (Q_{if'ft} - Q_{iff't}) + W_{ift} - D^T_{ift}, \forall i, f, t \quad (1)$$

3.2. Capacity Constraints

The actual capacities and capacity expansions of the production facilities are represented by a set of continuous variables (C^{PL}_{fit} and CE^{PL}_{fit}), whereas the number of capacity expansions executed in a sector are given by integer variables (N^{PL}_{fit}). Similar expressions are used for storage facilities.

$$C^{PL}_{fit} = C^{PL}_{fit-1} + CE^{PL}_{fit}, \quad \forall f, i, t \quad (2)$$

$$N_{fit}^{PL}\underline{C_{fi}^{PL}} \le CE_{fit}^{PL} \le N_{fit}^{PL}\overline{C_{fi}^{PL}}, \quad \forall f,i,t \tag{3}$$

Regarding the transportation constraints, there must be a product flow between sectors so that demands are fulfilled. The product flow between sectors *f* and *f'* only will exist if the transportation channel is set.

$$Q_i^{\min} X_{iff't} \le Q_{iff't} \le Q_i^{\max} X_{iff't} \qquad \forall i, f, f'(f \ne f'), t \tag{4}$$

being $X_{iff't}$ a binary variable for the existence of a channel.
The storage facilities absorb demand and supply fluctuations. The storage period *b* is introduced to define the average capacity S'_{ift}:

$$S'_{ift} = bD_{ift}^{T}, \ \forall i, f, t \tag{5}$$

3.3. Objective Functions

One of the objectives of the model is to minimize the total costs (*TC*) of the sugarcane SC. The capital costs are computed when manufacturing plants, storage facilities (FCC_t) and transportation channels (TCC_t) are established. The operational costs are computed daily and they correspond to the production and storage costs (FOC_t) and the transportation costs (TOC_t) throughout the SC:

$$TC = \sum_t \frac{FCC_t + TCC_t + FOC_t + TOC_t}{(1+IR)^{t-1}} \tag{6}$$

being *IR* the interest rate.
In order to define an environmental indicator, only two steps of a LCA study have been used (Consoli et al., 1993). In the first step, the process boundaries have been expanded to include the entire SC (see Figure 1), and the functional unit has been chosen as the tons of sugarcane consumed along the time horizon. The second step is an inventory of the emissions released and resources consumed as a function of the tasks carried out in the network. Among these, the biochemical oxygen demand (BOD_{20}) results to be the most relevant because of its importance as an indicator of the pollution of the watercourses. BOD_{20} is a variable depending on the continuous and discrete decision variables of the model (SC design and operation).

3.4. Multi-objective Optimization

Thus, two objective functions, f_1 and f_2, are included in the bi-objective formulation:

$$\min_{x,y} U \begin{cases} f_1(x,y) = TC \\ f_2(x,y) = BOD_{20} \end{cases} \tag{7}$$

U is the global objective function and *x* and *y* are vectors of the continuous and discrete model variables, respectively, defined into the feasible region of the constraints, such as material flows, facility capacities and binary variables related to the existence of a plant or distribution channel. The problem solution is a set of efficient or Pareto optimal points obtained by using the ε-constraint method, a well known method, whose solutions have to be checked for feasibility and efficiency.

4. Results

On solving the bi-objective MILP, the Pareto points showed in Figure 2 have been obtained, confirming the existent trade-off between the economic and environmental issues. The points with lower costs are those which have the highest environmental impact. It is hence responsibility of the decision-maker to choose which of the configurations (represented by a particular Pareto point) is what better fits her/his preferences. As can be observed, the slope of the Pareto curve is rather smooth on its left side becoming sharper as one moves to the right. These results indicate that it is possible to achieve significant environmental improvements at a marginal increase in cost in the Pareto points that are close to the minimum cost solution. The opposite situation occurs in the points on the other side. Figure 3 shows the configurations corresponding to the two extreme situations. As can be seen, the minimum cost solution entails a more decentralized network configuration. This is because the reduction in the total SC capital cost that is attained by opening a lower number of nodes compensates the increase in the transportation cost. On the other hand, in the minimum environmental impact solution, the transportation tasks, the most polluting ones, are minimized.

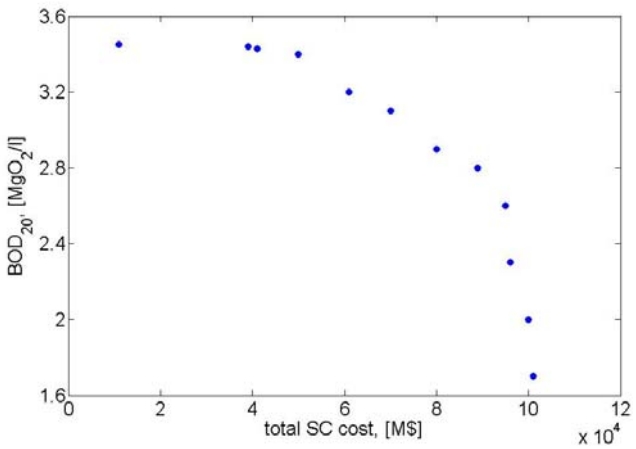


Figure 2. Pareto points between two objectives

The MILP models used have been solved on a Pentium M 730 machine, 1.6 GHz using CPLEX 9.0 through GAMS (Brooke et al., 1998). The optimization of one SC configuration involves about $3 \cdot 10^5$ equations, $5 \cdot 10^4$ continuous variables and $1.2 \cdot 10^3$ discrete variables, and it consumes 200 seconds on average.

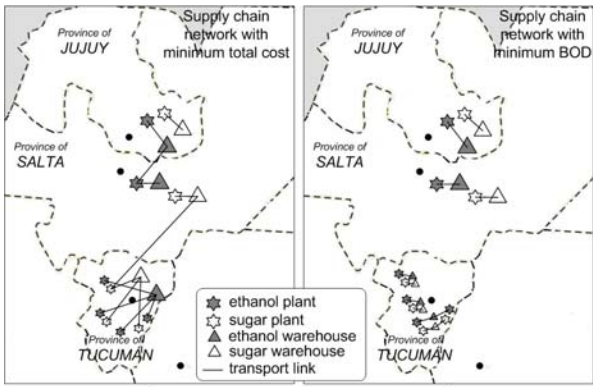

Figure 3. Two extreme cases

5. Conclusions

This work has addressed the design of SCs for sugar and ethanol production with economic and environmental concerns. The bi-objective MILP model of the sugarcane SC enables comparing the traditional economic indicators with the emerging environmental impact indicators. It has been shown how the solutions set can become valuable information from the environmental point of view for making SC strategic decisions.

Furthermore, the mathematical model has provided valuable insight into the design problem, suggesting the convenience of adopting more decentralized SC configurations in which the transportation tasks are reduced.

It is our current work to incorporate more details, decomposition strategies if necessary, as well as the treatment of the uncertain parameters and variables.

Abstract

Nowadays, a profound knowledge of all the stages involved in large scale processing of oil, natural gas or other fuels is necessary, due to the increased preoccupation with how to use the natural resources in a responsible way. The facilities for processing natural gas can be divided in two main parts, the first one responsible for the condensation of larger hydrocarbons (ethane, propane, butane, and the like) and the second one for the distillation of these larger hydrocarbons obtained. The first part of these facilities achieves a minimum temperature of -90°C due to a propane refrigeration system. This work studies a centrifugal compressor situated in the propane refrigeration system of a Natural Gas Liquid Recovery Unit (LRU) located in Macaé (Rio de Janeiro, Brazil) – Petrobras Transporte S.A. (Transpetro). This compressor is one of the most complex and important equipments of the LRU. The main contribution of this paper is to propose a dynamic model for this centrifugal compressor based on mass and energy balance coupled with thermodynamics equations for the nonidealities of the gas. This dynamic model was used to simulate real conditions in some situations observed in the LRU, analyzing its open loop behavior and investigating its automatic control (controller tuning and closed loop behavior). The situations studied consisted in applying step disturbances to the centrifugal compressor and then interpreting the results in the light of the developed model. The modeling, simulation and control investigations were achieved using a Brazilian simulator called EMSO (Environment for Modeling, Simulation and Optimization), which is a graphical environment that can be freely modified by all users. In this environment, the language is fully object-oriented, allowing the user to develop complex dynamic or steady models by composing them with existent small models or build specific models by deriving standard ones. EMSO was developed by the ALSOC Project (Free Environment for Simulation, Optimization and Control of Processes) which supplies this software without costs for partners and universities, aiming therefore to standardize and spread out its use. The present work provides information on the operation and control of the compressor allowing the further development of abnormal situation management tools that will support the control system and provide an easier and safer operation of the LRU.

Keywords: centrifugal compressor, dynamic simulation, capacity control, natural gas

1. Introduction

This work focuses on two Natural Gas Liquid Recovery Units (LRU), which are located in Macaé (Rio de Janeiro, Brazil) – Petrobras Transporte S.A. (Transpetro). On these LRU's, the treated natural gas passes trough heat exchangers (with propane as the refrigerating fluid), where it is cooled and, then, expanded in a turboexpander. Because of this expansion, the larger natural gas components are liquefied. This is the way that ethane is obtained for the petrochemical industry (Mendonça, 2007). Mendonça (2007) concluded that, if the main LRU's goal is to recover a maximum ethane quantity, the best strategy is to use the centrifugal compressors as much as possible, trying to reach the lowest temperature in the vessel which separate gases for the turboexpander. As the centrifugal compressor is a key equipment of these LRU's, its dynamic modeling and its control investigation are extremely useful for the proper operation of these facilities. Therefore, this work has as its main goal the proposal of a dynamic model for the propane compressors situated in the natural gas refrigeration system and, consequently, the analysis of its behavior. All the real conditions used in this work were provided by Petrobras Transporte S.A. (Transpetro).

The simulator used in this paper was the EMSO - *Environment for Modeling, Simulation and Optimization* (SOARES & SECCHI, 2003). This simulator has many advantages, like the availability of a range of models, that can be freely modified by the user, and the simplicity of the language which permits the user to write almost as can be written in a paper, besides being fully object-oriented.

1.1. Natural Gas Processing

In sum, the facilities for processing natural gas can be divided in two main parts, the first one responsible for the condensation of larger hydrocarbons (ethane, propane, butane, and the like) and the second one for the distillation of these larger hydrocarbons obtained. The first part of the facility employs an auxiliary system, where the so called propane refrigeration system is found, as can be seen in Figure 1.

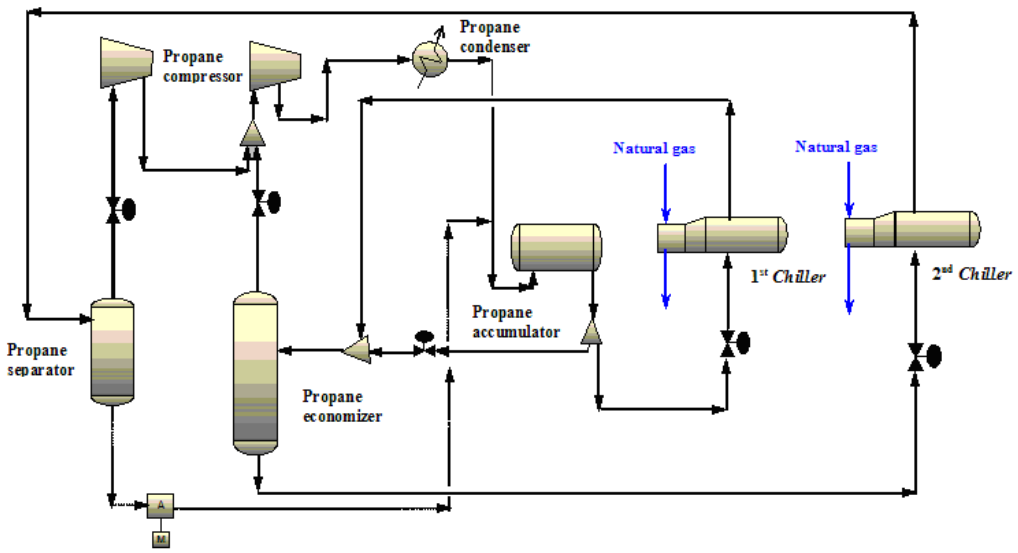

Figure 1. Simplified flowsheet of the propane refrigeration system (Source: Mendonça, 2007).

1.2. Thermodynamic Theory of Centrifugal Compressors

While the centrifugal compression takes place, the gas passes through the impeller and, hence, its energy increases (this energy is composed by enthalpy and, mainly, kinetics energy). After that, the gas enters in the diffuser, where the obtained kinetic energy is converted in enthalpy. This energy transfer that happens in the impeller can be represented by Equation 1 (Rodrigues, 1991)

$$dW = \frac{du^2}{2} + dh. \qquad (1)$$

where $u^2/2$ is the kinetic energy per mass unit, W is the work given to the gas per mass unit and h is the gas enthalpy per mass unit.

The work given to the mass unit of gas can be defined as (when compressors are the subject) head (H), therefore the enthalpy energy is also called static head (H_s) and the kinetic energy is also called dynamic head (H_d). When the gas exits the impeller, the dynamic head is converted into static head and, consequently, the pressure is increased; from this moment on the static head is called effective Head (which is nothing more than the total variation of enthalpy, after this gas passes through the impeller-diffuser). The effective head (or just enthalpy) definition allows the use of Equation 2:

$$H_{ef} = \int_{p_S}^{p_D} v.dp\,, \qquad (2)$$

where the interval between p_S e p_D are the pressure in the suction and discharge area, respectively and v represents the volume per mass unit. By the Equation 2, it is noticeable that a satisfactory relation between the pressure and the volume is necessary. Once defined this relation, Equation 2 can be integrated. The effective Head now can be called also as polytropic Head, since this one was computed in the polytropic base (the polytropic model $p.v^n=constant$, where n is the polytropic coefficient). Now the problem is to determine this polytropic coefficient. It is possible to demonstrate, that the polytropic and adiabatic coefficient have the following relation (Smith, Van Ness & Abbott, 2000):

$$\frac{n-1}{n} = \frac{k-1}{k.\eta_p} \qquad (3)$$

where η_p represents the polytropic efficiency ($\eta_p = H_p / H$). If α is defined as the followed ratio $\frac{n-1}{n}$ and R_c is defined as $\frac{P_D}{P_S}$, the Equation below is achieved:

$$H_p = z_m.\frac{R.T_S}{\alpha}.\left(R_c^{\alpha} - 1\right), \qquad (4)$$

where z_m is the compressibility factor, which intends to express the nonideality for the gas while it is compressed. This one can be computed as an arithmetic average between the calculated compressibility factor in the suction area and in the discharge area. The Virial Equations were used to calculate all the compressibility factors, because these are well fundamented in theories (Smith, Van Ness & Abbott, 2000). And the coefficient k

is obtained by its definition that means the ratio between the calorific capacities at constant pressure and constant volume.

1.3. Vessel Dynamics

Hypothetical accumulation vessels (a suction vessel and a discharge vessel) are used here to model the dynamics of the compressors. The dynamics of the vessels is described by:

$$\frac{d(P/z)}{dt} = \frac{R.T}{V.PM_{mist}}.(Q_{in} - Q_{out}), \qquad (5)$$

where PM_{mist} is the molecular weight of the mixture (kg/kmol) and Q_{in} and Q_{out} are the inlet and outlet mass flows to the vessel.

2. Results and Discussion

2.1. Analysis of the centrifugal compressor open loop

2.1.1. Step change in the inlet flow of the Suction Vessel in the first section

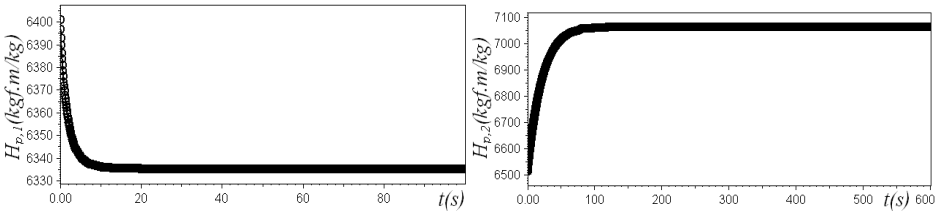
The centrifugal compressor has two sections. In order to analyze its behavior, a 1% positive step change was applied in the volumetric inlet flow (F_s) of the suction vessel in the first section, using the EMSO simulator. This step change affected the polytropic head, which was given for the gas in the first section, in a negative way as can be observed in the Figure 2(a). At the same time that the volumetric flow was increased, the ideal procedure would be to increase also the rotation of the impeller, trying to adjust the new flow as the operational flow of the compressor. Unfortunately, this procedure could not be realized, once the rotation of the impeller can not be changed. So the gas is going to enter in the impeller far from its ideal condition, which would be tangent to the blade of the impeller, therefore whirls will exist, dissipating, in this way, the energy and, consequently, decreasing the polytropic head that would be transferred from the blade of the impeller to the gas. The pressure in the discharge vessel located in the first stage also presented a satisfactory behavior and similar to the behavior of the pressure in the suction vessel.

The analysis of the polytropic head in the second section also showed that the step change did not approximate its flow to the operational flow and the reasons are the same explained above.

2.1.2. Step change in the outlet flow of the Discharge Vessel in the second section

This time a 10% negative step change was given in the outlet volumetric flow of the discharge vessel in the second section, using the EMSO simulator. In the first section practically no change was observed (Cunha, 2008), while in the second section the discharge pressure increased. However, the most interesting result was the polytropic head variation, as can be seen in the Figure 2(b).

Considering that the compressor was in steady-state before any disturbance, the compressor will not be anymore in steady-state after the negative step change, but now in a dynamic state, where the inlet flow will be greater than the outlet flow. Trying to achieve another steady-state condition, the compressor needs to decrease its inlet flow, what allows the gas to win more polytropic head. Therefore, it is concluded that the new flow adjusted is near to the operational flow.



(a) (b)

Figure 2. Dynamic behavior of the polytropic head. (a) Head in the first section after a positive step change in the inlet flow of the suction vessel; (b) Head in the second section after a negative step change in the outlet flow of the discharge vessel.

2.2. Analysis of the centrifugal compressor closed loop

A capacity control was implemented, where the controlled variable was the discharge pressure in the second section and the manipulated variable was the volumetric inlet flow of the suction vessel in the first section. The tuning procedure was as follows: the initial controller tunings were made using the Ziegler-Nichols method and, if this method was not efficient enough, the Tyreus-Luyben method (Edgard, Mellichamp and Seborg, 2004); if both methods still performed inefficiently, simple manual adjustments were used until the oscillatory behavior decreased significantly. The results for set-point (+ 1 %) change are discussed bellow.

The proportional control presented an expected strong oscillatory behavior behavior when the Ziegler-Nichols method was used, because this method is based in a one quarter decay ratio response. This oscillatory behavior shows that the gain controller is high, forcing the controller to act intensively in the system. Therefore, the gain was decreased, trying to obtain a better control over the discharge pressure. So, instead of multiplying the critic gain by 0.5, smaller values were used until the oscillation decrease significantly, as can be seen in Figure 3. It was also observed that the proportional control had no offset, due to the capacitive nature of the process.

The proportional-integral control was also tuned by Ziegler-Nichols, but instability was obtained with this set of parameters. Hence, the Tyreus-Luyben method was used. This one presented a better control, however oscillations were present. This problem was solved just with a manual adjustment, which made the behavior of the controller satisfactory. The results can be observed in Figure 3. Comparing the set of parameters obtained using the Ziegler-Nichols and the Tyreus-Luyben methods, it was noticed that the gain was decreased and the integral time was increased for the latter approach. Based on this rationale, the manual adjustment consisted of additional decreases in the gain and increases in the integral time.

A stable closed loop with the proportional-integral-derivative control tuned by the Ziegler-Nichols method was not obtained; therefore the Tyreus-Luyben method was used. This second method was sufficient and no manual adjustment was required. The result of this tuning is presented in the Figure 3. Analyzing again the set of parameters (Cunha, 2008), it was observed that the controller based on the Ziegler-Nichols method was acting strongly, what caused too much oscillation in the system. In the other hand, the Tyreus-Luyben method caused less oscillation, because the integral action was decreased significantly and the derivative action was increased, and this one has a stabilizing effect.

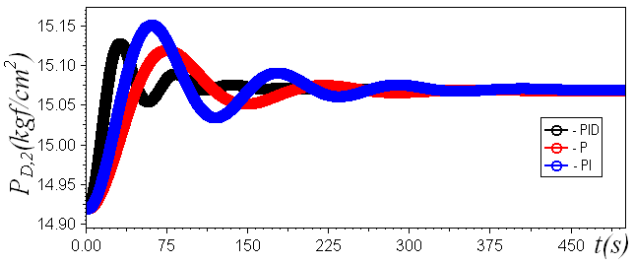


Figure 3. Results obtained for the three controllers.

It was noticed that the three controllers worked well, achieving the required set-point. Based on the set of parameters, the stabilizing effect of the derivative term allowed the increase in the proportional term. However it is important to keep in mind that the derivative action worked well, because the studied system is not subject to high frequency disturbances.

3. Conclusion

A dynamic mathematical model was developed for the propane compressor of the propane refrigeration system of the LRU. The EMSO simulations provided results that could be well analyzed, understood and explained in the light of the developed dynamic model. The feedback controllers employed for the capacity control had good servo performances, specially the PID control, which put the discharge pressure on its set-point in the shortest time. Regulatory tests were also performed and the controllers exhibited a similar performance (Cunha, 2008). More complete conclusions require the use of an anti-surge control coupled with the studied capacity control.

Abstract

Dynamic rigorous model of a complete plant of a Fuel Processor System (FPS) that reforms bio-ethanol to hydrogen-rich mixture to feed the anode of a fuel cell stack, along with a Proton Exchange Membrane Fuel Cell (PEM-FC) is presented. This is the first work that deals with this kind of integrated plant and is used to analyze the dynamic behavior and then propose a suitable control structure. The model can be implemented thanks to the use of a specific communication protocol between HYSYS® and MATLAB® to coordinate the calculations. The heat integration is achieved with the 'LNG' tool, available at HYSYS®, which applies the pinch analysis and provides an approximation of the optimal heat exchanges that can minimize the auxiliary services in steady state mode. It allows to assume that the stream temperatures are always at their optimum values, so their complex dynamic effects are neglected in this first problem approximation. On the other hand, the dynamic behavior of the reactors are modeled in MATLAB® including the PEM. The main objectives of the FPS control are to maintain H_2 levels on the anode of the FC, retain low CO levels at the inlet stream of the anode, and keep the temperatures of the reactors set and FC under rigorous specifications.

Keywords: Fuel processor, PEM, Rigorous dynamic model, Hydrogen generation.

1. Introduction

Ethanol is a very good fuel cell energy source because of its high efficiency and concentration of H_2 that can be obtained, also because of its environmental friendliness. Usual methods of converting bioethanol are catalytic partial oxidation and steam reforming, the latter is chosen here because of the high concentrations of hydrogen that can be obtained to feed the fuel cell stack.

Dynamic rigorous models of fuel cell power plants are extremely important in understanding the variable interactions, implications on system performance and transient behaviors, hardly analyzed nowadays. Designs for the Catalytic Partial Oxidation (CPO) and Water Gas Shift reactors in fuel cell power systems are presented in Görgün et al. (2004) and Görgün (2005) using natural gas (methane) as fuel. However, these designs are based on the reactors invariants and do not take into account reaction rate expressions. A control-oriented model of a CPO of natural gas processor is developed in Pukrushpan et al. (2004). A mathematical model of the reformer is developed by Chuang et al. (2008) and selected parameters of the model are fit to match experimental data from the dynamic response of the process.

2. Fuel Processor System

The FPS (illustrated in Fig. 1) consists of an Ethanol Steam Reforming (ESR) plug flow reactor, where most of the conversion of ethanol to H_2 is made. Carbon monoxide (CO) which poisons the fuel cell catalyst is produced in the ESR, so additional processing is needed to remove this substance. There are three reactors that configure the cleaning system; these are two Water Gas Shift, one of high temperature (fast), and the other of low temperature, that favors the equilibrium of the reaction to higher conversion rates of CO. The third is a Preferential Oxidation of Carbon monoxide (CO-PrOx) reactor, where oxidation of CO into CO_2 is made; also, the undesired oxidation of H_2 occurs, so the catalyst is selected to improve the conversion of CO.

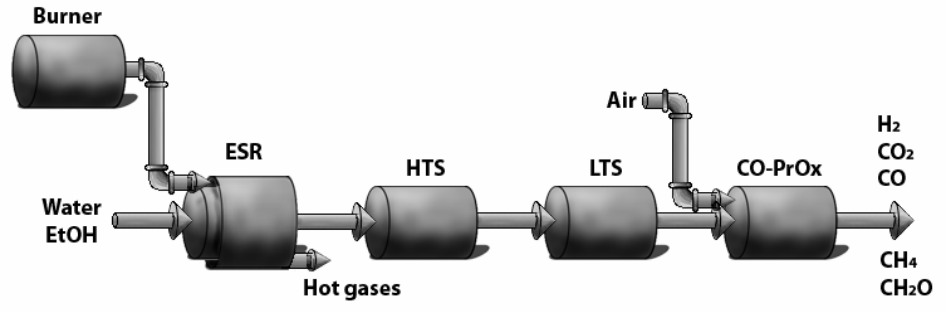

Figure 1. Fuel Processor System

The overall reaction is endothermic, and the heat requirement is supplied by a burner, which is fed with ethanol and compressed air, the transference of heat is achieved passing the hot gases through the jacket of the reformer.
There are two WGS reactors operating at different temperatures, and WGS reaction is produced inside them:

$$CO + H_20 \leftrightarrow H_2 + CO_2 \qquad \text{(Eqn. 1)}$$

This reaction produces heat and H_2. Levels of CO are still high even after the two WGS reactors, so the final elimination is made in the CO-PrOx reactor, which produces the oxidation of CO into CO_2 and the undesired combustion of H_2. The WGS reaction takes place in this reactor too. Oxygen is injected into the CO-PrOx, the amount needed is about twice the stoichiometric relationship to have a good selectivity and satisfy the requirements of the FC. The plug flow reactors are modeled with twenty lined-up Continuous Stirred Tank Reactors (CSTR). The molar flow between two volumes, and the exit molar flow of each reactor, is given by the orifice flow equation as a function of upstream pressure and downstream pressure. It is assumed that the ideal gas equation of state is valid, and for gas flow rate, a material balance on each species gives:

$$\frac{dy_{j,i}}{dt} = \frac{F_{i-1}y_{j,i-1} - F_i y_{j,i} + (1-\varepsilon)\sum_j \nu_{j,k} r_k \rho_{cat}}{vol_{slice}} \qquad \text{(Eqn. 2)}$$

Where y, F, ε, ν, r, ρ_{cat} and vol_{slice} are mole fraction, flow rate, void fraction, stoichiometric coefficient, reaction rate, catalyst density and volume of slice, respectively. Subscripts j, i and k refers to species, slice, and reaction.
The heat generated by the different reactions is supposed to vary with temperature. A thermal balance for each slice gives the equation for the temperature of the gas phase:

$$\frac{dT_i}{dt} = \frac{F_{i-1}\,\overline{cp}_{i-1}T_{i-1} - F_i\,\overline{cp}_i T_i + (1-\varepsilon)\sum_j (-\Delta H_k) r_k \rho_{cat} + Q}{vol_{slice}\,\overline{cp}_i} \quad \text{(Eqn. 3)}$$

Where T, $\overline{cp}$ and ΔH are temperature, specific heat, and heat of reaction, respectively. All units except the ESR are considered adiabatic; Q is a term that accounts for the exchanged heat so is the only calculated for the reformer.

2.1. Ethanol Steam Reforming

Despite the apparent simplicity of the stoichiometric reaction for the production of hydrogen:

$$CH_3CH_2OH + 3\ H_2O \leftrightarrow 6\ H_2 + 2\ CO_2 \quad \text{(Eqn. 4),}$$

actually, this reaction involves a complex system of reactions, and the selectivity towards H_2 is affected by a number of undesired secondary reactions.

The analysis made by Francesconi (2008) adjusting experimental data of a Cobalt catalyst supported in Zircon (CO/ZrO2), leads to the reaction scheme of acetaldehyde decomposition, according to the mechanism proposed by Benito et al. (2005).

To fulfill the heat requirements of the reactions, the ESR is provided with a hot gases chamber, it collects the products of combustion from the ethanol burner, and exchanges its heat with the main reactor through a jacket.

2.2. Water Gas Shift

In these reactors, the only reaction that takes place is the WGS. The main objectives of this reaction are to remove the CO from streams and adjust the H_2/CO molar rate. This reaction is moderately exothermic and its equilibrium constant decreases as temperature rises, so lower temperature favors high conversions. Reactors of the cleaning system are considered adiabatic, and this condition limits their performance, which is the reason that justifies the need of more than one WGS reactor with intermediate cooling.

2.2.1. High Temperature WGS

The High Temperature water gas Shift (HTS) reactor uses an iron based catalyst (Fe/Cr), and makes most of the conversion of CO.

2.2.2. Low Temperature WGS

The Low Temperature water gas Shift (LTS) reactor operates at lower temperatures and uses a $CuO/ZnO/Al_2O_3$ catalyst. It is thermodynamically favored, so higher conversions rates are obtained because the equilibrium constant is low.

2.3. Preferential oxidation of Carbon Monoxide

The main (desired) reaction given in this stage is the oxidation of CO into CO_2; the oxidation of H_2 is produced too, it is undesirable because reduces the efficiency of the FPS and increases the temperature of the stream. Although many publications present kinetic expressions for CO oxidation, only few of them consider the simultaneous H_2 oxidation. Choi and Stenger (2004) reported that WGS reaction should be considered at this stage and give equations for the three reactions, with a $Pt\text{-}Fe/Al_2O_3$ catalyst.

2.4. Burner

A stream of ethanol mixed with air is fed into this reactor to burn the ethanol and obtain hot gases that will go to the jacket of the ESR to provide the necessary heat to reach good yields. In addition, the exit gases from the PEM-FC are fed into this reactor to burn completely the remaining H_2 and methane.

3. The Mathematical Model Implementation

The pressure requirements are satisfied with compressors and turbines modeled in HYSYS®. In addition, it supports the important data bank information for the different components, and the LNG operation, useful for minimizing auxiliary services. On the other hand, the dynamic behaviors of the reactors are modeled in MATLAB®, which, supports the differential equations integration solving with the ode15s solver (variable order solver based on the Numerical Differentiation Formulas), together with the data obtained from the steady-state case in HYSYS®. The communication interface is performed by the use of the spreadsheets in HYSYS® and a specific library for doing the corresponding data transference and updating at scheduled sampling time between both programs.

3.1. Heat Integration

The heat integration needed for the model is achieved by the LNG tool in HYSYS®, it is an operation that solves material and heat balances for multi-stream exchangers and heat exchangers networks by means of the Pinch technology, as described in Linnhoff et al. (1994). With this tool the simulation of the heat exchangers network is defined without actually knowing its configuration. The minimum heat requirement of the system and the minimum heat to be evacuated can be computed for each operating point or with the system under different disturbances.

3.2. Proton Exchange Membrane Fuel Cell

A fuel cell stack is constituted by an anode, where the fuel is injected, and a cathode, where the oxidant, normally oxygen or air, is injected. The electrodes are separated by a semi-permeable membrane that allows the proton exchange and makes the oxidation reaction to produce electrical power. The cell generates an open-circuit voltage which is affected by a number of losses (activation, concentration and ohmic) that leads to a useful actual voltage. Pukrushpan et al. (2004) presents a rigorous dynamic model of a PEM-FC which is used in this work, adapted to produce a maximum power of 10 KW. Transient behavior of manifold filling, membrane hydration, air compressor and heat management are included in the model. Interactions between processes are also accounted. In that work, the necessary hydrogen production is calculated as a function of the stack current:

$$W_{H_2} = \frac{nI_{st}}{2F} \qquad \text{(Eqn. 5)}$$

Where W_{H_2} refers to H_2 production (taken as setpoint), n is the number of cells in the stack and F the Faraday constant.

4. Control Structure

The development of the control oriented dynamic model presented here allows a more efficient testing of the adopted control structure based on a previous analysis, completely performed in steady state model. It was described in detail in Biset et al. (2009) and is shown in Fig. 2. The most critical controlled variables were selected taking into account the objectives mentioned above, directly related to the optimal operating conditions of the FPS and the less sensitivity structure in terms of the regulatory problem. For analyzing the dynamic behavior, step changes of -5% at 0.25 seconds were made in the manipulated variables, that is, ethanol feed flow rate to the burner, heat exchanged in the ESR, and ethanol feed flow rate to ESR. The effects on the variables to be controlled were recorded, as can be seen in Fig. 3. Around this

operating point, the variables were linearized in order to obtain an acceptable nominal model for implementing internal model control (IMC) method. The tuning parameters were chosen following the recommendations given in Rivera (2007).

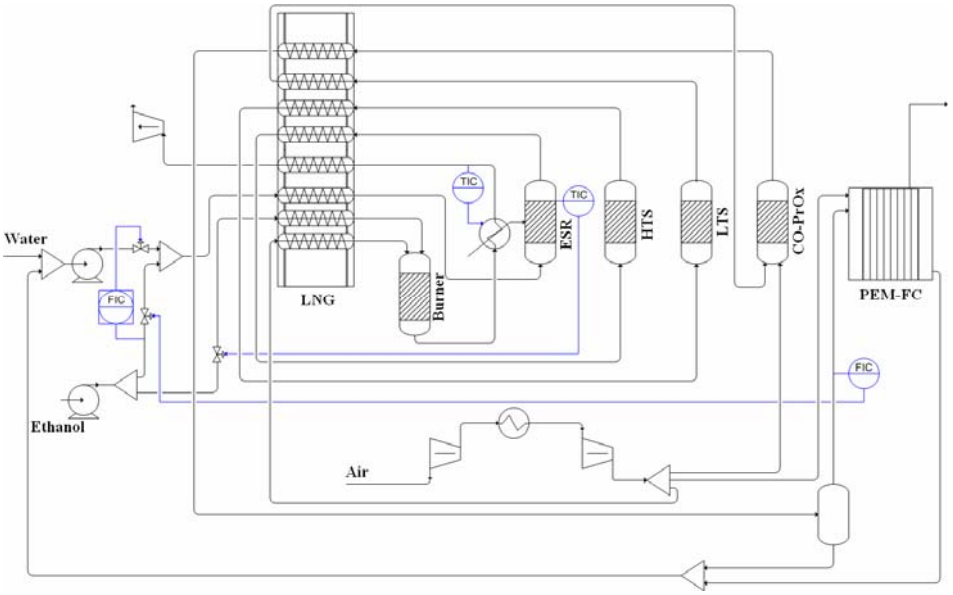

Figure 2. Implemented control structure.

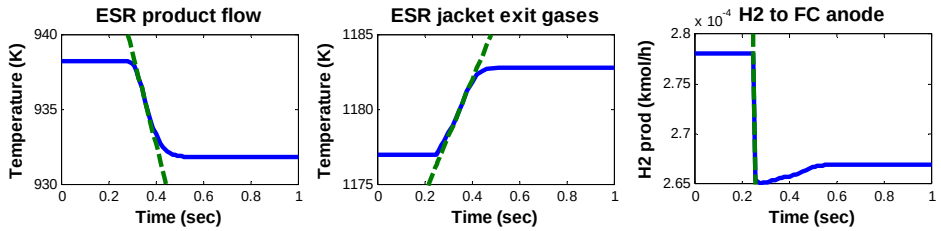

Figure 3. Linearization of controlled variables for controllers tuning.

5. Results

Since the authors of this work didn't find any reference of a dynamic model similar to the one presented here, the resulting responses were compared to the stationary states presented by Francesconi (2008) for the 10 KW FC, and the step changes considered at Biset et al. (2009). The comparison to those values is shown in Fig. 4. The applied steps were -1%, -5% and -10% at 20, 80 and 140 seconds, respectively. The first group of figures, on the left, corresponds to a step change disturbance in the current I_{st}, and the second group, on the right, in fresh ethanol molar fraction.

6. Conclusions

In this work, the main characteristics of the rigorous dynamic model of a Fuel Processor System along with a Fuel Cell Stack are presented. Both systems have been integrated so as to obtain good efficiencies and maximum heat recovery. Keeping the plant in desired conditions requires a well designed plant-wide control structure. In this context, the control oriented model makes it possible to obtain a preliminary control policy accounting with a good understanding of the dynamic interactions. The model is

flexible enough allowing to analyze other possible kinetics, sizing, etc., accounting different scenarios. As future work it is evaluated the use of this dynamic model for testing new methodologies of plant-wide control structure and optimal sensor location, including experimental data.

Abstract

A general multiperiod LGDP (Linear General Disjunctive Programming) model in a multiproduct batch plant has been developed. Both overall production planning and design decisions of the plant are encompassed considering uncertainty in demands represented by a set of scenarios. Specifically, the proposed model considers simultaneously the plant structure (duplication of units in parallel and the new option "in series"), the decision variables of the batch plant (unit sizes, number of batches, total time for producing each product), and the production planning decisions (e.g. plan of production, policy of inventory, purchases of raw materials and sales of products) in each time period within each scenario. Also, this model allows the incorporation of new equipment items in different periods. The overall objective is to maximize the expected net present value of the benefit. The benefits of the simultaneous optimization of production planning and design decisions under uncertain product demands in a multiscenario approach are demonstrated through a particular extraction process that produces oleoresins.

Keywords: Multiproduct batch plants, Demand uncertainty, Units in series, Design and planning.

1. Introduction

An important area of concern in the design of multiproduct batch plants is their ability to meet production requirements and maximize profits given uncertainties in the market demand for the products. The formulations presented in previous works in the multiproduct batch design area (Moreno et al., 2007; Moreno and Montagna, 2007) have been limited to deterministic approaches, wherein product demands are assumed to be known with certainty. However, when long time periods are assumed a mathematical formulation including uncertainty is more appropriate. Uncertainty is usual when long term variations are considered, for example with product demands forecasting. The scenario analysis approach has been considerably used in the literature and has proven to provide reliable and practical results for optimization under uncertainty (Subrahmanyam et al., 1994; Ahmed and Sahinidis, 1998; Gupta and Maranas, 2003). Hence, in this work, this approach is adopted for describing uncertainty in the random variables of product demands. Despite that many contributions dealing with the design of batch plants under uncertainty have been published, the simultaneous optimization of the design and planning conditions with capacity expansion of the plant has not been sufficiently studied including all the elements considered in this work.

The goal of this work is to propose a scenario-based approach for the simultaneous design and production planning of multiproduct batch plants under uncertain demands, considering different duplication options of units (in series and in parallel). Also, this

model allows a capacity expansion adding a set of new units in parallel working out of phase in different periods. A linear general disjunctive programming model is formulated for the optimization problem. The proposed model is finally tested by solving an example considering the production of oleoresins.

2. Problem Definition

Consider a multiproduct batch plant with $p = 1,\ldots, P$ operations that processes $i = 1,\ldots, I$ products over a time horizon H. These products are produced during a finite number of time periods $t = 1,\ldots, T$. Let H_t be the length of each time period, which may be different. Forecasts for market demands for each product come in a finite number of possible scenarios $s = 1,\ldots, S$, each of which has an associated probability ψ_s, where $\sum_s \psi_s = 1$. Thus, the different possible scenarios describe lower and upper bounds on product demand levels in each time period d_{its}^L and d_{its}^U. In this first work, it is assumed that there is a procedure for generating a set of scenarios representative of both optimistic and pessimistic situations within a risk analysis strategy (Vanston et al., 1977; Mulvey, 1996).

For each operation p there may be different configurations of units in series $h = 1,\ldots, H_p$ to performed it. Also, the selected configuration of units in series can be duplicated in parallel working out of phase. The duplication in parallel can be different in each time period allowing the capacity expansion of the plant. Let M_p^U be the maximum number of units that can be allocated in parallel in operation p. In each time period, $m = 1,\ldots, M_p^U$ sets of units of the same size operate out of phase. This amount can vary taking into account that each operation can be expanded with new sets of units. N_{pt} represents the number of set of units in parallel in operation p at each period t. This value is modified taking into account that $g = 0, 1,\ldots, M_p^U$ set of units in parallel can be added in each period t. Furthermore, the problem involves the design decision of selecting equipment sizes for batch units in each operation p, among a set $SV_p = \{ v_{p1}, v_{p2}, \ldots, v_{pn_p} \}$ of available discrete sizes. The basic data for representing the operations are the size factors S_{ipt} and processing time t_{ipt} required for each product i at each operation p in every period t.

The duplication in series selected in every operation not only affects itself but also the rest of the operations of the process. In order to maintain a posynomial approach, the yield for all the configurations in series in a given operation is assumed to be constant, through appropriate size factors values. This allows preserving the formulation with fixed size and time factors. In consequence, the size factor for product i at operation p remains equal regardless of the selected configuration. However, each configuration h of units in series now has a different time t_{ipht}. Detailed descriptions of this assumption can be found in Moreno and Montagna (2007).

In every scenario s, production planning decisions allow to determine at each period t and for each product i, the amount to be produced q_{its}, the number of batches n_{its}, and the total time T_{its} to produce product i. Furthermore, at the end of every period t, the levels of both final product IP_{its} and raw material inventories IM_{its} are obtained. Moreover, the total sales QS_{its}, the amount of raw material purchased C_{its}, and the raw material to be used for the production RM_{its} of product i in each period t are determined with this formulation. If time periods are equal, wastes due to the expired product shelf life PW_{its} and due to the limited raw material lifetime RW_{its} are also added in the

formulation. Also, late deliveries ϑ_{its} that take place in each period are determined. The objective is to determine the optimal design and the operation planning of the plant, in the face of uncertainties in market demand for products.

3. Linear Disjunctive Programming Model

Based on the above definitions, the optimization LPDG model is as follows.

$$\max NPV = \sum_s \psi_s \left[\begin{array}{l} \sum_{i,t} np_{it}\ QS_{its} - \sum_{i,t} \kappa_{it}\ C_{its} - \sum_{i,t} \varepsilon_{it} \left(\frac{IM_{i,t-1,s} + IM_{its}}{2} \right) H_t \\ - \sum_{i,t} \sigma_{it} \left(\frac{IP_{i,t-1,s} + IP_{its}}{2} \right) H_t - \sum_{i,t} \left(wp_{it}\ PW_{its} + wr_{it}\ RW_{its} \right) \\ - \sum_{i,t} \left(co_{it}\ q_{its} \right) - \sum_{i,t} \left(cp_{it}\ \vartheta_{its} \right) \end{array} \right] - \sum_t CE_{pt} \quad (1)$$

$$\underset{h \in H_p}{\vee} \left[\begin{array}{c} Z_{ph} \\ \underset{k \in SV_p}{\vee} \left[\begin{array}{c} W_{phk} \\ n_{its} \geq \left(\frac{S_{ipt}}{v_{pk}} \right) \cdot q_{its} \quad \forall\ i,t,s \\ CO_p = h \cdot (\alpha_p \cdot v_{pk}^{\beta_p}) \end{array} \right] \\ \underset{m \in M_p}{\vee} \left[\begin{array}{c} Y_{phmt} \\ N_{pt} = m \\ T_{its} \geq \frac{t_{ipht}}{m} \cdot n_{its} \quad \forall\ i,s \end{array} \right] \quad \forall\ t \\ \underset{g \in G_p}{\vee} \left[\begin{array}{c} X_{phgt} \\ N_{pt} = N_{p,t-1} + g \\ CE_{pt} = g \cdot CO_p \cdot \gamma_{pt} \end{array} \right] \quad \forall\ t \end{array} \right] \quad \forall\ p \quad (2)$$

$$\sum_i T_{its} \leq H_t \quad \forall\ t,s \quad (3)$$

$$IP_{its} = IP_{i,t-1,s} + q_{its} - QS_{its} - PW_{its} \quad \forall\ i,t,s \quad (4)$$

$$IM_{its} = IM_{i,t-1,s} + C_{its} - RM_{its} - RW_{its} \quad \forall\ i,t,s \quad (5)$$

$$IP_{its} \leq \sum_{\tau=t+1}^{t+\chi_i} QS_{i\tau s} \quad \forall\ i,t,s \quad (6)$$

$$IM_{its} \leq \sum_{\tau=t+1}^{t+\zeta_i} RM_{i\tau s} \quad \forall\ i,t,s \quad (7)$$

$$\vartheta_{its} \geq \vartheta_{i,t-1,s} + d_{its}^L - QS_{its} \quad \forall\ i,t,s \quad (8)$$

$$RM_{its} = F_{it}\ q_{its} \quad \forall\ i,t,s \quad (9)$$

The objective function maximizes the expected net present value (*NPV*) over a set of scenarios *S*. This function is the difference between the revenue due product sales and the overall costs, with the latter consisting of the cost of raw materials, inventory costs, operating cost, penalty cost for late delivery, and investment cost. The parameters np_{it},

κ_{it}, ε_{it}, σ_{it}, wp_{it}, wr_{it}, co_{it}, and cp_{it} are the corresponding cost coefficients for every mentioned term in the objective function.

The discrete choices are modeled with the embedded disjunctions (2) defined for each operation p. A Boolean variable Z_{ph} is true when configuration of units in series h is selected in operation p and is false in the opposite case. In the first embedded disjunctions, the Boolean variables W_{phk} is true when discrete size k is selected to carry out operation p with configuration h. Thus, constraints into this disjunction correspond to the sizing equation for the units and the equipment cost for this alternative CO_p. As was previously mentioned, units in parallel are added in each time period, so a set of embedded disjunctions is added where the Boolean variable Y_{phmt} is true when there are m units in parallel in operation p with configuration h at time period t. Each term of these disjunctions includes constraints that determine the number of set of units in parallel N_{pt} at each period t and the total time to produce each product. Finally, in the last embedded disjunctions, if the Boolean variable X_{phgt} is true, g units in parallel are added at time period t in operation p with configuration h. The first constraint in the last disjunctions determines the number of units in each period t considering the number in the previous one plus the units aggregated in the corresponding period. The last constraint determines the expansion cost in each time period, CE_{pt}, where the parameter γ_{pt} is a cost coefficient for operation p taking into account the period t involved.

Constraint (3) ensures that the total time required for producing all products cannot exceed the period length. Eqs. (4) and (5) state the inventory level of each product and raw material at the end of each period, respectively. When the lengths of time periods are equal, Eqs. (6) and (7) guarantee that the stock of both raw materials and products in each period cannot be used after the next ζ_i or χ_i time periods, respectively. Constraint (8) calculates the late delivery. The mass balance (9) determines the amount of raw material necessary for the production of product i in each period where the parameter F_{it} is the process conversion of product i in period t assuming that only one main raw material is used for the production of i.

4. Illustrative Example

To illustrate the proposed approach, a multiproduct batch plant that produce three oleoresins, namely, sweet bay (A), pepper (B) and thyme (C) oleoresins, is considered. All the products are manufactured via the following batch operations: (1) extraction, (2) expression, (3) evaporation, and (4) blending. The process data for this example are shown in Table 1 and prices of raw materials and final products are given in Table 2. A global time horizon of 3 years has been considered, which is divided in 6 equal time periods of six months each (3000 h). There are 4 possible configurations of units in series for the operation 1, with a countercurrent arrangement. Thus, processing times for each product take smaller values as the number of units in series grows (see Table 1). All the operations can be duplicated in parallel up to 3 set of units operating out of phase. A set of 5 discrete sizes is provided for process units. Table 3 shows the available discrete sizes for each operation and cost coefficient associated. Demand for the products is uncertain and 3 forecast scenarios with probabilities $\psi_1 = 0.5$, $\psi_2 = 0.3$, and $\psi_3 = 0.2$ are considered. In the first time period all the scenarios show the same upper demand, i.e., 12000, 9500 and 14000 kg, for product A, B, and C, respectively. It is assumed that product demand for each period will increase in comparison with the present conditions. Thus, scenario 1 expects a 20% growth rate per period, scenario 2 expects a 10% growth rate per period and for scenario 3 no growth rate is expected. Minimum product demands in each period for all scenarios are assumed as a 50% of

product demands. Products and raw materials lifetimes in time periods are 3 and 2, respectively. The problem was solved with GAMS via CPLEX solver with 0% optimality gap.

This example has 498 discrete variables, 647 continuous variables, and 4745 constraints and was solved in a CPU time of 170.34 s. The optimal solution yields an expected NPV of $2,546,346.65. The optimal plant structure obtained in every period and the unit sizes are shown in Fig. 1. In this figure, units in dotted line are included in different time periods. As can be seen, in time period 1 there is only one unit in all operations except in operation 1 which has 2 units in series. In period 2, a set of 2 units in series is incorporated in operation 1, working in parallel out of phase. Similarly, in period 3 a new set of units is added in extraction operation and the same structure is maintained until period 6. Production planning decisions for each product are different for each scenario in the optimal solution. In Table 4, the results of planning decisions for scenario 1 are reported.

Table 4. Optimal plan for scenario 1

Also, each scenario has been considered in isolation by formulating and solving the corresponding deterministic problem. The objective values obtained for scenarios 1, 2, and 3 are \$3,029,459.79, \$2,586,374.59 and \$2,223,378.12, respectively. In the first scenario, the optimal plant structure obtained is the same as Fig.1. On the other hand, for both scenarios 2 and 3, in the first time period, two sets with two units in series each one operate in parallel in operation 1 and a new set is added in period 2 for this operation. The unit sizes selected for each operation are 1000L, 1000L, 750L, and 100L.

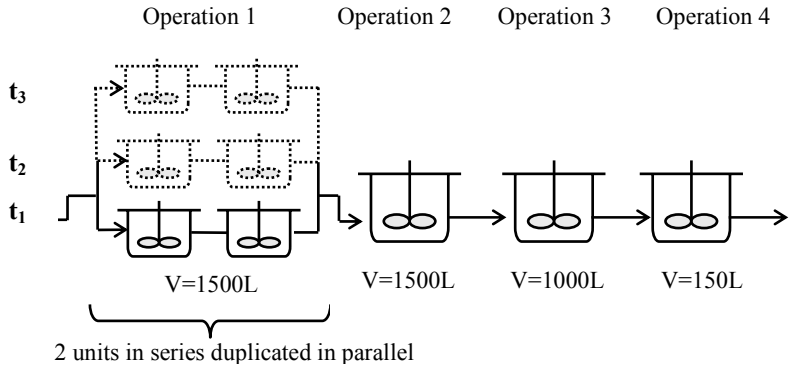

Figure 1. Optimal structure of the plant.

5. Conclusion

This work has presented a LGDP model for the optimal production planning and design of batch plants in the presence of uncertainties in product demands. The model takes into account both structural decisions of duplicating units in series and in parallel selecting the size of the units from a set of available discrete sizes. The proposed approach allows the incorporation of parallel units in different time periods. Design variables such as the selection of equipment of standard size and the addition of new units in parallel in each time period are independent of the scenarios. In contrast, planning variables which include working levels of the plants for each time period are scenario-dependent variables. As an example, the model was applied to the production of vegetable extracts, particularly the production of oleoresins.

Abstract

This work addresses the development of an optimization model to aid the operational decision-making of scheduling activities in a real-world pipeline network. In this network, inventory issues should be respected and different products should be transported in order to supply demands. Scheduling details must be given, including pumping sequence in each node, volume of batches, tankage constraints, timing issues, while respecting a series of hard operational constraints. In addition, temporal details must be specified by the system. Thus, the computational burden of determining the short-term scheduling within the considered scenario is a relevant issue. Therefore, a decomposition approach, based on the three key elements of scheduling, is proposed to address such real-world problem. In particular, the focus of this work is to solve the third key element: the timing problem. Such model is based on a combined approach, which uses a Pre-Analysis structure and Mixed Integer Linear Programming (MILP) in a collaborative combination. Many insights have been derived from the obtained solutions, and the proposed approach can aid the decision-making process.

Keywords: Scheduling, Pipeline Network, MILP, Heuristics, Oil Industry

1. Introduction

Nowadays, the majority of the oil derivatives transport is done using pipeline network systems, mainly because of the economical and environmental advantage, when compared to other transport systems. However, the determination of the scheduling of operational activities in pipeline networks is a difficult task and efficient methods to solve such complex problem are required. Mendéz *et al.* (2006) make a review of the optimization methods for the short-term scheduling of batch processes, and some recent papers have also addressed scheduling decisions within pipeline networks (*e.g.* Relvas *et al.* (2007), Moura *et al.* (2008), Cafaro and Cerdá (2008), Rejowski and Pinto (2008)), but the network considered in this paper is particularly complex. Boschetto *et al.* (2008), in a previous work, already introduced the proposed approach but the present paper gives additional information and extends the optimization model in a continuous process of improvement. This work describes an optimization model to aid the operational decision-making of scheduling activities in a real-world pipeline network, in which inventory issues should be respected and different products should be transported in order to supply demands. The complete problem of short-term scheduling was divided into smaller problems, which are based on the three key elements of scheduling: assignment of resources, sequencing of activities, and timing determination for

resources utilization by these activities (Reklaitis, 1992). Each problem is solved by an appropriate technique and integrated by a computational tool. In particular, the focus of this work is to solve the third key element: the timing problem. The assignment of resources and the batch sequencing are previously solved by Yamamoto *et al.* (2008) and the results are used by the timing model. Such model is based on a combined approach, which uses a Pre-Analysis structure and Mixed Integer Linear Programming (MILP) in a collaborative combination. This paper is organized as follows. Section 2 presents some operational details of the considered pipeline network. The problem solution, including a global overview of the proposed optimization approach, is given on Section 3. Section 4 presents the obtained results with conclusions in Section 5.

2. Problem Description

The considered scenario involves 14 areas (nodes), including 4 refineries, 2 harbors, which either receives or sends products, 6 distribution centers, and 2 final clients (Fig. 1). In addition, it includes 29 pipelines, and some of them can have the flow direction reverted, accordingly to operational procedures. Each product presents a specific tank farm, according to the considered node. More than 14 oil derivatives can be transported. During the scheduling horizon, many batches are pumped from (or passing through) different nodes. Scheduling details must be given, including pumping sequence in each node, volume of batches, tankage constraints, timing issues, while respecting a series of hard operational constraints including on-peak demand hours.

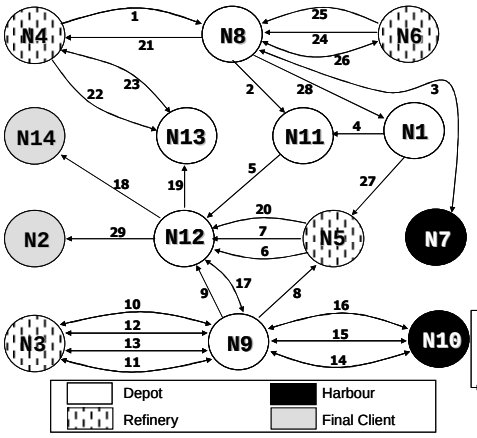

Figure 1. Pipeline Network

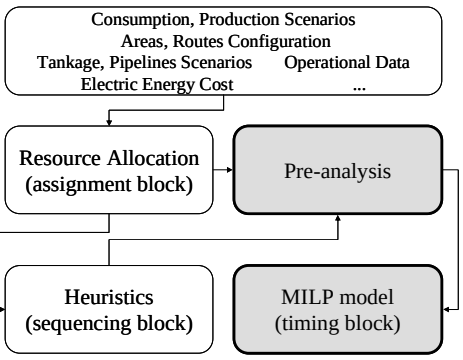

Figure 2. Decomposition Approach

3. Problem Solution

A decomposition approach is proposed to address the scheduling problem (Fig. 2). The input data (consumption/production conditions, areas/routes configuration, inventory management, electrical energy cost, and other operational data) characterizes a "problem instance", or a scenario, to be solved. The assignment block gets part of the information and uses a heuristic procedure to compute batch volumes and to indicate a route for each batch. The choice of the routes considers that incompatible products should be sent by different pipelines. So, undesirable contamination areas are avoided. The assignment takes into account production and consumption information received from the company planning, inventory management information, and available tank capacity for each area. Then, based on the input data, the assignment block calculates

time-windows to send/receive each batch in each origin/destination area, respectively. A list of batches, including the origin/destination area, route, volume, flow rate, and the time-windows for each batch are determined. The heuristic block (sequencing block) can be used or not. It reorganizes the list of batches previously sequenced by the assignment block. This module uses a GA algorithm to optimize the sequencing of batches to be pumped and it takes as inputs the previously calculated time windows, start-up conditions, and inventory levels given by the assignment block. The main goal is to provide one or more sequences of ordered batches that satisfy the consumption/production requirements for each area. To deeply exploit the assignment/sequencing blocks are not within the aim of this article. Further details of assignment/sequencing blocks can be attained in Yamamoto *et al.* (2008). The pre-analysis block evaluates the information derived from assignment/sequencing blocks and calculates temporal and volumetric limits (bounds). These limits present a preliminary indication on the feasibility of the programming. So that, the pre-analysis block provides valuable information, which is used as parameters by the MILP model. Finally, all the parameters calculated by previous blocks are used in a continuous time MILP model. This block determines the operational short-term scheduling for the pipeline network using, for instance, time windows and sequences of batches determined by previous blocks.

3.1. Pre-analysis

The pre-analysis was developed using the languages C++ and PL/SQL. This block allows the identification of conditions in which a batch can remain stopped into the pipeline and also indicates significant flow rate changes due to network constraints. Moreover, the pre-analysis evaluates, step by step, the batch that is being pumped and analyses the influence of this pumping operation on other batches into the pipelines. As a result, the pumping of a batch along the pipeline network is analyzed, and "volumetric parts" (portions of this batch) with similar pumping conditions are identified. The parameters derived from pre-analysis (*e.g.* Table 1) contain information to indicate the receiving of a batch in the end of a pipeline. By Table 1 it is possible to notice that the pumping procedure of the batch 40 (bo_b) was broken in four parts (p_{bo}=1,2,3,4). Each part influences the receiving of one or more batches that will be moved in the pipeline network. For example, the second part (p_{bo}) pumped of the batch 40 with 300 m³ ($part_{bo,p_{bo}}$) influences the receiving of the same volume of the part 2 (p_b) of the batch 14 (b) in the pipeline 18 (d) and of the part 1 (p_b) of the batch 24 (b) in the pipeline 5.

Table 1. Parameters determined by pre-analysis

b	d	bo_b	p_b	p_{bo}	$part_{bo,p_{bo}}$ (m³)	$flw_{bo,p_{bo}}$ (m³/h)
14	18	40	1	1	1700	500
14	18	40	2	2	300	600
24	5	40	1	2	300	600
24	5	40	2	3	1700	500
24	5	40	3	4	350	550
24	5	41	4	1	3350	600

3.2. MILP Model

A continuous time MILP approach is used to create the optimization model. The MILP model considers the route of a batch (origin area, pipelines, and destination area), the volume and the flow rate of each product from an origin area. Special attention is given to the fact that the pipelines have a considerable volume and always operate with full capacity. Also, they can "store" different products. When a new product is pumped from

an origin area, the products previously "stored" into the pipelines are pushed, in accordance with the "new flow rate". In each area, the batches arriving from the pipelines can be sent to tanks or can be deviated to other pipelines. A set of tanks in each area can store different products. The inventory level can increase or decrease according to the volume and the pumping flow rate of each product, or in accordance with the production and the "local" consumption. Moreover, the MILP model must consider the cost of electric energy in on-peak hours and a series of other operational requirements. The optimization model must satisfy a series of constraints. Timing constraints are added in order to make a connection among timing variables (*e.g.* $fb_{b,n,n',d,p}$ and $ib_{b,n,n',d,p}$), calculating the time that each part of a batch will be pushed into the pipelines. Other constraints are able to identify which batch will increase the total pumping time because of on-peak hours. An example of a constraint that uses the information obtained by the pre-analysis is shown in expression (1). The final sending (fb_{b,n,n',d,p_b}) of a batch *b* is calculated considering its start sending (ib_{b,n,n',d,p_b}) in the same pipeline *d*, added to the pumping time ($part_{bo,p_{bo}} / flw_{bo,p_{bo}}$) of another batch (bo_b) that has influenced the movement of the batch *b* (see Tab. 1). The batch bo_b is pumped in its origin area no_{bo} and can remain stopped α hours because of on-peak demand hours, if the binary variable $z_{bo,p_{bo},no_{bo},h}$ = 1. Finally, some constraints describe inventory management issues (*e.g.* the time windows violation). They can be violated, but a penalty is added in the objective function in order to minimize these violations. The objective function of the MILP model also minimizes the total scheduling horizon (the sum of pumping and receiving variables).

$$fb_{b,n,n',d,p_b} \geq ib_{b,n,n',d,p_b} + \left(part_{bo,p_{bo}} / flw_{bo,p_{bo}}\right) + \alpha \cdot \sum_{h \in HP} z_{bo,p_{bo},no_{bo},h} \quad (1)$$

4. Computational Results

The optimization model has been extensively tested in typical operational scenarios. The scenario herein presented, involves 247 batches for a month of planning. This typical instance yielded a large-scale MILP model with 9695 variables (2940 binary) and 38672 constraints. This model was solved to optimality in approximately 60 seconds using ILOG OPL Studio 5.5.1 and the solver CPLEX 11 (ILOG, 2007). The hardware was an Intel Core 2/2.13GHz processor with 2GB of RAM memory. The developed scheduling presents results with a detailed form, indicating various parts for a same batch. Fig. 3 shows the temporization result for the 11 first days of the scheduling horizon. It is presented all the used pipelines, being possible, therefore, to get a general vision on how the management of the pipeline network can be made. It is possible to observe various timing blocks (parts) with the same batch index in Fig. 3. For instance, there are four parts of the same batch 71 in pipelines 24, 28, and 4. So that, the route of batch 71 contemplates the following areas and pipelines: N6 → 24 → N8 → 28 → N1 → 4 → N11 (see Fig. 1). The pre-analysis block divides a batch in various parts and determines the number of parts that will be pumped (or received), supplying the MILP main model through parameters. The difference in size of batches among pipelines is a consequence that a batch is moved by another batch that is pumped in its origin area. So that, the flow rate and the moved volume vary in each pipeline. Moreover, some stoppages can be visualized in Fig. 3 through separations between parts of the same batch in a determined pipeline (*e.g.* batch 71 on pipelines 24, 28, and 4). Based on pumping and receiving times, it is possible to obtain the storage profile in diverse areas

for different products. The initial storage level of each tank, production campaigns, and local market consumption are also considered. In Fig. 4 is shown a typical tankage profile for the product naphtha in different areas. In particular, Fig. 4 presents the naphtha aggregated inventory forecast for a 30-day horizon. Since the area N14 (blue line) does not have a local production, then, an increasing "curve" indicates, in this case, the receiving of a batch of naphtha. In addition, N14 is a consumption area. So, the decreasing curves show the local consumption of naphtha in this area. The different increasing inclinations indicate receiving of (parts of) batches at different flow rates.

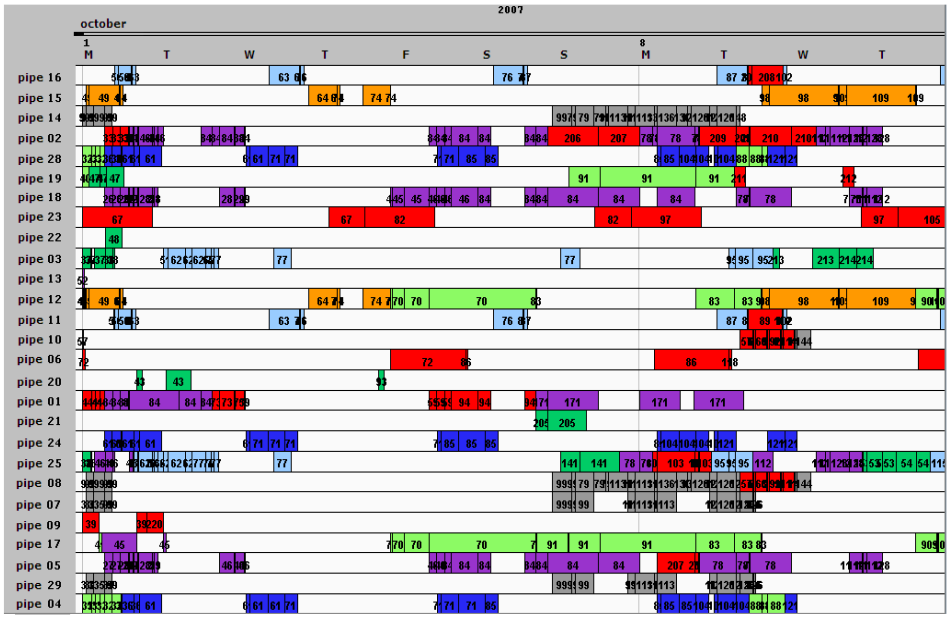

Figure 3. Gantt chart of sending procedure

Figure 4. Naphtha storage at different areas

5. Conclusions

In this paper, a decomposition approach, based on the three key elements of scheduling, is developed to address the scheduling of a real-world pipeline network. In particular, this paper focused on solving the third key element: the timing problem. Such problem is addressed through a Pre-Analysis structure and a MILP model in a collaborative combination. The optimization system has been applied to solve scenarios that represent real operational conditions of a multiproduct pipeline network that transport oil derivatives and organic products. The difficulty of obtaining a feasible scheduling of operational activities within this network is a day-to-day problem faced by the company schedulers, and such framework can be used as a decision support tool. The developed optimization system can attain a computational solution in a reduced time (order of seconds). Moreover, through the development of the Pre-analysis block, and using the parameters obtained by this block, the MILP model addressed in detail some operational conditions that were hard to be identified, even by the specialists. The optimization system is in phase of validation by the oil industry, and its use is expected to provide benefits from an operational/managerial point of view. The optimization of the transference procedures and the storage issues can reduce operational losses.

MODEL FOR THE FIRST-STAGE OF PYGAS UPGRADING: EXPERIMENTAL PROCEDURE AND PARAMETER ESTIMATION

Raquel M. Cavalcante,[a] Rafaella M. B. de Faria, [a] Ofélia de Q. F. Araújo, [a] José Luiz de Medeiros [a]

[a]*Departament of Chemical Engineering, Escola de Química da Universidade Federal do Rio de Janeiro. Sala E-201, Bloco E, Centro de Tecnologia, Ilha do Fundão, CEP: 21949-900 Rio de Janeiro, Brazil*

Abstract

Pyrolysis gasoline (PYGAS) is a by-product of the steam cracking of naphtha with high octane number and high aromatic contents (C5 to C12 range). PYGAS is unstable due to the presence of unsaturated compounds and must be hydrotreated before processing. Two-stage heterogeneous catalytic hydrogenation is commonly used to stabilize PYGAS. The First Stage uses a mild trickle-bed conversion for removing very reactive species (styrene and dienes), prior to the more severe Second Stage where sulfured and remaining olefins are converted in gas phase. This work investigates the First Stage of PYGAS hydrotreatment processes with commercial Pd/Al_2O_3 catalysts. The starting point is a data bank of conversion values for hydrogenating runs of synthetic feeds prepared with the representative reactive species in the First Stage scenario. These data were gathered from experimental runs in a short scale unit at pressures near 30 bar, temperatures between 50 and 70ºC, and weight hourly spatial velocity (*WHSV*) from $2h^{-1}$ to $70h^{-1}$. The data was used for parameter estimation of a kinetic model proposed to the First Stage of PYGAS plants. The obtained model can be employed to develop a computational tool useful in the design and optimization of PYGAS plants.

Keywords: pyrolysis gasoline, hydrotreatment process, parameter estimation

1. Introduction

Naphta steam cracking is the most used process for production of high-value petrochemical olefins. The main liquid byproduct of this process is known as pyrolysis gasoline or PYGAS. PYGAS is rich in benzene and monoaromatics (Table 1), but it also contains very reactive unsaturated species (e.g. styrene and dienes), which demand conversion by hydrogenation prior to the recovery of valuable monoaromatics (de Medeiros et al., 2007). This hydrogenation is normally designed in two stages. In the First Stage, the selective and complete hydrogenation of dienes and styrene is carried out under mild temperature and pressure, using supported Pd catalysts. The partial hydrogenation of mono-olefins and negligible conversion of sulfured species in this stage, demand the subsequent more severe Second Stage where complete vapor-phase destruction of remaining unsaturated and sulfured species takes place. The critical selectiveness issues in the First Stage, demand good kinetic models for designing PYGAS plants. Public studies on kinetic modeling on the First Stage of PYGAS upgrading are rare. Cheng et al. (1986) presented characterization data of typical PYGAS and kinetic data for the hydrogenation of isoprene and styrene. These results

were expressed as simple kinetic models using irreversible first order laws in terms of the reactants dissolved in liquid-phase. A previous study by de Medeiros et al. (2007) presented kinetic data from an experimental procedure reproducing the conditions of the First Stage of PYGAS plants. This study consolidated an experimental data bank of hydrogenating runs of synthetic feeds prepared with a set of reactant and inert model compounds pertinent to the First Stage scenario. These authors also presented a two-phase kinetic model for the First Stage of PYGAS hydrogenation.

Table 1. Typical Weight Composition of PYGAS

Component	Weight Composition (%)
Paraffins + Naphtenics	12
Olefins/Diolefins/Styrene	6 / 18 / 3
Benzene/Toluene/ Xilenes/ C_9+Aromatics	28 / 14 / 7 / 12

In the present work, we employ the experimental data bank and kinetic model of de Medeiros et al (2007) in order to estimate kinetic and adsorption parameters for the First Stage of PYGAS hydrogenation at 60ºC and 70ºC.

2. Experimental Data Base

All available experimental information belongs to the data bank consolidated by de Medeiros et al. (2007) built with 120 hydrogenation runs of synthetic feeds prepared with model compounds and toluene. A continuous bench plant with an up-flow fixed bed isothermal reactor was used. This unit operates under steady conditions via continuous pumping of liquid feed and hydrogen. The reactor temperature, pressure, *H_2/Feed* ratio and *WHSV* were controlled. All detailed techniques used in feed preparation, chemical analysis and process operation are described by de Medeiros et al. (2007). Feed compositions of reactant species (*1,7-octadiene, DCPD, styrene, 1-octene*) were chosen near real PYGAS values. Each feed gives rise to a group of runs with excursions of temperature (*T*) between 35ºC and 100ºC, and *WHSV* between 2 and 70 h^{-1} accordingly to two-dimensional factorial designs (*square-star* design) with 2 replicas in the central point (Montgomery, 2001). Reactor pressure (*P*) was set at 30 bar. *H_2/Feed* ratios were set between 24 Nl/kg and 137 Nl/kg, preferentially near 132 Nl/kg. All runs used a commercial Pd/Al_2O_3 catalyst (0.3wt% Pd). Experiment responses are measured stationary values of weight % of toluene (*TOL*), styrene (*ST*), ethylbenzene (*EB*), 1-octene (*R*=), 1,7-octadiene (*R*==), n-octane (*R*), 1,6 dimethyl-cyclohexane (*CR*), DCPD (*C*==) and adamantane (*C*).

3. Reaction Network and Kinetic Model

Fig. 1 defines the reaction network by the set of irreversible reactions (numbered by (.)) and kinetic rules (numbered by [.]). Reaction rates (mol/s.kgCat) are modeled via a four steps mechanism: (1)equilibrium dissociation adsorption of H_2 [$H_2(g)+2\sigma(s) \leftrightarrow 2H\sigma(s)$]; (2)equilibrium adsorption of hydrocarbon species [$HC(l)+\sigma(s) \leftrightarrow HC\sigma(s)$]; (3)slow hydrogenation of adsorbed species [$HC\sigma(s)+H\sigma(s) \leftrightarrow HC\sigma\text{-}H\sigma(s)$]; (4)fast subsequent hydrogenation [$HC\sigma\text{-}H\sigma(s) + nH\sigma(s) \leftrightarrow HCH\sigma(s) + n\sigma(s)$]. If f_i represents the fugacity of species i, $K_k(T)$ the kinetic constant of k^{th} reaction, and $K_j^{AD}(T)$ the Langmuir adsorption factor for species *j*, the rate expression for k^{th} reaction can be written as (de Medeiros et al., 2007):

$$R_k(T,\underline{f}) = K_k(T) * \Psi(\underline{f}) * K_j^{AD} * f_j \qquad (1)$$

$$\Psi(T,\underline{f}) = \frac{\sqrt{K_{H_2}^{AD} * f_{H_2}}}{\left(1+\sqrt{K_{H_2}^{AD} * f_{H_2}} + \sum_{j\neq H_2}\left(K_j^{AD} * f_j\right)\right)^2} \quad (2)$$

Defining:

$S_{kj} = 1 \Rightarrow k^{th}$ reaction rate is defined by species j, otherwise $S_{kj} = 0$; and

$D_{ki} = 1 \Rightarrow k^{th}$ reaction rate uses i^{th} kinetic rule, otherwise $D_{ki} = 0$;

the vector of reaction rates for all network can be written according to:

$$\underline{R}(T,\underline{f}) = \Psi(\underline{f})\left(\underline{\underline{Diag}}(\underline{\underline{D}}\underline{K}(T))\right)\underline{\underline{S}}\left(\underline{K}^{AD} \bullet \underline{f}\right) \quad (3)$$

Kinetic constants and Langmuir adsorption factors are expressed as function of temperature in Arrhenius representation, as shown below:

$$\underline{K}(T) = \underline{k}_0 \bullet \exp(-\underline{E}_A / T) \quad (4a)$$

$$\underline{K}^{AD}(T) = \underline{k}_0^{AD} \bullet exp(-\underline{E}_A^{AD} / T) \quad (4b)$$

where $\underline{E}_A$, $\underline{E}_A^{AD}$, $\underline{k}_0$ and $\underline{k}_0^{AD}$ express vectors of activation energies (K), reference kinetic constants (mol/s.kg$_{Cat}$) and reference Langmuir factors (bar^{-1}). Symbol • stands for multiplication of corresponding components of vectors. Spatial reactor time is defined – Eq. 5 – from reactor section A (m^2), axial position z (m), bed density ρ^{cat} (kg/m^3), and feed rate F_0 (kg/s). Stationary component material balances are written as in Eq. 6, where $\underline{N}$ and $\underline{\underline{H}}$ express, respectively, the vector of component molar rates and the stoichiometric matrix. Reactor (or experiment) responses are produced by integrating Eq. 6 from *t=0* to *t=3600/WHSV* as in Eq. 7, where $\underline{N}_0$ is the vector of component molar rates at the reactor inlet, defined by F_0, the feed composition and the *H_2/Feed* ratio.

$$t = z * A * \rho^{CAT} / F_0 \quad (5)$$

$$\frac{d}{dt}\underline{N} = F_0\Psi(\underline{f})\underline{\underline{H}}\,\underline{\underline{Diag}}(\underline{\underline{D}}\underline{K}(T))\underline{\underline{S}}(\underline{K}^{AD} \bullet \underline{f}) \quad (6)$$

$$\underline{N} = \underline{N}_0 + \int_{t=0}^{t=3600/WHSV} F_0\Psi(\underline{f})\underline{\underline{H}}\left(\underline{\underline{Diag}}(\underline{\underline{D}}\underline{K}(T))\right)\underline{\underline{S}}(\underline{K}^{AD} \bullet \underline{f})\,dt \quad (7)$$

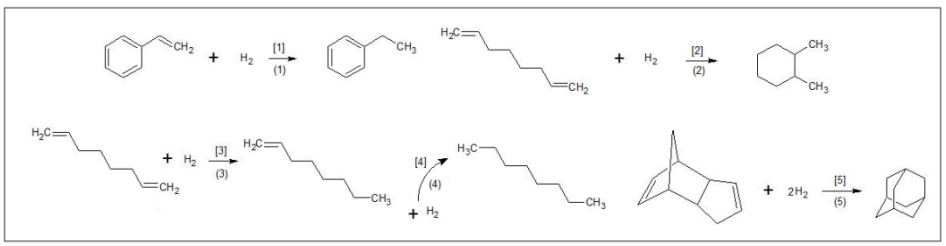

Figure 1: Network of Irreversible Reactions for PYGAS Hydrogenation

Eq. 6 is numerically integrated via adaptive methods suitable to stiff problems. Along the integration path, successive vapor-liquid equilibrium problems with specified $T,P,\underline{N}$ – $flash(T,P,\underline{N})$ – are solved via Newton-Raphson method. Thermodynamic properties are calculated for both phases by Soave-Redlich-Kwong equation of state with classical mixing rules. Critical constants are estimated by Joback Method.

4. Parameter Estimation

The procedure follows closely the proposition given in de Medeiros et al. (2007). At a given temperature, the vector of *np* parameters ($\underline{\theta}$), is estimated with the corresponding isothermal slice of database runs. The estimate of $\underline{\theta}$ is $\underline{\hat{\theta}}$, containing *nk=5* kinetic constants and *nc=10* component Langmuir factors ($\underline{\hat{\theta}}^T = [\,\underline{\hat{K}}^T\ \underline{\hat{K}}^{AD^T}\,]$). Each run *i* produced a *ny x 1* vector of experiment responses with *ny=9*. The prediction of model responses for this run is $\underline{\hat{Y}}_i(\underline{\hat{\theta}})$. If $\underline{\hat{Y}}_i(\underline{\hat{\theta}}) - \underline{Y}_i^{EXP}$ is the vector of response residue for run *i*, and neglecting constant terms, the minimum of the negative of the sum of logarithmic Likelihood Functions for runs is given by Eq. 8, where *m* is the number of runs considered and $\underline{\underline{W}}_i$ is a *ny x ny* diagonal weighting matrix for run *i*:

$$\underset{\{\underline{\theta}\}}{Min}\left(\frac{1}{2}\right)\sum_{i}^{m}(\underline{\hat{Y}}_i(\underline{\hat{\theta}})-\underline{Y}_i^{EXP})^T\,\underline{\underline{W}}_i\,(\underline{\hat{Y}}_i(\underline{\hat{\theta}})-\underline{Y}_i^{EXP}) \qquad (8)$$

This problem was solved numerically via a Nelder-Mead Simplex Method, after a suitable change of variables in order to impose bounded search domains.

5. Statistical Analysis

Statistical entities are used for evaluation of the estimation process. Statistics S_R^2 is an estimator for the intrinsic variance (Eq. 9). The variance-covariance matrix of estimated parameters and correct parameter confidence domain at level (1-α)*100% (α=0.01) are given in Eq. 10, where $\underline{\underline{J}}_i = (\nabla_{\underline{\theta}}\underline{\hat{Y}}_i^{\,T})^T$ is the jacobian matrix of *i* responses with parameters and $\phi_{1-\alpha}$ is the Fisher abscissa with (*np,ny*m-np*) degrees of freedom.

$$S_R^2 = \left(\frac{1}{ny*m-np}\right)\sum_{i}^{m}(\underline{\hat{Y}}_i-\underline{Y}_i^{EXP})^T\,\underline{\underline{W}}_i\,(\underline{\hat{Y}}_i-\underline{Y}_i^{EXP}) \qquad (9)$$

$$\underline{\underline{C\hat{O}V}}(\underline{\hat{\theta}}) = S_R^2 * \left(\sum_{i=1}^{m}\underline{\underline{J}}_i^{\,T}\,\underline{\underline{W}}_i\,\underline{\underline{J}}_i\right)^{-1} \quad , \quad (\underline{\theta}-\underline{\hat{\theta}})^T\left(\sum_{i=1}^{m}\underline{\underline{J}}_i^{\,T}\,\underline{\underline{W}}_i\,\underline{\underline{J}}_i\right)(\underline{\theta}-\underline{\hat{\theta}}) \le np * S_R^2 * \phi_{1-\alpha} \qquad (10)$$

6. Results

Kinetic constants were estimated for data at temperatures of 60ºC and 70ºC. At 60ºC, all parameters $\underline{\hat{\theta}}$ were estimated due to the high number of observed values (59 runs). On the other hand, at 70ºC (19 runs) only the five kinetic constants and the Langmuir factor of H_2 were estimated, whereas the adsorption factors of remaining species were kept at the 60ºC values. Table 2 shows all estimated parameters and respective Arrhenius coefficients (Eqs. 4). Figs. 2A and 2B show the distributions of observed and estimated *wt% styrene* at 60ºC and 70ºC. Fig. 3 shows a 2D projection of the 99% confidence

region for kinetic parameters of styrene (K_1) and 1,7-octadiene (K_2) conversions at 60ºC. Figs. 4 show plots of observed versus predicted responses for 60ºC and 70ºC.

Table 2. Summary of Estimation Results

Adsorption Factors (bar^{-1})			Kinetic Const.($mol/s.kg_{Cat}$)			Arrhenius Coefficients

7. Conclusions

The reactor model of de Medeiros et al. (2007) for the First Stage of PYGAS plants was approached for parameter estimation over 120 hydrogenation experimental runs with synthetic feeds made with model compounds. The model takes into account the two-phase (equilibrated) flow along the reactor and kinetic rates expressed with adsorption effects and component fugacities. Model parameters were estimated at 60 and 70ºC via statistical processing of experimental data. Arrhenius coefficients were generated for these estimations whenever possible. These forms are useful for developing an engineering model of the (adiabatic) industrial reactor for PYGAS upgrading. The adsorption constants were only estimated for 60 ºC, due to the difficulty to estimate them with few experimental data (19 runs at 70 ºC).

Abstract

A general mathematical model for 1,3-butadiene/methylmethacrylate emulsion copolymerization process in batch reactor is presented. The model is able to explain the effects of simultaneous changes in emulsifier concentration, initiator concentration, and monomer feed composition on conversion, average particle size, and pressure evolution histories. The main features of the system, such as the increase of the rate of polymerization as emulsifier and initiator concentrations increase and the dependence of the reaction on the number of particles, are correctly represented by the model. The model accounts for the basic features of the process and may be useful for practical applications, despite its simplicity and reduced number of adjustable parameters.

Keywords: emulsion copolymerization, mathematical modeling, methyl methacrylate, 1,3-butadiene.

1. Introduction

Emulsion polymerization is an important industrial process for manufacturing commercial products such as rubbers, paints, and adhesives. It is a very complex heterogeneous process involving several chemical and physical phenomena, many of which have not yet been completely elucidated. Because of its industrial relevance, it is important to develop mathematical models that can represent the mechanisms involved in these processes. This is an essential task to better understand a given system, reflecting the knowledge on the interactions between all the factors that affect it. As opposed to many vinyl copolymer systems, the emulsion polymerization of methyl methacrylate (M) and 1,3-butadiene (B) has received very little attention in the literature. To the authors' knowledge, only the works by Shapiro *et al*. (1981) and Araujo *et al*. (2001) have focused on experimental investigations on this system. Similarly, modeling of this process seems to have received attention only by Saldívar *et al*. (2002) so far. In this work, a general mathematical model has been developed and validated by comparison with the experimental data of Araujo *et al*. (2001), aiming at getting an insight on the mechanisms governing emulsion copolymerization processes of this copolymerization system. The influence of several process variables, such as initiator concentration, emulsifier concentration, and feed composition has been examined.

2. Theory

The mathematical model used in this work is based on the approaches of Casella *et al*. (2003), Zubitur *et al*. (2004), and Pinelli Filho *et al*. (2006). Following Casella *et al*. (2003), the main idea is to provide and test a general common model with a reduced number of adjustable parameters applicable to many copolymerization systems. The main model equations are detailed in the next sections.

2.1. Monomer Balances

The emulsion copolymerization process begins with the thermal decomposition of an initiator in the aqueous phase. The initiator decomposition is represented by a first-order reaction (Casella *et al*., 2003). Polymer chains start to grow from the reaction of these radicals with the monomers. The conversion of monomer i (i = 1 or 2), x_i, is calculated from the monomer balance, written as (Casella *et al*., 2003):

$$M_{io}\frac{dx_i}{dt} = R_{pi} \tag{1}$$

where M_{io} is the initial ratio of monomer i to volume of water, and R_{pi} is the molar rate of polymerization of monomer i, accounting for the polymerization in both the aqueous and polymer particle phases. Assuming a pseudo-homopolymerization approach and terminal model (Gilbert, 1995; Casella *et al*., 2003), it is calculated by

$$R_{pi} = \left(k_{p1i}P_1^p + k_{p2i}P_2^p\right)[M_i]_p\frac{N_T\bar{n}}{N_A} + \left(k_{p1i}P_1^{aq} + k_{p2i}P_2^{aq}\right)[M_i]_{aq}[R\cdot]\phi_w^{-1} \tag{2}$$

where k_{pij} is the propagation rate constant between radical type j and monomer type i, $[M_i]_p$ is the concentration of monomer in the particles, $[M_i]_{aq}$ is the concentration of monomer in aqueous phase, $[R^-]$ is the concentration of hydrophilic sulfated radicals in the aqueous phase, N_T is the total number of particles per volume of water in the reactor, N_A is Avogadro's number, ϕ_w is the volume fraction of water in the aqueous phase, and $\bar{n}$ is the average number of radicals per particle. The probability of finding an active chain with ultimate unit (1 or 2) in the polymer particles (p) or aqueous phase (aq), P_i^k (k = p or aq), can be calculated from k_{pij} and the concentration of monomer in the respective phase (Casella *et al*., 2003).

2.2. Concentration of Free Radicals in the Aqueous Phase

For the balance of free radicals in the aqueous phase, it was considered that the radicals containing hydrophilic sulfate groups, $[R^-]$, with size larger than a certain length, z, can be captured by micelles or particles or can be consumed by propagation and termination reactions. However, the radicals with size ranging from 1 to z – 1 cannot be absorbed by micelles or particles (Gilbert, 1995). They can grow until the reach of a critical size, jcr, from which they precipitate out from the aqueous phase and form new particles by homogeneous nucleation. For homopolymers, jcr and z can be estimated from the correlations proposed by Gilbert (1995). For copolymer radicals, following a suggestion from Dubé *et al*. (1997), jcr and z were obtained from the average of the values for the homopolymers, weighted by the instantaneous composition of the copolymer. The radical balance for the radicals produced in the aqueous phase can be represented by equations similar to those described by Araújo and Giudici (2003). Radicals can also be present in aqueous phase due to desorption from particles. The generation of these is usually attributed to chain transfer reactions to monomers inside the particles (Dubé *et al*., 1997; Asua, 2003). They have a distinct chemical nature from the previous radicals, being much less hydrophilic. Therefore, they can readily be reabsorbed by the particles. Their concentration, $[M^-]$, can be obtained by a balance similar to that proposed by Casella *et al*. (2003) for the free radicals in the aqueous phase.

2.3. Number of Polymer Particles

The total number of particles is calculated considering that they are formed from homogeneous and micellar nucleation (rates: R_{hom} and R_{mic}, respectively).

$$\frac{dN_T}{dt} = R_{mic} + R_{hom} \quad (3)$$

$$R_{mic} = k_{am}\left\{\left[\frac{\alpha_2 - \alpha_2^{jcr-z+1}}{1-\alpha_2}\right](\alpha_1)^{(z-2)}\alpha_3^{-1}[R\cdot] + [M\cdot]\right\}N_m \equiv k_{am}\sigma_1 N_m \quad (4)$$

$$R_{hom} = (k_p[M]_{aq})(\alpha_2)^{(jcr-z)}(\alpha_1)^{(z-2)}\alpha_3^{-1}[R\cdot]N_A/\phi_w \quad (5)$$

$$\alpha_3 \equiv \left[(1-\alpha_1^{z-1})/(1-\alpha_1) + (\alpha_2 - \alpha_2^{jcr-z+1})/(1-\alpha_2)\right](\alpha_1)^{(z-2)} \quad (6)$$

where k_{am} is the rate constant of radical capture by micelles, ($k_p[M]_{aq}$) is the average propagation rate coefficient (Casella *et al.*, 2003), α_1 and α_2 represent the probability that radicals of sizes smaller than z and from z or higher to propagate in the aqueous phase, respectively (Casella *et al.*, 2003; Araújo and Giudici, 2003). N_m is the concentration of micelles and can be determined from the emulsifier balance.

2.4. Concentration of Free Radicals in the Polymer Particles

The average number of radicals per particle, $\bar{n}$, depends on various phenomena such as absorption and desorption of radicals and termination within the particles (Casella *et al.*, 2003; Asua, 2003) and is calculated from the following differential equation:

$$\frac{d\bar{n}}{dt} = k_{ap}\sigma_1 - k_{des}\bar{n} - \frac{2(2k_{ap}\sigma_1 + k_{des})k_{tp}}{(2k_{ap}\sigma_1 + k_{des} + k_{tp}/v_p N_A)v_p N_A}\bar{n}^2 \quad (7)$$

where k_{ap} is the rate constant of radical capture by particles, σ_1 is defined in Equation (4), k_{des} is the desorption constant, k_{tp} is the termination rate constant in the particles, and v_p is the volume of a polymer particle. Values of k_{tp} were determined according to Casella *et al*. (2003) while those of k_{des} were calculated using the simplified version of Asua's model (Asua, 2003).

2.5. Concentration of Monomers and Other Components

Monomer concentration in the dense phases (aqueous, monomer droplets, and polymer particles) were evaluated by assuming phase equilibrium at each instant of the copolymerization process and employing the partition coefficient method as described by Pinelli Filho *et al*. (2006). From the method it is also possible to determine the volume of a polymer particle (v_p).

Following Pinelli Filho *et al*. (2006), the number of mols of water and less volatile monomers in the vapor phase can be determined from the balance equation:

$$\frac{dN_i^v}{dt} = -\frac{k_L a_T}{PM_i}\left(Py_i - P_i^{sat}x_i^{aq}\gamma_i^{aq}\right) \quad (8)$$

in which N_i^v and PM_i are, respectively, the number of mols in the vapor and molecular weight of water or monomer, k_L is the mass transfer coefficient, a_T the gas-liquid interfacial area, y_i and x_i^{aq} are the mole fractions of water or the monomer in the vapor and aqueous phase, respectively. γ_i^{aq} is the activity coefficient of these compounds in the aqueous phase, P_i^{sat} is the vapor pressure of the compounds at the reaction temperature, and P is the pressure inside the reactor, which was calculated assuming ideal gas behavior (Pinelli Filho *et al*., 2006). Adapting the approach of Zubitur *et al*. (2004) to the more volatile monomer (1,3-butadiene), Equation (8) becomes

$$\frac{dN_i^v}{dt} = -\frac{k_L a_T}{PM_i}\left(Py_i - H_i x_i^{aq}\right) \quad (9)$$

where H_i is the Henry's law constant for 1,3-butadiene in water at the reactor pressure and temperature.

3. Methods

Details of the experimental procedure are described elsewhere (Araujo *et al*., 2001). The experiments that were simulated and compared with the model are shown in Table 1.

Table 1. 1,3-butadiene/methylmethacrylate experiments at 70ºC (Araujo *et al*., 2001).

Test	B/M (mol/mol)	B (g)	M (g)	Initiator (g)	Emulsifier (g)	Water (g)
BM-1	30/70	109.6	474.1	0.78	6.93	1717
BM-5	30/70	109.6	474.1	1.57	13.86	1717
BM-15	30/70	109.6	474.1	0.78	13.86	1717
BM-2	70/30	310.5	246.1	0.75	6.61	1637
BM-6	70/30	310.5	246.1	1.49	6.61	1637
BM-14	70/30	310.5	246.1	1.49	13.22	1637

Three parameters (k_{am}, k_{ap}, $k_L a_T$) were estimated by minimizing a weighted nonlinear least squares criterion involving monomer conversion, particle diameter, and pressure in the reactor using Marquardt and Simplex algorithms (Bevington, 1969; Rowan, 1990; Casella *et al*., 2003). The results were very similar. One set of parameter values was fitted for systems with a monomer molar ratio of 30/70 B/M and another to those displaying molar ratio of 70/30 (Table 1). The system of differential equations present in the model was solved numerically using Gear's method.

4. Results and Discussion

Comparison of experimental and model predictions for conversion, average particle size, and pressure is made in figures 1 to 3 for batch 1,3-butadiene/methylmethacrylate emulsion copolymerization reactions at 70ºC. Results for batches with less butadiene in the feed are shown on the left and those more concentrated on the right side.

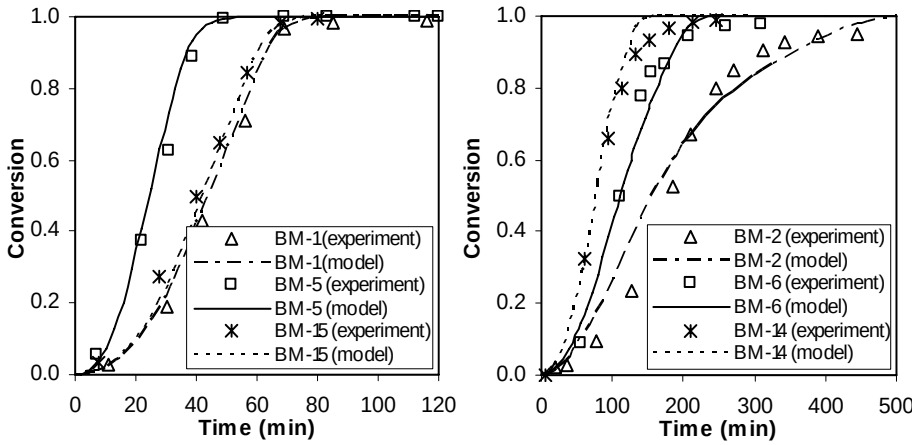

Figure 1. Evolution of conversion during B/M batch emulsion copolymerizations.

Polymerization is faster as initiator concentration increases and raises slightly by increasing the amount of emulsifier. This behavior can be related to an increase in particle nucleation that, in turn, leads to a more rapid conversion of the monomers to polymers (Gilbert, 1995). As the quantity of methyl methacrylate increases, the reaction rate also becomes faster since this monomer reacts more rapidly than butadiene (Araujo *et al*., 2001). The congruence of simulated and experimental results is quite good, being similar to that of the model proposed by Saldívar *et al*. (2002) and employing only half the number of adjustable parameters.

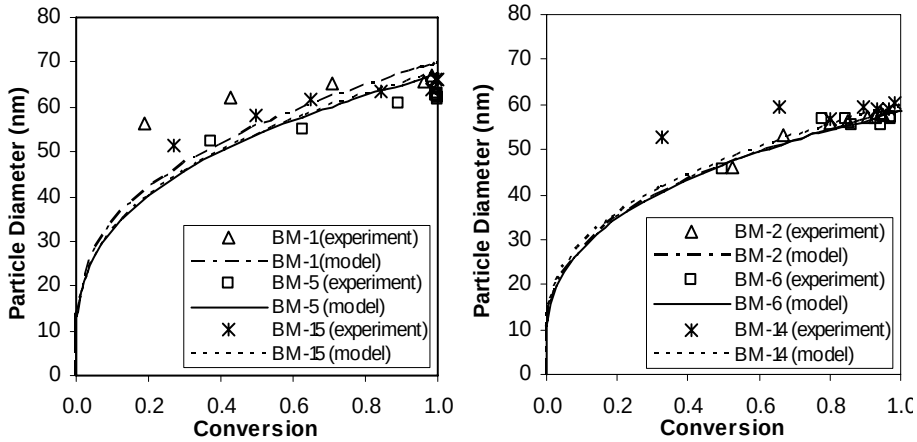

Figure 2. Evolution of particle diameter during B/M batch emulsion copolymerizations.

It is generally expected that the higher the initiator and emulsifier concentrations the faster the reaction rate and the smaller the particle size (Casella *et al*., 2003). This trend can be observed in batches with a monomer molar ratio of 30/70 B/M. However, results of particle diameter for systems richer in butadiene are barely distinguishable. The model correctly predicts the trends shown in Figure 2; however, the evolution of the particle diameter is described only in a semi-quantitative way as also reported by Saldívar *et al*. (2002). Problems in measuring this property (Casella *et al*., 2003)

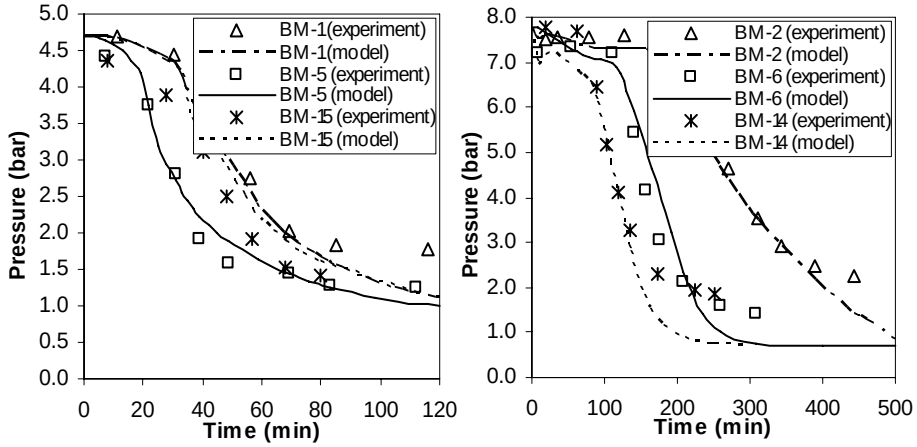

Figure 3. Evolution of reactor pressure during B/M batch emulsion copolymerizations.

and difficulties in improving the theoretical description of particle nucleation phenomena (Saldívar *et al*., 2002) contribute to this.

An additional contribution of the present model, not found in most approaches in the literature, is the prediction of the pressure-time history in the reactor. Pressure measurements are useful to identify some changes during polymerization reactions involving volatile monomers such as 1,3-butadiene. For instance, the inflection points observed in pressure evolutions (Figure 3) coincide with the instant in which the monomer droplets disappear (Pinelli Filho *et al*., 2006). Comparison of experiments and predictions for the pressure (Figure 3) indicate that the model is able to correctly describe the variation of pressure inside the reactor as the formation of polymer occurs. As there is a correlation between the variations of pressure and monomer conversion during the batch (figures 1 and 3), this points to the possibility of using the model as a state estimator for monitoring the monomer conversion from readily available, simple pressure measurements in industrial 1,3-butadiene-methylmethacrylate emulsion copolymerization processes.

Dynamic modeling and simulation of dividing-wall distillation column systems

Maria A. Vargas,[a] Gerit Niggemann,[a] Georg Fieg[a]

[a] *Institute of Process and Plant Engineering, Hamburg University of Technology Schwarzenbergstr. 95c, Hamburg 21073, Germany*

Abstract

Possible configurations of two dividing wall column systems are investigated for the separation of a five component feed mixture. Hence, a rigorous mathematical model is develop, which allows the stationary and dynamic simulation of the process. Steady state optimization is performed for the design of the column system and the selection of the configuration with the minimum total annualized costs. The selected configuration for our study case is subjected to numerous steady state sensitivity analyses. Furthermore, dynamic simulations in open loop mode are performed to analyze the transient behavior of the column system.

Keyword: dividing-wall column, distillation, column system, optimization

1. Introduction

Distillation remains the most commonly used separation process in the chemical industry. The separation of a homogenous multicomponent mixture into more than two products is usually realized in sequences of conventional distillation columns. This sequential separation does not only require high capital cost but also high amounts of energy. Complex column arrangements, such as dividing-wall columns, have been proposed as alternative to significantly reduce distillation costs. Theoretical studies (e.g., *Petlyuk et al. 1965* and *Kaibel 1988*) have revealed that in the separation of ternary mixtures, dividing-wall columns are capable of achieving 30% of energy savings.

However, in the industrial practice it is usually necessary to separate mixtures into more than three pure fractions. In that respect, dividing-wall column systems arise as an alternative. *Shah et al. 2002*, determined that these systems can reduce the energy costs in more than 20 % compared with traditional arrangements for the separation of five components mixtures. Operability issues and lack of knowledge that arise from a more complex dynamic behavior have discouraged wider industrial acceptance of these systems.

The separation of a five components mixture A,B,C,D,E (A is the lightest and E the heaviest boiling component) in a dividing-wall column system can be accomplished in three different configurations (Figure 1). The connection between the two columns could be either the bottom, the side or the distillate stream. The best sequence depends on the characteristics of the feed mixture. The complexity in the dynamic behavior of this system lies in the variable conditions in flow, temperature and composition of the connecting stream between the two columns in case of disturbances in the first column.

The purpose of this work is to perform a detailed analysis of dividing-wall column systems for the separation of five components feed mixtures. In earlier studies a rigorous process model for one dividing-wall column has been developed (Niggemann

et al., 2006). The mathematical model was subjected to an extensive validation with experimental data of our pilot plant. Based on this model, a new rigorous model for the simulation of a two dividing-wall columns system is developed for a theoretical examination. In this paper, simulation studies include steady state sensitivity analysis and analysis of the transient behavior of the system subjected to feed disturbances are conducted.

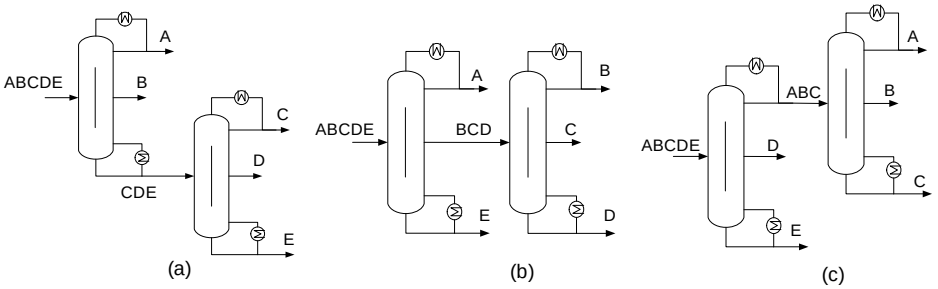

Figure 1. Configurations of dividing-wall distillation column systems for the separation of a five components mixture (a) bottom-feed BF, (b) side-feed SF and (c) distillate-feed DF.

2. Modeling

In previous studies, a rigorous mathematical model was developed for the detailed analysis of dividing-wall columns (Niggemann *et al.*, 2006). The model consists of ordinary differential equations (Eq. 1) obtained from mass and energy balances around each theoretical stage and a set of algebraic equations (Eq. 2) which are used to predict the physical properties, the vapour-liquid equilibrium and the column hydrodynamic.

$$\frac{d\dot{y}}{dt} = f(\dot{y}, y, u_d, u_o) \tag{1}$$

$$0 = g(\dot{y}, y, u_d, u_o) \tag{2}$$

The variable y denotes a vector of process state variables; u_d and u_o are the design and operating parameters. The highly nonlinear differential algebraic equation system is implemented in the commercial software tool Aspen Custom Modeler^{TM}. Important characteristics of dividing-wall columns, as the self adjusting vapour split, are considered in the model.

An extensive validation with experimental data of our pilot plant demonstrated the capability of the model to predict the steady state and transient behavior for the separation of a ternary mixture of linear alcohols.

Based on this model, a new model for the simulation of two dividing-wall columns system is developed. In our case study, a five component feed mixture, consisting of linear fatty alcohols (n-hexanol C6, n-octanol C8, n-decanol C10, n-dodecanol C12 and n-tetradecanol C-14) is separated into pure products with concentrations higher than 0,991 kg/kg. The components in the feed mixture have equal mass concentration and a feed flow rate of 5000 kg/h is used. The two dividing-wall column system configuration with the lowest total annualized costs (TAC) is selected to perform the task. Hence, the design and operating parameters of the three different arrangements DF, SF and BF (Figure 1) were optimized to minimize the objective function value TAC.

$$\min_{u_d, u_o} TAC \tag{3}$$

$$TAC = \frac{k \cdot \sum_i E_i}{n} + \sum_i U_i \tag{4}$$

The first part of Eq. 4 indicates the annualized investment cost and the second part the production costs. The investment costs are determined as the summation of column cost and periphery equipments such as condenser and reboiler. The factor *k* considers the installation costs and *n* is the plant life time. The operation variables that affect the operating costs are the reboiler and condenser duty, which values are used to determined the utility costs (*U*).

The steady state optimization problem is constrained by the mathematical process model (Eq. 1-2), the product purities (Eq. 5), liquid load (Eq. 6), the optimization bonds of the design parameters (Eq. 7) and the operating control variables (Eq. 8).

$$x_i \geq x_{i,\min} \tag{5}$$

$$B \geq B_{\min} \tag{6}$$

$$u_{d,\min} \leq u_d \leq u_{d,\max} \tag{7}$$

$$u_{o,\min} \leq u_o \leq u_{o,\max} \tag{8}$$

In this work, the set of operating variables includes the reboiler heat duty (QR) and the liquid split (Ls). The design variables include the number of theoretical stages in all segments of the dividing wall column. The feed and side streams are always located in the middle of the column. The diameter of the columns are determined to satisfied the hydraulic constrains of the column packing (F-factor ≤ 2,5 $Pa^{0,5}$). For the solution of the optimization problem was used the deterministic solution method SRQP (Successive Reduced Quadratic Programming).

The configuration BF resulted to have the lowest TAC. Figure 2 depicts the optimized operating and design parameters. The first column of the arrangement operates with a reflux ratio of 1,8 and heat duty in the reboiler of 698 kW. The column has 26 theoretical stages and diameter of 1,32 m. The second column operates with a reflux ratio of 2 and heat duty in reboiler of 402 kW. The column has 34 theoretical stages and diameter of 1,13 m.

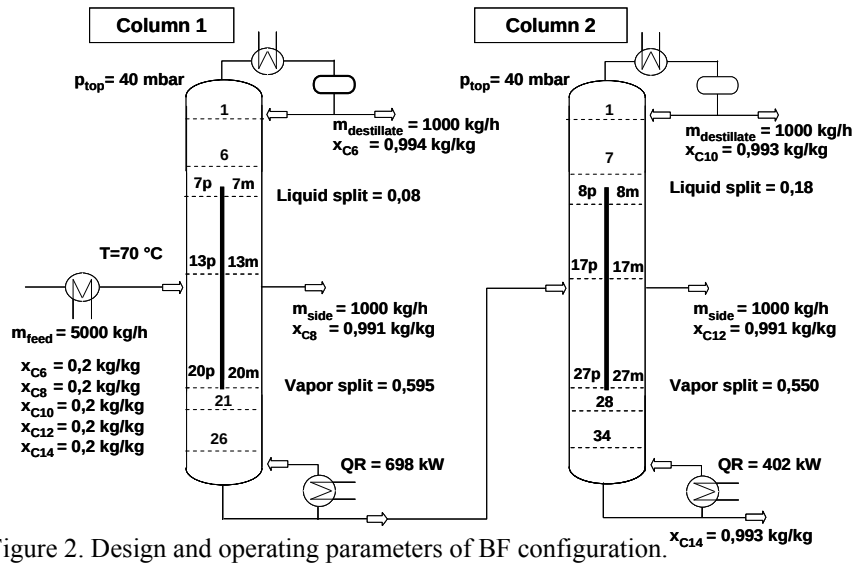

Figure 2. Design and operating parameters of BF configuration.

3. Steady state simulation

The dividing-wall column system BF selected for our study case was subjected to numerous sensitivity analyses. The high complexity of this system lies in the variable conditions in flow, temperature and composition of the connecting stream between the two columns, in case of disturbances in the first column. These disturbances can be produced by variations of process parameters in column 1 during the operation. Among these parameters are the liquid split (Ls), heat duty (QR) and the product streams flow rate. In the sensitivity analysis one operating parameter is changed while the rest parameters are kept constant.

Increments of the heat duty in column 1 result in an increase in the concentration of the key components (Figure 3). The connecting stream between the two columns experiences a reduction of impurities. These impurities, which are composed by C8, contaminate the distillate stream of column 2. In this case the maximum concentration of impurities in the feed stream of column 2 must be lower than 0,3 % w/w, otherwise the desired purity of top product in column 2 cannot be achieved. On the other hand, reduction of the heat duty in column 1, does not affect the concentration of key components in the side and bottom stream of column 2. In column 2, only the concentration of the top product is affected, due to the higher amount of C8 in the connecting stream.

Another important parameter considered in the sensitivity analysis is the liquid split. Its variation implies also changes in the vapor split (Vs), which is determined in the model by self adjusting to equalize the pressure drop in both sides of the dividing wall column. Figures 4 (a) shows that increasing Ls in column 1, produces the reduction of the key components concentration in column 1 and only affects the concentration of the key component of the top product in column 2. The explanation is similar to the case of heat duty variation. Unexpectedly, the vapor split in column 2 shows a slight increase (Figure 4 (b)). The higher amount of C8 in column 2 reduces the density of the vapor in the prefractionator, resulting in an increase of Vs. The small change does not affect the concentration of the key components in side and bottom of column 2.

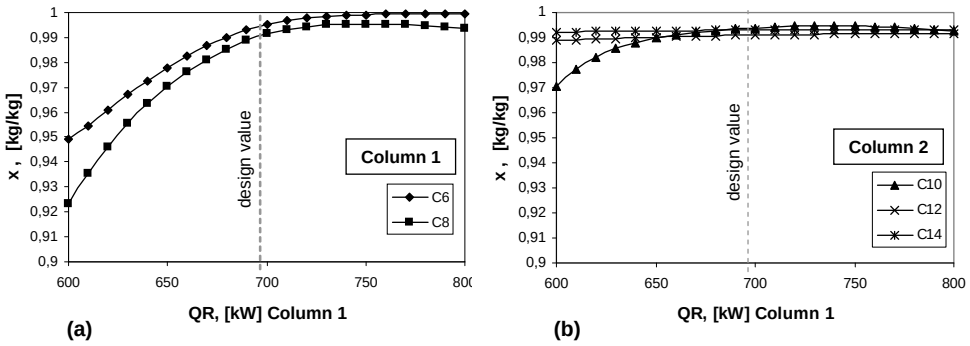

Figure 3. Variation of key components concentration in dividing-wall (a) column 1 and (b) column 2, as function of reboiler heat duty in column 1.

From the previous analysis it can be concluded that changes in the Ls and QR of column 1, can increase the concentration of C8 in the connecting stream. This produces the increment of impurities in the top stream of column 2. The concentrations of key components of side and bottom stream are not affected by changes in Ls and QR of column 1.

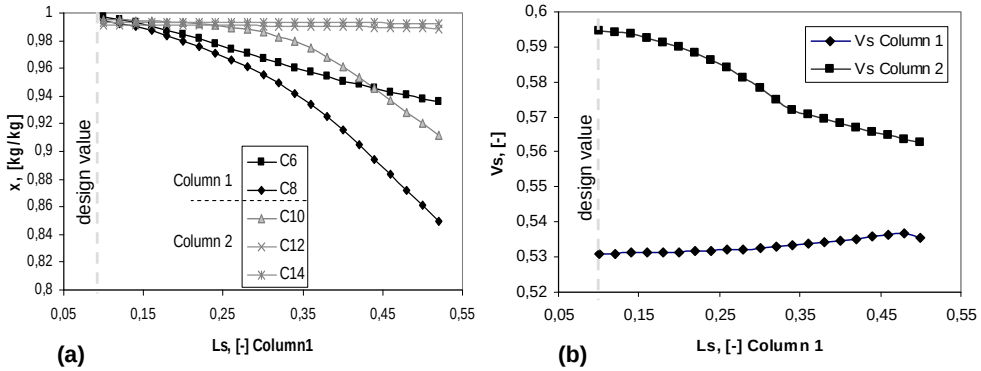

Figure 4. Variation of (a) key components concentration and (b) vapor split in dividing-wall column 1 and 2, as function of liquid split in column 1.

The performed sensitivity analyses provide important information about the interaction between the two dividing-wall columns in the system configuration BF. They quantitatively depict the variation of usual controlled variables such as temperature and concentration of key components as function of changes in process variables. These results facilitate the selection of appropriate variables for the control of the dividing-wall column system.

4. Dynamic simulation

Theoretical examinations, of the transient behaviour of a dividing-wall column system are one part of the integral analysis of this contribution. The developed mathematical model is tested and verified for dynamic simulations. The dividing-wall column system BF is inspected. Hence, perturbations in the composition of components in the feed of ± 3% are assigned. The transient behaviour of the system is analysed in open loop mode.

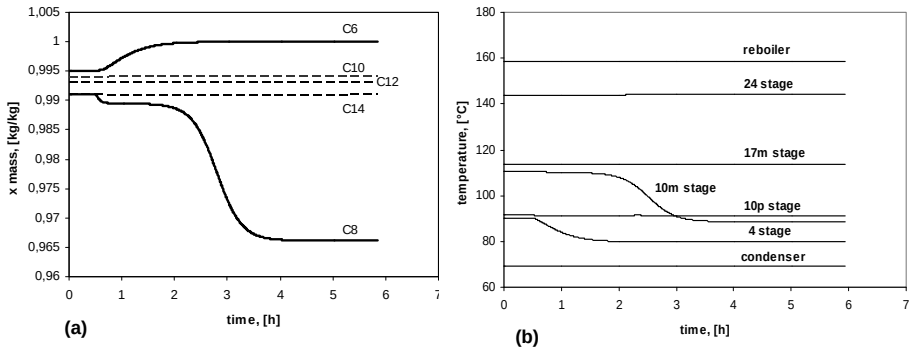

Figure 5. Transient behavior of the BF configuration in open loop mode with feed concentration disturbance, x_{C6} = + 3 % and x_{C8} = – 3 %, (a) concentration of key components and (b) temperature profiles in column 1.

In the first case, Figure 5, the concentration of C6 is incremented in 3 %, while the concentration of C8 is reduced in 3 %. The perturbation is introduced at t = 0,5 h. First, the temperature in the segment above the dividing-wall (4 stage) of column 1 decreases

and reaches a new steady state at t = 2 h. At the same time the temperature in the dividing-wall segment above the side stream withdrawal (10s stage) starts to decrease. It coincides with the high reduction in concentration of C8 in side stream column 1 (Figure 5 (a)). The temperature profile of the column 2 is not affected by the disturbances, which can be seen in the invariability of the key components concentration in column 2 (Figure 5 (a)). After around t = 4 h the system reaches a new steady state.

In the second case analyzed, the concentration of C6 is reduced in 3 % and the concentration of C14 is incremented in 3 %. Figure 6 depicts the transient behavior of the temperatures in column 1 and column 2. In both columns the disturbances increases temperature, which are stabilized again at t = 3,5 h.

The performed dynamic simulations give a first insight of the transient behavior in open loop mode of a two dividing –wall column system.

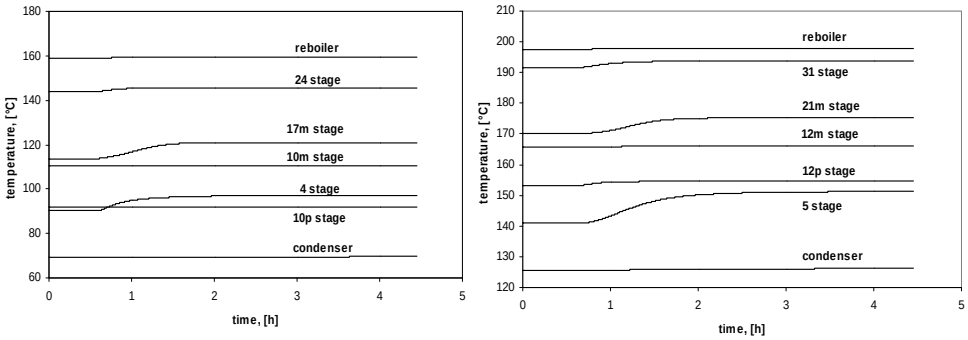

Figure 6. Transient behavior of the BF configuration in open loop mode with feed concentration disturbance, x_{C6} = - 3 % and x_{C14} = + 3 %, (a) temperature profile column 1 and (b) temperature profile column 2.

5. Conclusion

A rigorous mathematical model, developed for steady state and dynamic simulation of a two dividing-wall column system have been tested and verified. The results showed the robustness and stability of the numerical solution. In our study case, the design and operating parameters of the possible column configurations were optimized to minimize the TAC. The configuration with the minimum TAC (BF configuration) was investigated. Steady state sensitivity analyses revealed the influence of changes in process variables in the purity of the products. Furthermore, a first insight of the transient behavior in open loop mode of a two dividing–wall column system presented. The results of this contribution serve as a promising basis for the development of control concepts in dividing-wall column systems.

Abstract

Recently, how to design reacting systems that are inherently safer is a problem of common interest. Clearly, instability limits the degree of inherent safety of a reacting system, but so far much more attention has been paid to the analysis of the multiplicity features of reacting systems while only a little works has been reported on the stability analysis of reacting systems under open-loop conditions. This paper presents a singularity theory based stability analysis method that could characterize regions in parameter space over which different kinds of stability characteristics may exist. Thus, the stability characteristics of different scenarios could be quickly identified under the open-loop condition, based on which the inherently safer operational space could be located at the conceptual design stage. A case is studied to demonstrate the effectiveness of the proposed method.
Keywords: Steady state solutions; Stability analysis; Singularity points

1. Introduction

As modern chemical plants are becoming more complex and bigger in scale, the associated chance of things going wrong is also increasing rapidly. Due to the flammable, explosive, toxic and corrosive nature of chemical process, any single accident may trigger a major catastrophe that brings tremendous environmental, social and economical loss. For insurance of running chemical process safely, how to design reacting systems that are inherently safer--with the focus on disturbances having the potential for hazardous responses--is a problem of common interest.

As we all know, chemical process are strongly non-linear systems [1, 2], usually there are multiple steady state solutions [3-8]. Much attention has been paid to these solutions. Uppal [9] studied the dynamic behavior of continuous stirred tank reactors, Balakotaiah [10], YUAN Qi-peng [11], Xu [12] using bifurcation Theoretical Analysis the multiple steady state solution of reactors, Razon [13, 14] reviewed multiplicities and instabilities in chemically reacting systems, Seider [1, 15, 16] also studied multiple steady-state solutions of reactors. Some of these solutions are instable.

Clearly, instability limits the degree of inherent safety of a reacting system, but so far much more attention has been paid to the analysis of the multiplicity features of reacting systems while only a little works has been reported on the stability analysis of reacting systems under open-loop conditions. This paper presents a singularity theory based stability analysis method that could characterize regions in parameter space over which different kinds of stability characteristics may exist. Thus, the stability characteristics of different scenarios could be quickly identified under the open-loop condition, based on

which the inherently safer operational space could be located at the conceptual design stage.

2. Algorithm

The method is described as follows. First of all, the homotopy-continuation method which is effective in achieving global convergence is applied to get the all steady state solutions of a reacting system in its parameter space. Then, the singularity theory is introduced to analyze these steady state solutions and to identify their stability characteristics. The stability characteristics of the reacting system will change along with the system's parameter variation. So it is important to identify singularity points where the change of a reacting system's stability characteristics occurs. As a result, the parameter space can be divided into several subspaces over which different characteristics in terms of stability exist.

Assume the chemical process $\frac{dX}{dt} = F(X,\lambda)$, where X is the state variables, $X \in R^n$, λ is the parameter. $F_X(X,\lambda)$ is the Jacobian matrix of $F(X,\lambda)$. X_0 is the solution of $F_X(X,\lambda)=0$ when $\lambda=\lambda_0$. The stability of system is determined by the eigenvalues of Jacobian matrix, if all eigenvalues are in left panel the system is stable, otherwise the system is instable.

The algorithm is described as follows:

1. Computing all steady state solutions of chemical systems.

Computing the solutions of $F_X(X,\lambda)=0$ under different values of λ.

2. Computing singular values of chemical systems' Jacobian matrix.

Computing the rank of matrix $F_X(X,\lambda)$ under certain λ and the related solution of X. If $r(F_X)=n-1$, the λ and related X are singularity point. The stability of system would change a lot between two sides of the singularity point. Record the singularity point (X_s,λ_s).

3. Determine the stability status at two sides of the singularity points.

Get one point at each side of singularity point in solution curve, computing all eigenvalues of $F_X(X,\lambda)$, if all the eigenvalues are at left panel, the system at the operation point is stable, otherwise the system is instable. The stability status is continuous, often changed pass through the singularity points. In this way only few points are calculated to determine the stability status.

4. Repeat the above process to calculate all the singular points and determine the stability of singular points on both sides.

There are 3 kinds of subspaces: the stable subspace, the unstable subspace and the mixed subspace. Within the stable subspace the system will run smoothly still, even if some variable disturbance is encountered, within the unstable subspace the system may change a lot or run away even under very little disturbance. This subspace is dangerous, so effort should be made at the conceptual design of a reacting system to avoid selecting process operating region in this subspace. The mixed subspace is the one within that the system may change a lot or not change at all when disturbance occurs. This situation is also should be avoided in order to guarantee the designed reacting system is an inherently safer one. Thus, the elimination of instability could be achieved through changes in the operating conditions, such as the inlet changes involving feed concentration and/or the cooling water temperatures.

3. Example

In this example, an anaerobic fermentor is designed for high product quality. A continuous culture of K. pneumoniae is grown on glycerol. The fermentation products

are ethanol, acetic acid, and 1,3-propanediol, with 1,3-propanediol being the main product.[15, 17]

$$\frac{dX}{dt} = X(\mu - D)$$

$$\frac{dC_s}{dt} = D(C_{s0} - C_s) - Xq_s$$

$$\frac{dC_p}{dt} = Xq_p - DC_p$$

Where

$$\mu = \mu_{\max}\frac{C_s}{C_s + K_s}\left(1 - \frac{C_s}{C_s^*}\right)\left(1 - \frac{C_p}{C_p^*}\right)$$

$$q_s = m_s + \frac{\mu}{Y_s^m} + \Delta q_s^m \frac{C_s}{C_s + K_s^*}$$

$$q_p = m_p + Y_p^m \mu + \Delta q_p^m \frac{C_s}{C_s + K_p^*}$$

Here X is the biomass concentration, C_s is the substrate concentration in reactor, C_{s0} is the substrate concentration in feed medium, C_p is the product concentration, D is the dilution rate.

For Convince, the dimensionless model as follows.

$$\frac{dx}{d\tau} = x(u - d)$$

$$\frac{dy}{d\tau} = d(y_o - y) - x\phi_1(\beta_1 + \gamma_1 u + \frac{y}{y + \alpha_1})$$

$$\frac{dz}{d\tau} = x\phi_2(\beta_2 + \gamma_2 u + \frac{y}{y + \alpha_2}) - zd$$

$$u = \frac{y}{y + \alpha_3}(1 - y)(1 - z)$$

Here x is the dimensionless biomass concentration, y is the dimensionless biomass concentration in reactor, z is the dimensionless product concentration, d is the dimensionless dilution rate and y_0 is the dimensionless biomass concentration in feed medium.

When $d=0.2$ $d$imensionless product concentration z various with y_0. Figure 1 shows the result, there two singularity in the system, marked as LP.

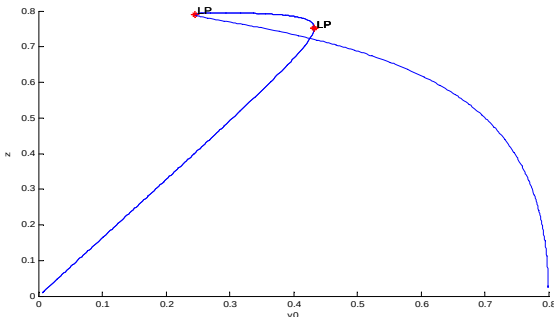

Fig 1. when d=0.2 the dimensionless product concentration varies with dimensionless biomass concentration in feed medium

Calculate the Jacobian matrix to determine the stable status. As we know there are there eigenvalues of Jacobian matrix in this reactor. Here we focus on the value of eigenvalue varies with the dimensionless biomass concentration in feed medium.

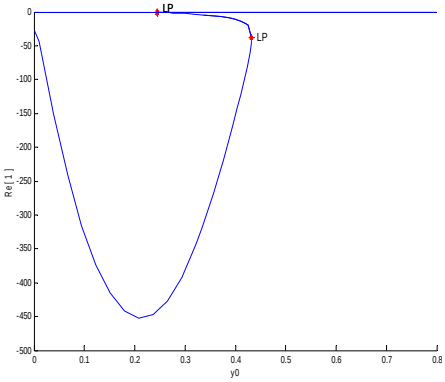

Fig 2. the first eigenvalue's real part's curve

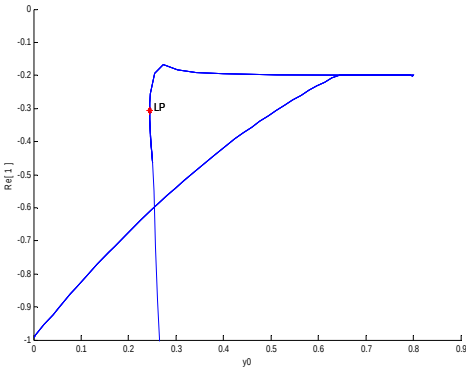

Fig 3. the first eigenvalue's real part's curve (partly)

Fig 2 and Fig 3 show that the first eigenvalue's real part is always below zero, so the stability status is determined by the other eigenvalues.

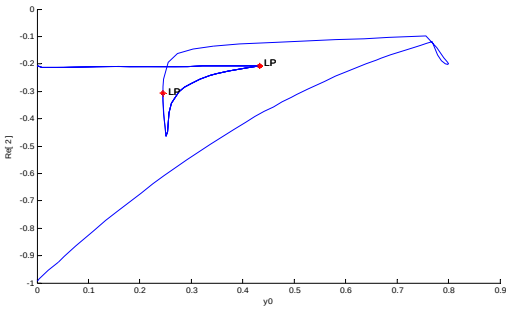

Fig 4. the second eigenvalue's real part's curve

Fig 4 shows that the second eigenvalue's real part is also always below zero.

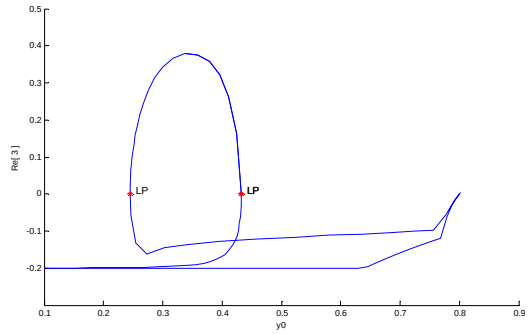

Fig 5. the third eigenvalue's real part's curve

Fig 5 shows that the third eigenvalue's real part changes pass zero just at the singularity points, where system's stability status changed a lot.

According to the character of stability, the stability of system in Fig 1 is showed as Fig 6. There are three areas, two of them are stable and one of them is unstable.

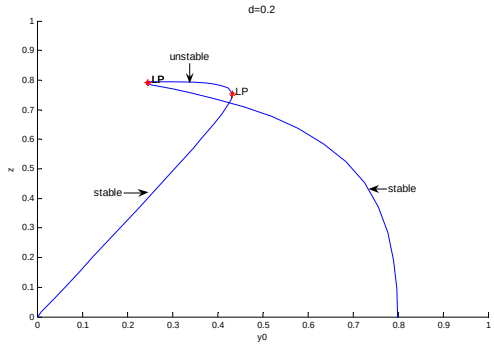

Fig 6. the different stable areas separated by singularity points

The results are showed in Fig 7-10 when d changes. Singularity points are marked as LP. The dimensionless dilution rate varies from 0.3 to 0.6, the systems stability status varies. There are three different stability statuses in each scenario. It is a convenient method that using singularity point theory to determine the system's stability status.

4. Conclusion

The proposed singularity theory based stability analysis method provides a guidance on how to make a change of the operating conditions so that to achieve an elimination of instability. Also, this method reduces a lot of works for the identification of the stability characteristics of a reacting system to compare with the existing approaches. In this paper, a case is shown to illustrate the effectiveness of the proposed method.

Abstract

In this work, a novel systematic approach to achieve an efficient mechanistic modeling and simulation of fed-batch fermentations is presented. In order to show the efficiency of the developed simulation framework, data of *Escherichia coli* fed-batch fermentations are used. Fermentation processes are characterized by its dynamic behavior described by parameters such as growth rate, substrate concentration and cellular metabolic activity. Although there are models able to describe individual fed-batch fermentations, they become unreliable when fitted to new fermentations. To overcome this drawback, in this work different models are used at different optimal time points enabling not only a better description of the process, but also a better understanding of non measurable characteristics. By these means, three models compete in different intervals of the process. The candidate models are: an Overflow metabolism model (OF), a Citric Acid Cycle model (CAC) and a Survival or Maintenance model (M). Using an adequate model sequence, acetate formation, substrate consumption and cell growth are predicted with high accuracy. Moreover, the data needed to fit the models are reduced and a standardization of the model to be applied in different process states is enabled. Besides, with the development of a robust and effective model, the possibility of an online implementation for monitoring and control of the fermentation is exhibited. The results show that an efficient process monitoring based on the Dissolved Oxygen Tension and the Mechanistic Recognition is only limited by the convergence velocity of the algorithm.

Keywords: Mechanistic Recognition, Model Discrimination, *Escherichia coli*, Fed-Batch Fermentation.

1. Introduction

1.1. Process simulation and control in biologic systems

The importance of real-time measurement and parameters determination in bioreactor processes is rapidly increasing. Adapted regulatory guidelines encourage the biotechnological industry to apply innovative process development, manufacturing technology, and quality system approaches (fda.gov). The purpose is to accomplish a quality control based on the process instead of the product by means of Process

Analytical Technology (PAT) (Pillai 2005). This enhances the benefits of an accurate process description through simulation.
It is well known that mechanistic (rigorous or first principle) models offer a number of advantages over "black-box" modeling e.g. a higher process comprehension and a more accurate scale-up capability. By this means, rigorous models provide the basis needed for an efficient quality control based on the process. Nevertheless, the simulation of dynamic processes based on rigorous modeling is confronted with an important problem. Due to the physical foundation of the model, the choice of the mechanistic model to be used for the simulation is based on the dominant physical phenomena of the process. These phenomena, which dictate the process behavior, change over the process run. Hence, the appropriate approach would be to simulate the process with various models changing over time based on how and when these phenomena change. Most of these processes can be simulated effectively for short time periods but not for the complete process.

1.2. Mechanistic recognition in biologic systems

Every cell is adapted to different conditions which give them an advantage on the competition against other organisms. Factors like temperature, pH, salinity, dissolved oxygen (for aerobes), substrate availability and coexistence with other organisms are major aspects for bacteria survival. Models proposing to explain biological systems depend on many parameters, which have to be determined each time the system passes slight variations. E. *coli* fermentations are a significant example. The preculture conditions have an enormous influence on the behavior of devolution of cultivation parameters. This leads to models that are usually over-parameterized and have to be fitted with heuristic approaches. Instead, a number of simpler models, which can only predict specific stages of the process, can be applied. By this means it is possible to reduce the number of parameters, increase model flexibility and model validity with less experimental information. Further development could present important support to the theory of Nonlinear State Observer (Soroush 1997). A reliable mechanistic recognition will also allow process monitoring of non-measurable variables through the determination of the prevailing physical phenomenon. The simplicity of the models applied, the robustness and a better evaluation of the changing states of the process through are potential contributions of the mechanism recognition to the control of dynamic systems..
Many indirect methods have been studied with respect to the determination of cell activity and product concentration in fermentation processes. Some examples are dissolved oxygen tension (dot) (Whiffin 2004), on-line high performance liquid chromatography (*on-line* HPLC) (Turner 1994) and *at-line* and *in-situ* near-infrared spectroscopy (NIR) (Arnold 2002). The proposed mechanistic recognition has an advantage over them, because it evaluates the run of the curve instead of the data points separately. In other words, it enables the accumulation of more information without increasing the recollected data.

1.3. Principle of mechanistic recognition

The mechanistic recognition is an effort to overcome the problems confronted when modeling dynamic systems. In a previous work, a first attempt towards mechanism identification was proposed for a heterogeneous catalytic reaction (Schöneberger, Arellano-Garcia et al. 2006). A similar concept was published by Keneth D. Forbus (Forbus 1984). Forbus proposes the Qualitative Process theory (QP), a model discrimination based on qualitative information. A disadvantage of this method is the implementation of quantitative analysis. Most of the processes can not be described

with such simple concepts as positive-negative slope or open-closed valve. Neither semi-quantitative programing can be applied in most cases. A common problem is that quantitative variables or changing parameters can not be measured neither directly nor indirectly with the precision needed, e.g. catalyst fouling or bacterial stress.
In this work, the proposed approach substitutes the qualitative concept of QP theory with a quantitative model discrimination as used in the Optimal Experiment Design (OED) (Box and Hill 1967) in order to select the appropriate model. OED is a statistical method used to reduce the costs of experimental work needed so as to select the model which best describes the investigated topic. An analysis of the correlations and variances of the model parameters determines how many experiments have to be realized, and which inputs and initial conditions will provide the most information (Bauer, Bock et al. 2000).

2. Simulation of E. *coli* Fed-Batch Fermentations

2.1. Application

In this work, the mechanistic recognition approach is applied to the model developed by Lin *et al* based on a dynamic maximal uptake rate of glucose and oxygen. This model successfully described the process run of ten fed-batch fermentations of *E. coli* by considering that both, the glucose and oxygen uptake, depend on the growth rate. Nevertheless, the model contains an excess of parameters and is very difficult to fit without using heuristic rules as well as an important quantity of experimental data.
The model prediction relies on the coordination of three sub-models (reduced models): an overflow metabolism (OF) at substrate excess where the intermediate acetate is accumulated and the process is limited by the oxygen uptake; a citric cycle metabolism (CAC) where the process is limited by the substrate uptake; and a survival stage (M), at which the cell employs all the substrate and acetate available to survive. A sensitivity study verifies that the model is highly unstable (data not shown). Minor changes in the parameters hinder the ODE-Solvers to converge. The reason for this instability is that the intervals, where each submodel is active: Overflow, Citric Acid Cycle and Survival, is drastically affected by changes in the parameters. This produces discrete changes during the numerical integration. When these changes exceed a certain value, the ODE-Solver is not able to continue with the integration.
This example is perfectly suited for the application of the mechanistic recognition. First, the general model is divided into three simplified ones, based on the sub-models obtained from Lin *et al*. Then a model discrimination is performed in each interval throughout the process. Finally, it is determined which model fits which interval with the highest accuracy and is applied.

2.2. Material and Methods

All the information regarding the experimental procedure can be obtained from (Lin, Mathiszik *et al*. 2001). The original model written in SciLab was implemented into Matlab 7.7.0. The routine of SNOPT with the help of the TomLab interface was applied to estimate the parameters with a sequential optimization.
The parameters considered for the model fit are:

K_A:	Saturation constant for acetate [g/L]
K_La:	volumetric oxygen transfer coefficient [1/h]
K_s q:	Saturation constant for substrate uptake [g/L]
q_Esd, q_Eod:	specific death rates for the uptake enzymes of substrate and oxygen respectively [g/(gL)]

q_Smax:	Maximal specific substrate uptake rate [g/(gh)]
q_Omax:	Maximal specific oxygen uptake rate [g/(gh)]
Y_EOX,Y_ESX:	Yield of the enzyme for substrate uptake and respiration from the biomass growth, respectively [-]
Y_XA:	Yield of the enzyme for acetate from the biomass growth [-]
Y_XSof Y_XSox:	Yield of the enzyme for overflow and oxidative energy production from the biomass growth, respectively [-]

The solution strategy to generate the model sequence is briefly described in fig.1.

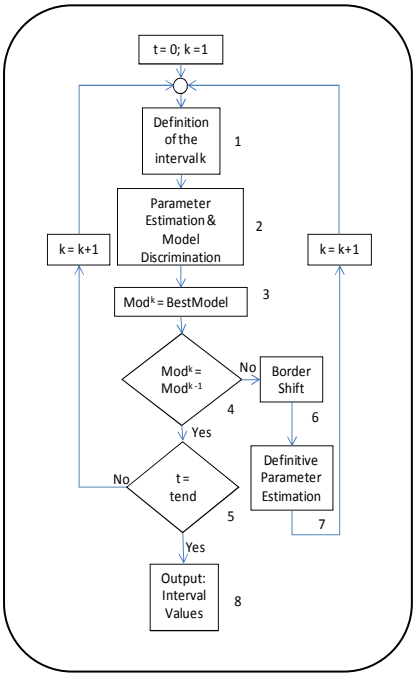

Figure 1: Flow chart of the algorithm for mechanism recognition

1. Definition of the interval k (between bounds k-1 and k). The length of the interval depends on the differentiability and identifiability of the process as well as the models considered (Franceschini and Macchietto 2007). All the mechanistic models, which are proposed for the process, are taken into account and analyzed.
2. A model discrimination is carried out. The parameters of each model are estimated and the models are compared in order to detect the model that best fits the process in the present interval.
3. The model selected by the model discrimination as the "best" model is applied to the interval.
4. If the "best" model of the interval k corresponds to the "best" model of the interval k-1 $Mod^{k-1}=Mod^{k}$, then the bound is considered to be an "invalid" bound and the algorithmproceeds to step 5. Invalid bounds are bounds located between intervals where the "best" model is the same. This means no change on the process behaviour is to be seen. Otherwise, if $Mod^{k-1}\neq Mod^{k}$, the bound is considered to be a representative bound (RB) and its exact location is searched in step 6.
5. If the interval k is the last interval of the process and the final point t = tend is reached, the program proceeds to step 8. Otherwise k is set to k+1 and the loop is restarted.
6. The representative bound (RB) is shifted step by step throughout the time interval between the bounds k-1 and k. The model k-1 is applied between k-1 and RB. The best model k is applied between RB and k. The Maximum Likelihood (MXL) is calculated in every new location of the RB. Finally the position of RB which shows the smaller MXL is set as the final location of the bound and though as the location where the model-switch takes place.
7. A final parameter estimation of the active model, between the new representative bounds and the last representative bound registered, is calculated to determine the definitive value of the parameters.

8. The program terminates the loop and prints a report with the representative bounds, the active model in each interval and the corresponding parameters estimated in each interval.

An example should illustrate the concept of the mechanistic recognition. In this example, a fictitious experimental data is simulated. Three equations are used during the process at different intervals. Each equation is considered to be a mechanistic model describing a certain phenomenon in the process under study.

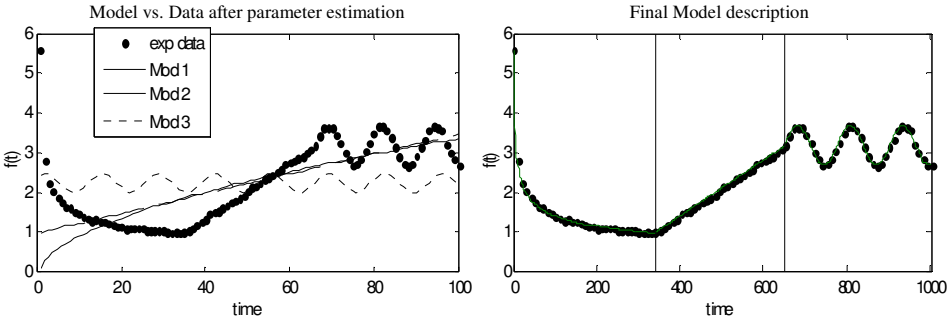

Figure2: *left:* Simulated "Sample Data" and prediction of the three models after a parameter estimation. *Right:* the mechanistic recognition enables a better prediction of the process as well as a deeper understanding.

The responses of the three different models (equations 1, 2 and 3) after parameter estimation are compared in fig.2 left). As it can be seen, none of the models is able to describe the process. A conventional model discrimination would discard all models and no solution for the simulation of this process would be found. This result is actually correct, though none of these three models is able to describe the complete process.
Nevertheless, without any further change on the models, a smart combination of them is able to reproduce the experimental data perfectly, as it can be seen in fig.2 right). In addition the time periods, where each phenomenon occurs, are detected.

3. Results

The following model sequence was detected by the mechanistic recognition: OF, CAC, OF, M fig.3.

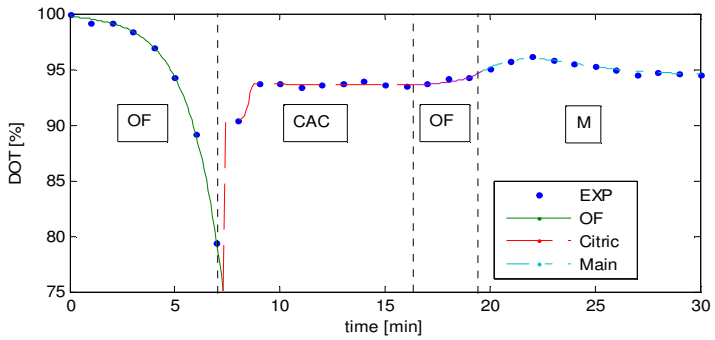

Figure 3: Validation of the data simulated with mechanistic recognition. The experimental results of the dissolved oxygen tension (dot) and the simulation results obtained with mechanistic recognition are compared.

The result was compared with the original model. It shows an acceptable similarity in the outputs. The first advantage is that the model sequence allows fitting to different data sets automatically and a reduction on the number of parameters to be fitted simultaneously. Second, an indicator of the current cell state is obtained. The mechanistic recognition is able to report whether the metabolism is dominated by overflow (acetate production), conversion of metabolits in the citric acid cycle or by maintenance. Finally, the new model sequence can be fitted with less experimental data. One measured variable, the dot, leads to a satisfying model fit. This suggests the possibility to adopt the mechanistic recognition technique to monitor and control the fed batch fermentation of *E. coli* based on the model developed by Lin *et al*.

4. Conclusions

The proposed approach to mechanistic recognition proved to be able to transform the model originally proposed by Lin *et al* 2001 into one suitable for parameter estimation and *on-line* applications. This was achieved by dividing the original model in three simpler ones and applying them in the precise process interval. The evidence provided in this project suggests a robust and efficient model sequence which can be applied in different fermentations and can also be effectively fitted.

A sophistication of the model through the evaluation of the "model health", based on the analysis of the parameter changes and its position with respect to the parameter bounds, should allow further information recollection as predicting a change in the bacteria state with anticipation, and speed up the interval shift procedure. In order to enable the application of the mechanistic recognition as an *on-line* tool, a compromise between conversion velocity, robustness and accuracy must be evaluated.

Abstract

This study proposes an analysis of biomass gasification using two mathematical models: one equilibrium model and one kinetic model based on the level of details and input data. After validation with data from literature, the models were applied for analysis of a combined gasifier-combustor unit for processing of solid wastes (biomass) of footwear industries. The gas product predicted by the models was indirectly validated with experimental data. For this, the adiabatic flame temperature estimated from the gas product was confronted to experimental temperature of the combustor unit, showing the accuracy of each model. Sensitivity analyses of the models were carried out regarding to the feed air flow rate. The responses to parametric changes were observed in major output parameters: low heating value (LHV) of gas product, and cold gas efficiency, which are important measures to quantify the performance of the system.

Keywords: biomass gasification, combined gasifier-combustor unit, equilibrium model, kinetic model.

1. Introduction

An alternative destination to solid wastes in general is the thermal treatment technologies. By this is possible to reduce filled volume and to stabilize dangerous components. One of these technologies is the gasification which generates a useful gas fraction under moderate conditions. According to Higman and van der Burgt [1], the gasification is a thermochemical process of conversion of any carbonaceous fuel to gaseous product with a useable heating value. As a result it can be to use like fuel gas or syngas to after using.

This study proposes an analysis of biomass gasification through mathematical modeling. However it is well-known that practical data (geometric measures, identification of intermediary compounds, etc.) are oftentimes available on high or low detailed levels to satisfactory process simulation. In this sense, two mathematical models are presented: one equilibrium model and one kinetic model based on the level of details and input data. After validation with data from literature, the models were applied for analysis of a pilot combined gasifier-combustor unit for processing of solid

wastes (biomass) of footwear industries. As a renewable resource, the processing of that abundant biomass is enclosed inside the natural carbon cycle unlike fossil-derived resources such as oil and coal.

2. Modeling of the process

Biomass gasification models are predominantly separated in two groups: equilibrium approach and kinetic approach [2]. Kinetic models take into account the chemical kinetics of the main reactions and the transfer phenomena among the phases, estimating the composition of each species on any point of space and time of a system. These models are specific in general for each process, providing important considerations related to chemical mechanisms and ways to increase reaction rates and process performance. On the other hand, equilibrium models provide the greatest possible conversion of each species regardless the system size and the time needed to reach equilibrium. These models do not require details of system geometry neither estimate the necessary time to reach that equilibrium.

2.1. Equilibrium model

Among the equilibrium modeling, two approaches can be cited: stoichiometric and non-stoichiometric [2]. Although equivalent in essence, the stoichiometric approach applies the equilibrium constants from related chemical reactions [3-4], while the non-stoichiometric approach minimizes the Gibbs free energy subject to mass balance and non-negative constraints [2, 5].

A stoichiometric model was developed in this work, assuming as major hypotheses: all carbon of biomass is gasified, making char formation negligible; the system is adiabatic and isobaric; and all oxygen is consumed on the process. In Table 1, the main equations of the equilibrium model are depicted.

Table 1. Main equations of the equilibrium model.

Overall mass balance:	Equilibrium constant of reaction *j*:
$F_{in}\sum_{in} n_{k,i}x_i = F_{out}\sum_{out} n_{k,i}x_i$ (1)	$K_j = \prod_i (P_i/P_o)^{\nu_{i,j}}$ (3)
where $n_{k,i}$ is the number of atoms k of a molecule i, and x_i is the molar fraction of a component i.	which is related to temperature by:
Overall energy balance:	$-RT\ln K_j = \Delta G_j^o$ (4)
$F_{in}\sum_{in} x_i H_i(T_{in}, P) = F_{out}\sum_{out} x_i H_i(T_{out}, P)$ (2)	where ΔG_j^o is the variation of standard Gibbs free energy of reaction j as function of temperature.

In this case, two equilibrium reactions are considered: water-gas shift reaction (5) and metanation (6):

$$CO + H_2O \leftrightarrow CO_2 + H_2 \quad (5)$$

$$C + 2H_2 \leftrightarrow CH_4 \quad (6)$$

By means of the energy balance is possible to estimate the final temperature for a specific kind of biomass and fraction of air stream. As a result, the flue gas composition is estimated as function of temperature.

2.2. Kinetic model

The important features of the kinetic model are the chemical kinetic approach and transfer phenomena relations. In this sense, in literature, only few models were found for concurrent biomass gasification [6-7]. The proposed model is based on mass and

energy balances for solid- and gas-phases, described by a dynamic system and one-dimensional equations, and involving the following components: *B* (biomass), *M* (moisture), and *C* (char), for solid-phase and *T* (tar), O_2, CO_2, H_2, H_2O (steam), CH_4, CO, and N_2, for gas-phase. The following processes are considered in the model: moisture evaporation (m), biomass pyrolysis (p_1), thermal cracking of the tars (p_2), combustion of the volatiles (c_1-c_4), and char combustion and gasification (c_5, g_1-g_3).
The main model assumptions are: single size of the particles; no momentum transfer; constant bed porosity; heat and mass transfer across the bed resulting from macroscopic (convection) and molecular (diffusion and conduction) exchanges; extra-particle mass transfer resistance; and solid- and gas-phase heat transfer with the reactor walls. In Table 2, the main equations of the kinetic model are depicted.

Table 2. Main equations of the kinetic model.

Mass balance for solid-phase:

$$\frac{\partial \rho_i}{\partial t} + \frac{\partial (\rho_i U_s)}{\partial z} = \sum_j \nu_{i,j} R_j \quad (7)$$

where i = *B*, *M*, *C*; $j = m, p_1$.
Overall mass balance for solid-phase:

$$\rho_s \frac{\partial U_s}{\partial z} = \sum_i \sum_j \nu_{i,j} R_j \quad (8)$$

where i = *B*, *M*, *C*; $j = m, p_1, c_5, g_1$-g_3.
Mass balance for gas-phase:

$$\varepsilon \frac{\partial \rho_i}{\partial t} + \frac{\partial (\rho_i U_g)}{\partial z} = \frac{\partial}{\partial z}\left(D_i \rho_g \frac{\partial x_i}{\partial z}\right) + Mw_i \sum_j \nu_{i,j} R_j + \omega_i \quad (9)$$

where i = *T*, O_2, CO_2, H_2, H_2O, CH_4, CO; $j = c_1$-c_5, g_1-g_3, wg, and ω_i is the rate of species i generated in solid-phase.
Overall mass balance for gas-phase:

$$\varepsilon \frac{\partial \rho_g}{\partial t} + \frac{\partial (\rho_g U_g)}{\partial z} = \sum_i \sum_j \nu_{i,j} Mw_i R_j + (1 - \nu_{C,p1}) R_{p1} + \sum_i \nu_{i,p2} R_{p2} \quad (10)$$

where i = *T*, O_2, CO_2, H_2, H_2O, CH_4, CO, N_2 and $j = m$, c_1-c_5, g_1-g_3, wg.
Energy balance for solid-phase:

$$\frac{\partial (\rho_s H_s)}{\partial t} = \frac{\partial}{\partial z}\left(\lambda_s^* \frac{\partial T_s}{\partial z}\right) + \frac{\partial (U_s \rho_s H_s)}{\partial z} - \sum_j R_j \Delta H_j - Q_{sg} - Q_{sw} \quad (11)$$

where $j = c_5$, g_1-g_3, p_1; Q_{sg} is the heat exchange between solid- and gas-phase; and Q_{sw} is the heat exchange between solid-phase and walls.
Energy balance for gas-phase:

$$\varepsilon \frac{\partial (\rho_g H_g)}{\partial t} = \frac{\partial}{\partial z}\left(\lambda_g^* \frac{\partial T_g}{\partial z}\right) + \frac{\partial (U_g \rho_g H_g)}{\partial z} - \sum_j R_j \Delta H_j + Q_{sg} - Q_{gw} \quad (12)$$

where $j = c_1$-c_4, wg, p_2; and Q_{gw} is the heat exchange between gas-phase and walls.
Pressure drop (modified Darcy law):

$$\frac{K}{\mu} \frac{\partial P}{\partial z} = U_s - U_g \quad (13)$$

where *K* is the permeability to gas flow.

The coefficients of heat and mass transfer are calculated according to Hobbs, Radulovic and Smoot [8]. The gas thermal conductivity and viscosity are described as in Purnomo, Aerts and Ragland [9]. The specific heats (available at 1000 K) and diffusivity are considered constants.

2.3. Implementation and validation of the models

The models were implemented in the equation-based process simulator EMSO (Environment for Modeling, Simulation and Optimization [10]). The validation of the equilibrium model was made in two steps: (1) comparing equilibrium constants of considered reactions with tabulated and predicted data from Sharma [4]; (2) comparing composition of gaseous product with experimental and predicted data from Melgar *et al.* [3]. For the kinetic model, it was validated by predictions of Di Blasi's [6] model.

3. Application to a combined gasifier-combustor unit

3.1. Description of the pilot unit

The pilot unit (Fig. 1) is basically formed by one combined gasifier-combustor and one air pollution control system. The gasifier is a downdraft type so that feedstock is

concurrent to gas flow. There are two incoming air points along gasifier height. Other three air injections are fed in the combustor to oxidize the fuel gas coming from the gasifier.

The input solid wastes are leather strips with ultimate analysis of 49.31%C, 8.52%H, 24.7%O, 12.42%N, and 1.83%S, and a HHV of 18,448 kJ/kg (d.b.). And their proximate analysis afford 77.3% volatile matter, 5.8% ash, and 16.9% carbon fixed (as received with 14.1% moisture content) [11]. A specific parameter related to this waste is the mass relation of O_2 to complete oxidation of biomass: 1.57 kg_{O2}/kg_B. The gasifier is a reactor of 1.465 m height and 0.611 m equivalent diameter, where the bed density is 400 kg/m^3 and the void fraction is 0.5. A typical operation involves 60 kg/h feedstock that is gasified by two air injection at 300 K of 102.4 Nm^3/h and 55.7 Nm^3/h, respectively. The acquisition of experimental data is made by 5 thermocouples (T1, T2, T11, T12, and T13) along the gasifier and 1 thermocouple (T5) in the final of the combustion chamber.

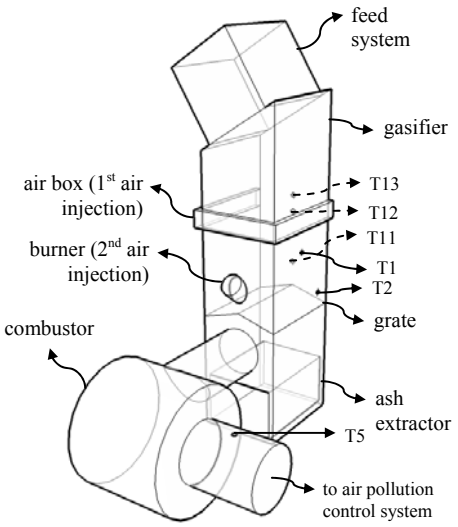

Figure 1. Combined gasifier-combustor unit.

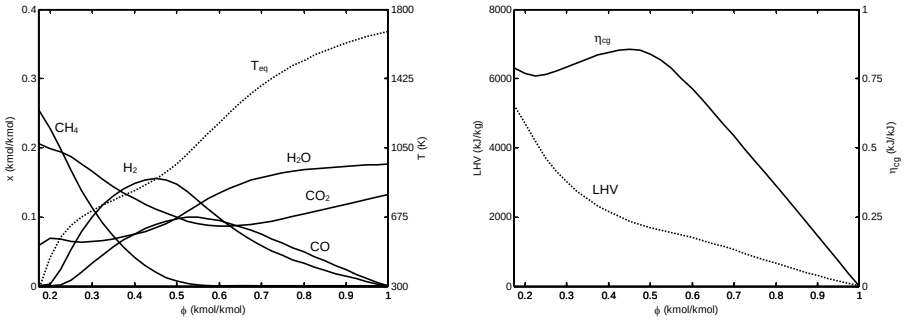
3.2. Simulation of the pilot unit

Sensitivity analyses of the process were carried out regarding to the feed air flow rate as an operating parameter. The responses to parametric changes were observed in output parameters: low heating value (LHV) of the energetic gas product (CO, H_2, and CH_4) and cold gas efficiency (η_{cg}), according to the equilibrium model. These output parameters are important to quantify the performance of the process. In this study, the feed air flow rate is related to the feedstock by a parameter called equivalence ratio (ϕ), which indicates the oxygen used relative to that required for complete combustion.

The predictions of the equilibrium model for typical operating conditions from measured and predicted data by Godinho [11] have shown good accuracy. Divergences could be justified by assuming an adiabatic system. Figure 2a shows the molar fractions of gaseous products, beyond adiabatic reaction temperature, related to the feeding air amount (equivalence ratio). Taking into account only components of energetic gaseous product, it is possible to observe that CH_4 increases with low equivalence ratios (ϕ<0.5) and CO and H_2 is maximum within $0.3 < \phi < 0.7$. The equilibrium temperature is minimum (T = 300 K, ambient temperature) at ϕ = 0.175 and maximum (T = 1680 K) at ϕ = 1, where CO_2 and H_2O (inconvenient to the process) are maximum and CO, CH_4, and H_2 are negligible. Cold gas efficiency (η_{cg}) and low heating value (LHV) to flue gas, related to conditions of Fig. 2a are shown in Fig. 2b. The maximum efficiency (85.5%) is reached at ϕ = 0.45. Therefore the optimal range for gasification of leather strips is $0.34 < \phi < 0.53$ (±5% maximum efficiency range).

The predicted gas composition at average conditions was also compared to experimental data, indirectly. It is possible to relate the measured temperatures in the reduction zone of the gasifier (T11) and the combustion chamber (T5) estimating the gaseous product at measured average temperature (906 K, ϕ = 0.467) and, from this fraction, the

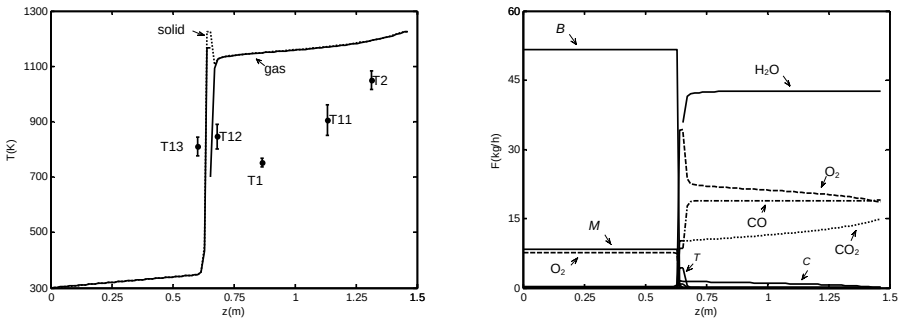
adiabatic flame temperature at a range of feeding O_2. At the last step of combustion, there is an average amount of 11% O_2 (v/v, d.b.) in excess [11] which corresponds to an adiabatic flame temperature of 1174 K. This value is close to the average value measured in T5: 1133 K.



(a) (b)

Figure 2. Properties to $0.175 < \phi < 1$ by the equilibrium model: (a) Gaseous product and adiabatic reaction temperature. (b) Cold gas efficiency and low heating value to energetic gaseous product.

Likewise, the same conditions of the process were simulated using the kinetic model at steady-state. In this case, the reactor was divided in three sections defined by the top-gasifier (0 m), first air injection (0.655 m), second air injection (1.315 m), and bottom-gasifier (1.465 m). The results present here were applied to the first two sections. In Fig. 3a, the predicted profiles have qualitative agreement with respect to experimental data.



(a) (b)

Figure 3. Results of kinetic model: (a) Temperature profiles of solid- and gas-phase, and measured data. (b) Mass flow rate of solid- and gas-phase species along gasifier before second air injection.

The inflection point in 0.655 m means the cold feeding air mixed to the preceding hot gas stream from first section. In Fig. 3b, the fast consumption of O_2 and formation of H_2O close to the air injection are observed. After that point, all small amounts of volatile materials are quickly consumed and, as result, there is an excess of O_2 to oxidize. For solid-phase (Fig. 3b), despite the fast conversion of biomass, small amounts of char are created. The inconsistencies associated to low release of volatiles and low formation of char are justified by the quality of kinetic parameters for pyrolysis reactions (p_1-p_2) adapted from literature data to leather wastes [12-13]. The uncertainties in the heat transfer coefficients also have significant role in the results. Another important factor to take into account, not observed in literature [6-7], is the reflux of air in two directions for one-dimensional representation by injecting air in intermediate

heights. In this case, the model considers that first feeding air (102.4 Nm^3/h) is portioned between the top (25%) and the first air injection point (75%).

4. Conclusion

The proposed models, equilibrium and kinetic, presented compatible results compared with literature data. The equilibrium model reached good accuracy to predict the steady-state behavior of the gasifier. With this approach it was possible to identify an optimum range of operation within $0.34 < \phi < 0.53$ and to confront measured temperature from the combustor with predicted data from the gasifier. Besides, due to poor quality of kinetic parameters and heat transfer coefficients, which are not full available for the specific case, the kinetic model could only predict qualitative steady-state behavior of the gasifier. Also, the representation of a three-dimensional system into one-dimensional model has limited prediction capability.

Tool for Optimizing the Design and Operation of Reverse Electro-Enhanced Dialysis of Monoprotic Carboxylic Acids

Oscar A. Prado-Rubio, Sten B. Jørgensen, Gunnar E. Jonsson

CAPEC, Depertment of Chemical and Biochemical Engineering, Technical University of Denmark, DK-2800 Lyngby, Denmark

Abstract

A dynamic model is derived to describe the simultaneous transport of multiple ions through anion exchange membranes and Nernst diffusion layers in a cell of the Reverse Electro-Enhanced Dialysis (REED) module. The model is based on first principles for dissociation, diffusion, convection and migration of species commonly found in a fermentation broth. The approach leads a system of multiregion partial differential equations that are solved numerically. The developed tool provides insight into the transport phenomena in the electrochemical system when it is operated with or without imposing an electrical field. Potentially, it can be applied to optimize the design and the operation of the REED module for different production scenarios.

***Keywords**: Reverse Electro-Enhanced Dialysis (REED), Donnan dialysis (DD), lactate recovery, ions transport modelling.*

1. Introduction

The removal of carboxylic acids from diluted solutions has been a complex separation problem. Presently, economical and sustainability issues are the driving competitive forces behind improving process design and operation. Particularly, improvements in sustainable production of commodity chemicals, such lactic acid, are desirable. Lactic acid is attractive since it is widely used in industry and recently the most interesting industrial application is as feedstock for the production of Poly-Lactic Acid (PLA). Derivates of PLA are sustainable polymers which have potential to substitute hydrocarbon based polymers in several applications. Even though PLA polymers can not be considered completely biodegradable anymore, it will definitely reduce our dependency on fossil feedstock.

It is well known that the bioproduction of lactic acid by lactic acid bacteria is impaired by lactate inhibition, like many other fermentation processes at a certain concentration level of the product or one of the bi-products. From this point of view, reducing the concentration of the biotoxic lactate in the culture solution will enhance the productivity and product yield, under controlled pH environment. Integrating separation and fermentation will also enable operation at higher cell densities, thereby providing additional enhanced productivity potential.

Since 1960's, membrane separation processes have been suggested as an alternative for lactic acid removal and biomass confinement, their application is well documented. The purpose of this paper is to depict a model which describes the multiple ion transport through anion exchange membranes under current reversal conditions, when the separation is carried out by Reverse Electro-Enhanced Dialysis. This device was

recently designed, its performance suggests it to be a promising alternative for continuous removal of lactic acid during fermentation (Rype, 2003). This paper is organized as follows. In section 2 the system is described and the assumptions are depicted. Afterwards, the model is presented. Section 3 addresses how the model is solved and a brief description of the parameter estimation procedure. In addition, some simulation results of ion transport under current reversal conditions are discussed. Finally, the conclusions are drawn.

2. Modelling Reverse Electro-Enhanced Dialysis

Since electrically driven membrane separation processes have been proposed as an *in situ* alternative for removal of carboxylic acids in 1980's, several problems have been pointed out: membrane fouling due to the biomaterial content of a fermentation broth and the presence of divalent ions generates scaling and, when bipolar membranes are used for a further concentration and recovery of the lactic acid, those ions can impair the membrane (Hongo *et al*., 1986; Rype, 2003).

The REED design and operation minimize the impact for the above mentioned aspects. The REED can be described as a Donnan dialysis (DD) device which is operated as Electrodialysis Reversal (EDR) module. The REED stack is composed by several cells in parallel. A cell consists of two feed channels with one dialysate channel in between, separated by anion exchange membranes (AEM). Using only AEM, scaling and bipolar membrane degradation problems are avoided due to Donnan exclusion. When no currrent is applied, fouling problem is reduced employing high flow velocities and a destabilization mechanism, the last is generated by hydroxyl flux through the membrane in opposite direction of the fouling layer formation. However, the main drawback using no current is the rather low anion flux. REED design emerges as a potential method to enhance the lactate fluxes in conventional Donnan dialysis operation, this is done by imposing an external electrical field. The external potential gradient changes the transport mechanism from counter ion transfer to a competitive ion transport. In addition, the unfavorable fouling influence is reduced further by periodically reversing the current (Rype, 2003).

Even though ion exchange membranes have been used widely in industry, the transport mechanism has not yet been completely understood. Thus, it is desirable to develop reliable models which can provide a better understanding of the transport phenomena in such electrochemical systems. Furthermore, models will enable optimization of the design and operation of the modules.

It is challenging to model this system, since several phenomena must be taken into consideration such as diffusion, the influence of electrical potential, migration effects, ion dissociation degree and membrane water content. A dynamic model in two spatial dimensions is derived from first principles for dissociation, diffusion, convection and migration of the species for a cell of the REED stack, by employing an irreversible thermodynamic approach. The modelled cell is depicted in Fig. 1, the system is divided in regions: three the bulk solutions, two membranes and four boundary layers. The species found in each section are also shown in the figure, for the lactic acid recovery case.

2.1. Model assumptions

Due to the complexity of real REED system, any theoretical analysis is of necessity based on a simplified model of the actual process. The assumptions taken are listed.

- General: electroneutrality condition at any location in the system, current is carried by ions, constant temperature, ideal solution and the process is carried out at sub-limiting current densities. Species included in the model are: carboxylic anion, hydroxyl, sodium, dissociated protein, carboxylic acid and undissociated protein. A protein specie is included to account for the buffer effect commonly found in cultivation solutions.
- Membrane: there are diffusive and electrophoretic transport in the *x*-direction, transport of water by osmosis and electro-osmosis is neglected, there is no transport of uncharged or large molecules through the membrane, equilibrium at membrane surface and constant membrane dimensions.
- Boundary layer: diffusive and electrophoretic transport in the *x*-direction are investigated, convective transport is neglected and the thickness of the boundary layers are constant for a given flow condition.
- Bulk channels: there is convective transport in *y*-direction in the bulk channels and tank is series model is used.

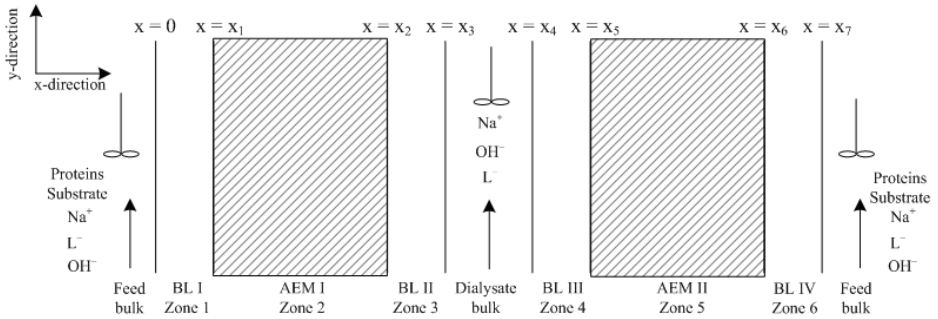

Figure 1: sketch of a cell in the REED module for lactate recovery. BL: boundary layer, AEM: anion exchange membrane, x_j: interface *j*

2.2. Nernst layer and membrane transport

Mass balances are formulated for transport through boundary layers and membranes in *x*-direction. Substances and phases are denoted by the subscripts *k* and *p*, respectively.

$$\frac{\partial C_{k,p}}{\partial t} + \nabla J_{k,p} - \Delta R_{k,p} = 0 \tag{1}$$

The species dissociation and buffer effect are introduced into the model employing the reaction rate term ($\Delta R_{k,p}$). Nernst-Plank equation for ideal solution is used to estimate the fluxes $J_{k,p}$, this equation describes diffusion and migration through the section. The convective transport is neglected in *x*-direction (Strathmann, 2004):

$$J_{k,p} = -D_{k,p}\left(\frac{\partial C_{k,p}}{\partial x} + \frac{z_k F C_{k,p}}{RT}\frac{\partial \psi}{\partial x}\right) \tag{2}$$

Where $D_{k,p}$ is the diffusion coefficient, z_k the valence, F is the Faraday number, R is the ideal gas constant, T is temperature and ψ is the electrical potential. For undissociated species, the terms involving potential gradients are eliminated since the current is exclusively carried by ions. The required first and second derivatives of the potential can be calculated using the assumption that the entire current I_d is carried by ions, substituting the Nernst-Plank equation into Eq. 3 .

$$I_d = \sum_k z_k F J_{k,p} \tag{3}$$

2.3. Bulk channel model

Mass balances are approximated using tanks in series approach in the *y*-direction. Each tank has mass exchange with the adjacent membranes. The dissociation reactions are present as well. The mass balance for each tank in the feed channel is depicted in equation (4), where q is the flow rate and h, L, W are the height, length and width of the channel, respectively. The model for the dialysate channel is completely analogous.

$$\frac{dC_k^{feed}}{dt} = \frac{q_{feed}}{h_{feed} L W}\left(C_k^{feed,in} - C_k^{feed}\right) + \frac{1}{h_{feed}}\left(J_k\big|_{x=x_7} - J_k\big|_{x=x_o}\right) + \Delta R_{k,p} \tag{4}$$

2.4. Boundary conditions at the interfaces

At the membrane surface, the electrochemical potential in the solution and on the membrane side are identical, this condition is denoted as Donnan equilibrium. This condition defines the potential build up at the membrane interface and determines the transport of charged molecules. The following relation arises for an ideal solution (Strathmann, 2004). Where $\Delta\psi_{Don}$ is the Donnan potential and superscripts s and m correspond to solution and membrane sides of the interface, respectively.

$$\Delta\psi_{Don} = \frac{RT}{z_k F} \ln\left(\frac{C_k^s}{C_k^m}\right) \tag{5}$$

The fluxes are continuous at the interfaces, it means there is no accumulation. In equation (6), the points x_j^- and x_j^+ correspond to left and right hand side of the interface located at x_j, respectively (Fig.1).

$$J_k\big|_{x=x_j^-} = J_k\big|_{x=x_j^+} \tag{6}$$

Electroneutrality condition defines the concentration distribution in both membrane and solution zones. For the solution and membrane sides the following algebraic relations arise:

$$\sum_k z_k C_k^s = 0 \quad \text{and} \quad \sum_k z_k C_k^m + z_{fix} C_{fix}^m = 0 \tag{7}$$

Where the subscript *fix* is related to the fixed charge in the membrane. Finally, the assumption that all current is carried by ions remains.

3. Results and discussion

3.1. Model Solution

The model consists of a system of multiregion partial differential equations. The method of lines is employed to discretize the spatial *x*-dimension, resulting in a system of differential and algebraic equations (DAEs). Sixth order Taylor expansion was used to achieve the desired accuracy using a reasonable computational time. Besides, asymmetric centered differences were employed to deal with the equilibrium boundary conditions. A feasible set of initial conditions must be known in order to ensure convergence. An inconsistent set of initial conditions leads to numerical problems (index of the DAE's is larger than one). Møllerhøj (2006) proposed an initialization procedure in order to guarantee, to some extend, convergence.

3.2. Parameter estimation for model tuning

The model is tuned for neutralization dialysis of some monoprotic carboxylic acids, when no current is imposed to the system. The experimental data are taken from Zheleznov (1998). From a sensitivity analysis, the thickness of the boundary layers and the ion exchange capacity of the membrane were fixed. Employing the interior reflective Newton method for non linear minimization subject to bounds (Coleman and Li, 1994), a black box swelling model was tuned for three different monoprotic carboxylic acids: acetate, lactate and propionate. Details about the model tuning are illustrated by Prado Rubio *et al.*, 2009.

3.3. Ions transport under current reversal conditions

Membrane fouling is an important factor since carboxylic acids are recovered from fermentation broths, which are characterized by high biomaterial content that easily can be adsorbed at the membrane surface. The adverse fouling influence in REED is diminished by periodically reversing the current density. REED is operated using a constant absolute value of current density, this implies that the strength of the external potential gradient must be enlarged with time to counteract the increasing electrical resistance. Through simulations, the potential average lactate recovery is estimated under current reversal conditions, for pseudo steady state operation. For this simulation case, the imposed current is $\pm 100\ A/m^2$ and the inlet lactate and protein concentrations in feed channel are *100*, *10* mol/m^3, respectively. Besides, inlet hydroxyl concentration in dialysate channel is *50* mol/m^3. The results are depicted in Fig. 2. It is expected to obtain higher recoveries by increasing the reversal time as the concentration profiles develop. The recovery achieved without imposing an external potential gradient is located at zero reversal time (Donnan dialysis conditions). It can be seen that for low reversal times the average lactate recovery increases linearly, this condition remains up to a reversal time of 20 min. For higher reversal times, lactate recovery reaches a limit since the maximum fluxes are practically achieved before the current is reversed. The maximum average lactate recovery is approximately 58% higher that under Donnan dialysis conditions, and it is obtained for $t_{rev} \approx 76.67\ min$. On the other hand, average lactate recovery obtained with Donnan dialysis is higher than expected. The reason being that the experiments used pure carboxylic acid solutions, therefore the fluxes were not affected by fouling (Zheleznov, 1998).

In spite of the maximum lactate recoveries are obtained at long time reversal times, the main drawback is the energy requirements to keep constant current density operation. For that reason is important to identify a potential REED operating window. In previous experimental work in a REED cell, the potential build up during lactic acid recovery was measured (Rype, 2003). From there, the potential gradient can be correlated with reversal time (shown in Fig. 3). Prolonged operation at constant current requires a higher potential gradient and therefore the energy consumption increases as well. The regressed model predicts a continuous linear increment of the potential gradient. However, there is a maximum potential gradient allowed by power source which defines the operative window for REED unit. Once the current source reaches its limit, operation at constant current conditions is not longer feasible. This means the operation mode switches to constant voltage conditions, implicating a reduction in the ion fluxes and lactate recovery. It must be stressed that the presented model was not developed to predict operation under constant voltage conditions. The optimal operating point for the equipment represents a trade off between the carboxylic anion recovery and the energy consumption, subject to the operation constraints.

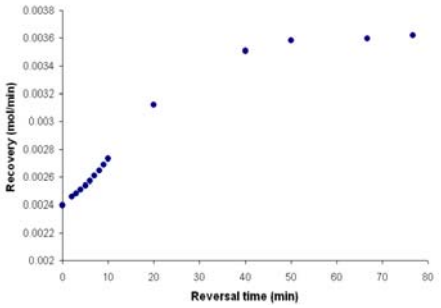

Figure 2: average lactate recovery as a function of the reversal time for a current of I_d=±*100 A/m*^{2} and $C_{dbin,NaOH}$=*50 mol/m*^{3}

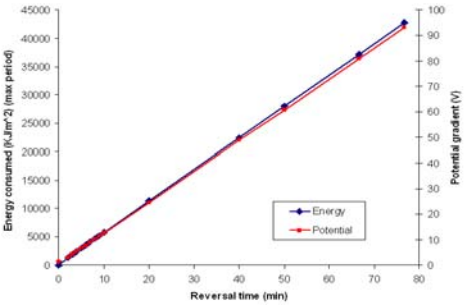

Figure 3: maximum potential and energy requirements for REED

4. Conclusions

Using first principles, simultaneous transport of multiple ions across anion exchange membranes in a REED cell is modelled. The solution of the system of multiregion partial differential equations is approximated numerically, employing sixth order Taylor expansion with asymmetric centered differences. The tuned model is used to investigate the average lactate recovery as a function of the reversal time, under pseudo steady state operation. Maximum recovery is basically achieved for t_{rev}>*50* min. However, there is a maximum potential gradient allowed by the power source that ultimately defines the operative window. Finally, this model is implemented as a tool which can be used to study the competitive ion transport through ion selective membranes under current load conditions, and therefore it is useful for development of an optimal design and operation of REED in dependence of different objective functions.

Abstract

Discrete optimization problems, which give rise to the conditional modelling of equations through representations as logic based disjunctions, are very important and often appear in all scales of chemical engineering process network design and synthesis. Disjunctive-Genetic Programming (D-GP), based on the integration of Genetic Algorithm (GA) with the disjunctive formulations of the Generalized Disjunctive Programming (GDP) for the optimization of process networks, has been proposed in this work. With the increase in the problem scale, dealing with such alternating routes becomes difficult due to increased computational load and possible entanglement of the results in sub-optimal solutions due to infeasibilities in the MILP space. In this work, the genetic algorithm (GA) has been used as a jumping operator to the different terms of the discrete search space and for the generation of different feasible fixed configurations. This proposed approach eliminates the need for the reformulation of the discrete /discontinuous optimization problems into direct MINLP problems, thus allowing for the solution of the original problem as a continuous optimization problem but only at each individual discrete and reduced search space.

Keywords: Process Optimization, Genetic Algorithm, Generalized Disjunctive Programming

1. Introduction

Processes with nonlinear functions and discontinuities in the objective and/or constraint space are found in a large number of synthesis problems. It has been shown that using disjunctions for expressing the discrete decisions, which conditions the selection of process units among various alternatives, can be very beneficial in handling of discontinuities in chemical process systems (Vecchietti et al., 2003; Turkay and Grossmann, 1996). The Generalized Disjunctive Programming (GDP) is an efficient method for Mixed Integer Non-Linear Programming (MINLP) for discrete/continuous optimization problems (Turkay and Grossman, 1996; Lee and Grossman, 2000). In GDP, problems are modeled with Boolean and continuous variables for the optimization of a given objective function subject to different types of constraints. GDP represents discrete decisions in the continuous space with disjunctions, and constraints in the discrete space with logic propositions.

Evolutionary search methods, of which the most widely used is the Genetic Algorithm, originally initiated by Holland (1975), has been known to be less susceptible to the existence of locally optimal solutions in optimization problems, yielding very good

solutions even with discontinuous objective and/or constraint functions. The evolutionary search method solutions have been found in some cases, to outperform those obtained through traditional deterministic approaches, by exhibiting robustness through the use of the objective function information and not derivatives, as well as by the ease at which they handle discrete and integer variables as well as non-smooth and non-continuous functions (Androulakis and Venkatasubramanian, 1991). Yet, the overall applicability of these algorithms to constrained problems remains an active research focus, especially taking into consideration the fact that they may exhibit slow convergence and may have difficulties finding the optimal solution to a problem with very small feasibility space. However, promising results are being obtained in joint heuristic and evolutionary (deterministic and stochastic) approaches to the efficient solution of engineering processes (Leboreiro and Acevedo, 2004).

This work is based on the integration of GA with the disjunctive representation of discrete/continuous optimization problems. The strategy involves the decoupling of the disjunctions and the propositional logics from the overall disjunctive formulation to the GA space where these constraints are treated before being returned as active terms with satisfied logics to the resulting NLP space. The population of disjunctive terms, corresponding to the different process superstructures or configurations are manipulated by the genetic operators in an evolutionary manner in order to obtain the best NLP solution. The implication of this is the final solution of an optimization problem with smooth nonlinear constraints and objectives confined within a reduced search space corresponding to specific active terms of a set of disjunctions, as determined by the GA. An advantage of this approach is that, apart from the fact that the dimensionality of the optimization problem can be considerably reduced due to the reduction in the total number of constraint equations (only common and active disjunctive terms equations are analyzed at each NLP call), only feasible superstructures are generated.

2. Disjunctive-Genetic Programming Method

The basic idea behind the D-GP approach involves the decoupling of the disjunctive terms represented by Boolean variables as well as the propositional logic constraints these variables form, to the genetic algorithmic space where they are encoded into chromosomes with specific structures corresponding to potential superstructure solution alternatives. In a typical solution framework such as the Big M - OA approach (Williams, 1999), the reformulation of optimization problems with discontinuous functions modeled with disjunctions involves conversion of the Boolean variables to binary and the proposition logics into simple linear equations, leading to MINLP problems, which in turn are solved using an iterative MILP-NLP scheme (Fig. 1).

An important feature of our proposed approach is that no MINLP reformulation of the disjunctive representation is needed. Terms of the disjunctions only need to be identified, well defined and coded into strings or chromosomes. For the adaptation of GA to the efficient handling of the generated chromosomes, we propose a segment-based crossover and mutation strategy. Furthermore, we apply the all-feasible populations approach, consisting of the creation and use of chromosomes that always satisfy the logic constraints (Odjo et al., 2008). The basic steps of the D-GP framework are depicted in Fig. 2.

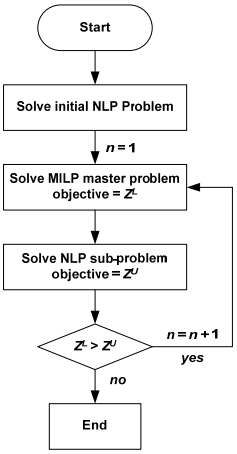

Figure 1. *MILP-NLP iterative solution*

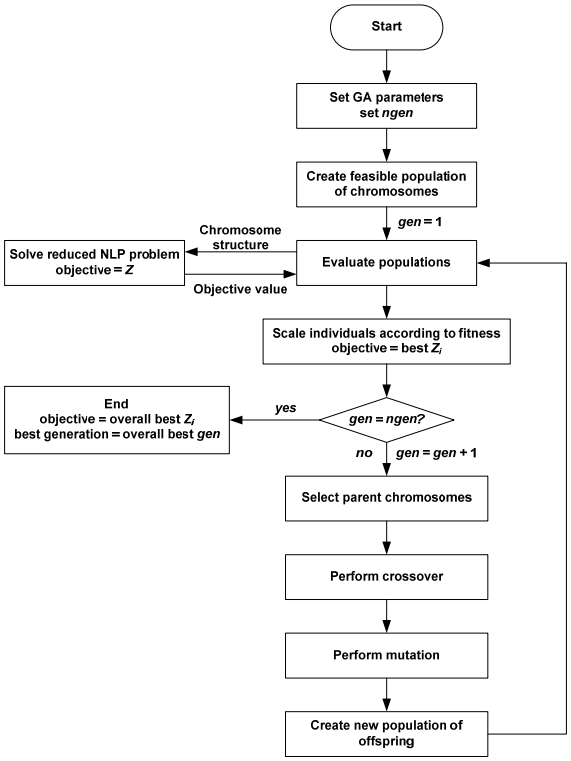

Figure 2. *The D-GP solution framework*

An important step in the application of GA to the solution of optimization problems is the creation of random individuals of a population with a fixed number of members. This population typically corresponds to the search space of the optimization problem, for example randomly generated temperature or pressure values between a specified lower and upper limit. However, in large synthesis problems with large numbers of variables, this gives rise to huge combinatorial problems such as possible different flowsheet configurations of a process with large number of units and process streams. Coupled with the existence of a narrow feasibility region due to different specifications and restrictions, the traditional approach for the generation of individuals within the optimization search space might lead to slow convergence and even sub-optimal solutions. In this work, a population of feasible chromosomes approach is adopted. The important aspect of this approach is that infeasible chromosomes have been eliminated from the initial population before the GA fitness function evaluation stage, as opposed to the traditional approach where feasibility constraints defined by the logic propositions and embedded as linear algebraic equations were satisfied during the GA fitness function evaluation.

3. Segment-Based Cross-over and Mutation Strategy

In order to conserve parts of the feasible configuration from the parents to the offspring, and also to achieve less disruptive chromosomes, the crossover operation strategy

employed in this work involved the selection of two strings (parent chromosomes) with the subsequent identification and exchange of identical segments of the parents. The number of identical segments in a parent string or chromosome is independent of the size of the optimization problem, but depends on the number of disjunctions in the synthesis problem. The genes in each segment represent the terms of the disjunctions. The rules governing the cross-over of identical segments, involve the selection and direct inter-exchange of the bulk of those segments, but not individual genes in them.

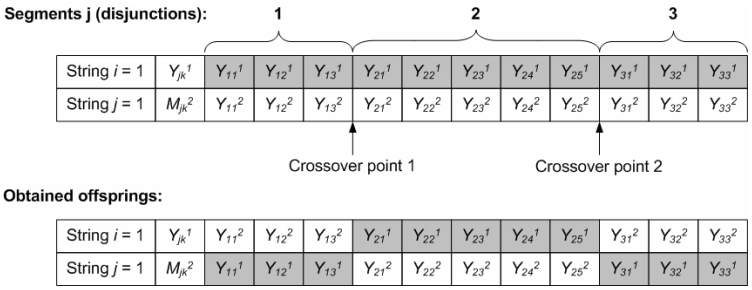

Figure 3. *Adopted crossover operation strategy for the D-GP approach*

Mutation, carried out at random on any bit of a string (gene) of the population, often leads to infeasible configurations. This can be improved, however, if the operator is modified by incorporating specific information on desired mutation routes. Rather than carry out mutations on individual genes, mutations are performed on segments of specific size and position in the string, corresponding to individual disjunctions and the order in which they are placed, respectively. It is worth noting, that the length of each segment (the number of genes in it) corresponds to the number of terms in each disjunction. In this work, this leads to the creation of mutant genes, which basically can be considered as sets of disjunctions of the current problem with different configurations of the propositional logics. In this way, diversity of the next population is guaranteed without loss of feasibility (Odjo et al., 2008).

4. Case Study – Process Network

This process network problem was taken from the works of Lee and Grossmann (2000). It was sought to determine the most profitable flowsheet configuration involving the possible selection of eight processes from the network as represented in Fig. 4.

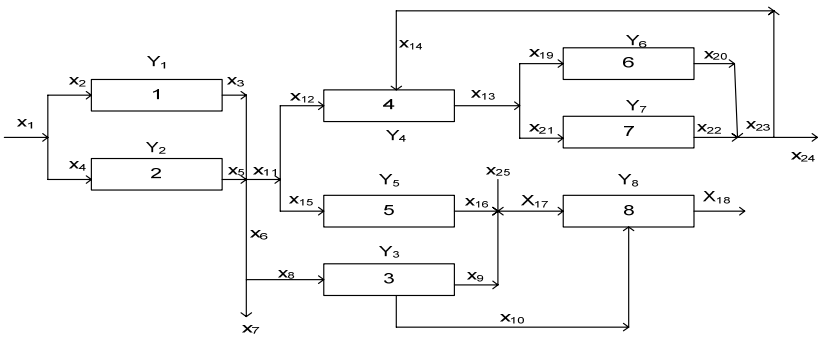

Figure 4. *Superstructure for process network*

This model was originally formulated as a MINLP and later as a GDP problem by Lee and Grossmann (2000). The problem formulated as a D-GP problem involves disjunctions for the selection of units, and propositional logic for the relationship of these units. Each disjunction contains the equations for the given unit. The model is shown in Eqn 1.

$$\min Z = \sum_{k=1}^{8} c_k + a^T x + 122$$

$$\begin{bmatrix} Y_7 \\ \exp(x_{22}) - 1 - x_{21} = 0 \\ c_7 = 4 \end{bmatrix} \vee \begin{bmatrix} \neg Y_7 \\ x_{21} = x_{22} = 0 \\ c_7 = 0 \end{bmatrix} \qquad \begin{bmatrix} Y_8 \\ \exp(x_{18}) - 1 - x_{10} - x_{17} = 0 \\ c_8 = 5 \end{bmatrix} \vee \begin{bmatrix} \neg Y_8 \\ x_{10} = x_{17} = x_{18} = 0 \\ c_8 = 0 \end{bmatrix}$$

$$a^T = [0,1,-10,1,-15,0,0,0,-40,15,0,0,0,-40,15,0,0,0,15,0,0,80,-65,25,-60,35,-80,0,0,-35]$$

$$x_j, c_k \ge 0, Y_k \in \{true, false\}, k = 1,2,...,8; j = 1,2,...,25.$$

propersitional $\log ic[\Omega = (Y_k)]$ $Y_1 \Rightarrow Y_3 \vee Y_4 \vee Y_5$ $Y_2 \Rightarrow Y_3 \vee Y_4 \vee Y_5$ $Y_3 \Rightarrow Y_1 \vee Y_2$ $Y_3 \Rightarrow Y_8$ $Y_4 \Rightarrow Y_1 \vee Y_2$ $Y_4 \Rightarrow Y_6 \vee Y_7$

$Y_5 \Rightarrow Y_1 \vee Y_2$ $Y_5 \Rightarrow Y_8$ $Y_6 \Rightarrow Y_4$ $Y_7 \Rightarrow Y_4$ $Y_8 \Rightarrow Y_3 \vee Y_5 \vee (\neg Y_3 \wedge \neg Y_5)$

specifications $Y_1 \forall Y_2$ $Y_4 \forall Y_5$ $Y_6 \forall Y_7$ (1)

As can be seen in Eqn. 1, each chromosome contained 10 genes, with the first eight containing the information on the activation or non-activation of a certain term of each disjunction. The GA returned a chromosome with an optimal objective value of 68.01 at the optimal flowsheet configuration that involves selection of units 2, 4, 6 and 8. It implies the feasible chromosome was generated during the GA first population creation (with the structure 01010101(+1)). Table 1 shows the comparison of the problem reformulated from the D-GP to the MINLP and iteratively solved between the NLP sub-problem and MINLP master problems (Lee and Grossmann, 2000). It can be seen that the reduced NLP problem of the D-GP approach is more simplified by the existence of fewer nonlinear constrains.

Table1. Comparison of NLP model parameters of G-DP with GAMS SNOPT7 output.

Model parameters	Formulations	
	Reduced NLP (D-GP)	NLP
Objective value	68.01	68.01
Number of variables	33	34
Total number of equations	38	61
Constraints: Linear	10	10
Nonlinear	28	51
Number of bonds	33	34

5. Conclusions

In this paper a joint genetic algorithm-disjunctive representation approach to synthesis of process networks involving discrete/discontinuous functions has been presented. Special modified GA operators were presented to better handle the proposed solution approach, and it was found that the generation of feasible populations yield better results as compared to the case when the population is composed of randomly generated individuals that underwent feasibility test at the fitness function evaluation stage. An interesting feature of the D-GP approach is that it eliminates the need for the reformulation of the GDP problems into a direct MINLP problem, thus allowing the solution of the original problem as a continuous optimization problem but only at each individual discrete and reduced search space. The effectiveness of the D-GP algorithm has been illustrated using a benchmark case study of process network design. An important aspect of this work is the use of an evolutionary algorithm for the efficient handling of discontinuities in optimization problems, while simultaneously applying deterministic approaches to handle the continuous functions. Reformulation of the benchmark case showed significant reductions in the number of constraints/equations compared to the standard formulation. The objective function value in this case remained unchanged, but other examples have been solved where improved objective function values have been obtained. No comparison of CPU time is included at this stage, as the software implementation is not yet seamless and as a result, there is some lag time when transferring information between the GA solver in MATLAB and the NLP solver in GAMS. In future works, this lag time will be eliminated to enable direct comparison of solution time.

Abstract

Petrobras – Petroleo Brasileiro S.A., is an active player in research, oil and gas exploration and processing, petrochemical and fertilizers industries as well as in bio fuels production. As the process designs are elaborated with a high degree of innovation, the utilization of an in-house process simulator has strategic advantages.
PETROX – Petrobras' Process Simulator comes from this conception. The simulator is being developed in Petrobras' Development & Research Center since the late 80's and is now on its 20 year birthday. PETROX' success over 20 years, coexisting with commercial simulators, is due to its insertion in Petrobras' Technology System and to the importance that the company gives to innovation. This work will discuss general and specific features of the simulator, structure and its utilization in research, development and design of production facilities and processing units of oil and gas.

Keywords: oil refining, modeling, simulation, design.

1. Introduction

Petrobras – Petroleo Brasileiro S.A., is an integrated energy company which plays in oil and gas exploration and processing, petrochemical and fertilizers industries as well as in bio fuels production. The company researches and develops technology on deep water oil and gas production, as well as refining technologies, in CENPES, its research and development center. These new/improved technologies are applied in the design of production facilities and refining units. The concretization of the new technologies in engineering designs, in the RD&E concept (research, development and engineering), passes through the elaboration of mathematical models of the new processes and the implementation of these models in computer programs for process simulation. Most part of the oil refined by Petrobras is domestic, so it is necessary to research and develop novel refining technologies and process schemes, as well as catalysts suited to processing national feed stocks. As the process designs are elaborated with a high degree of innovation, the utilization of an in-house process simulator has strategic advantages. In this scenario, building process models and implementing them in simulators is a very important part in the technology development.

PETROX – Petrobras' Process Simulator is fruit of this conception. The simulator is being developed in Petrobras' Development & Research Center since the late 80's and is now on its 20 year birthday. PETROX' success, coexisting with commercial simulators, is due to its insertion in Petrobras' Technology System and to the importance that the company gives to innovation. These factors are responsible for the characteristics that make PETROX unique, when compared to commercial process simulators.

Examples of these unique characteristics are the models of proprietary conversion process like fluid catalytic cracking, delayed coking and hydro treating; rigorous heat exchanger models from Heat Transfer Research Inc (HTRI) and the integration with software from Fractionation Research Inc (FRI) and the Centre for Process Integration (CPI), from the University of Manchester.

Petrobras' affiliations to consortiums like HTRI, FRI, CPI, Center for Phase Equilibria and Separation Processes (IVC-SEP) and Computer Aided Process-Product Engineering Center (CAPEC), as well as collaboration with Brazilian universities, like UFRJ, USP and PUC-RJ, and also Brazilian companies, potentialized the development of specific models and correlations for domestic oils.

2. History

Process simulation in Petrobras using computers started in the late 1960s, when independent programs for vapor-liquid equilibrium and thermal properties calculations were developed and used for design and education purposes (Niederberger et al, 2005). These programs were unsuitable for large plant simulations as the results had to be transferred manually between each module. Nevertheless, a gas processing unit was designed in 1976 using this approach. In 1979 the first commercial simulator (Process) was used by process design groups. Hysim followed shortly after as the choice of most of our refineries staff.

With the main purpose of acquiring know-how, a small group of engineers started the development of PETROX, using an executive program bought from Rio de Janeiro Federal University (Castier, 1985). The academic program was thoroughly modified keeping only the basic structure. In 1993, after the implementation of the distillation module, the simulator was ready to be used by the whole company (Niederberger et al, 2005).

Due to a strong research investment on exploration and production, national crude feed has been continuously increased by Petrobras' refineries, hence, considerable changes in the feed stocks composition and characteristics have been taking place. Brazilian crude oils use to be much heavier than the average crude imported, therefore, new correlations had to be developed in order to best simulate oil blends properties and processing units. Furthermore, PETROX has been an important tool which includes these original simulation models of specific oil blends in Brazil.

Development of proprietary conversion process started with the FCC technology transfer from Pullman Kellog, including a simulation tool for this process. At the same time, some models for Delayed Coked yields and Hydrotreating were developed at Petrobras' Development & Research Center.

A brief timeline of PETROX development is as follows:

- 1987: Acquisition of PSPE – Simulation Program for Stationary Processes from Rio de Janeiro Federal University (COPPE/UFRJ)
- 1989: Starting of PETROX development.

- 1993: Release of 1.0 version (DOS)
- 1999: Release of 2.0 version (Windows)
- april/2008 - Version 2.9
- **september/2008 - Version 3.0**

3. Structure

PETROX is a process simulator with a graphical user interface written in C++, C and C#.NET and a Simulation Engine written in C and FORTRAN. Figure 1, as follow, shows this structure.

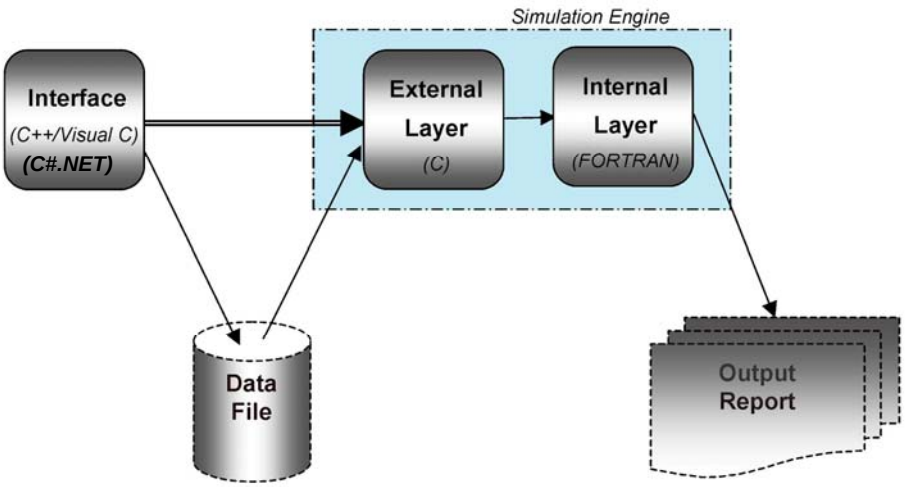

Figure 1 – PETROX Structure

The infrastructure of CENPES also has a virtualization software which allows any PETROX user runs simulations from all machines connected to the intranet.

4. Features

PETROX has several thermodynamic models and property methods required for simulating crude refining, gas processing, offshore production facilities and basic petrochemical units.
The process flow sheet visualization became available in its 3.0 version, released in September 2008, but there are some special features that make PETROX unique:

- **Crude Oils Data Bank.** It contains information on 378 crude oils. The data includes complete TBP and API gravity curves, light ends contents and composition, viscosity data for the crudes, distillates and residues, crude oil sulfur content, among others. Most of these properties were measured in our laboratories.

- **Conversion Processes Models.** Proprietary models for fluid catalytic cracking, delayed coking, mild thermal cracking, hydrotreating/hydrocracking and sulfur recovery units (SRU) are available.
- **HTRI's Rigorous Heat Exchanger Models.** The rigorous models developed by HTRI for shell and tube, air cooler, plate and frame and economizer heat exchangers are available in PETROX.
- **Integration to other process design and process analysis tools.** PETROX is capable of exchanging data with software from FRI and CPI, as well as the system COMOS® and other proprietary refining process design tools.
- **Unit operations.** Some of the available unit operations are: Flash drum, Rigorous Distillation (three different models: Inside-out, Sour-water(Wilson, 1978) and Newton), Shortcut distillation column, Mixer, Splitter, Separator, Valve, Pump, Turbine, Reciprocating compressor (uses adiabatic paths and efficiencies, with or without aftercoolers), Centrifugal compressor (uses the polytropic analysis made by Schultz (1962), with or without aftercoolers), Turboexpander, Depressurizer, Simplified heat exchanger, LNG heat exchanger, Rigorous heat exchanger (uses HTRI (2004) program to simulate equipment behavior), Feedback controller, Reactors (Shift, Stoichiometric, Gibbs and Hydrotreater), Material recycles (uses methods of successive substitution, Wegstein or dominant eigenvalue) and Calculator.
- **Proprietary correlations for Brazilian heavy oils.** As the major part of the oil refined in our refineries is domestic, and as the major part of the Brazilian oils are heavy, it was necessary to adapt literature methods for a better description of heavy oil fractions phase equilibrium and transport properties.

5. Applications

PETROX has been successfully used in revamps and design of new refining units such as atmospheric and vacuum distillation, fluid catalytic cracking, delayed coking, hydrotreating / hydrocracking, natural gas processing, basic petrochemicals, offshore production facilities and treating units like sour water treatment and sulfur recovery units. It is also used for product quality prediction and other process analysis tasks. Some applications are:

5.1. Process design of hydrodesulfurization unit of naphta catalytic cracked

Due to environmental rules, the allowed sulfur content of fuels is decreasing. In 2008, our first proprietary design of a hydrodesulfurization unit of catalytic cracked naphtha was delivered. This process uses hydrogen in order to reduce the sulfur content in this kind of stream without reducing the content of olefins and, as a consequence, the octane number of the final product. Figure 2 shows a simplified process flowchart.

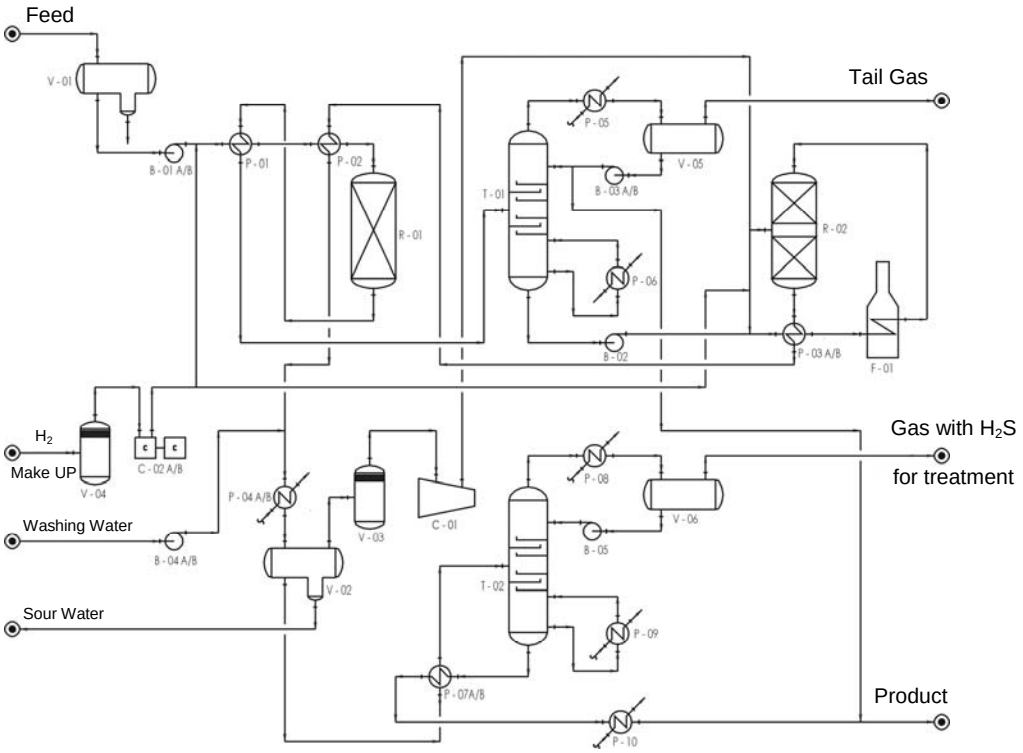

Figure 2 – Flowchart

5.2. Off-line Optimization

The sulfur recovery in industrial units is enhanced by the removal of intermediate product, by decreasing temperatures in the reactors and the number of reactors. Therefore, to optimize the performance, the design of a sulfur plant must take into account all these variables. The Sulfur Recovery Unit (SRU) is one of the Conversion Process Models available in PETROX. A thermodynamic model, based on the equilibrium of the reaction, was developed and successfully applied to the Modified Claus Process.

As environmental laws regulating the emission of sulfur are becoming more stringent, this process is increasingly important in Petrobras' refineries. Some of them use the simulator to evaluate critical data and optimize operating conditions, helping to reduce utilities comsuption and maximizing the sulfur removal.

5.3. On-line Optimization

Another Conversion Process Model is the Fluid Catalytic Cracking (FCC). It is a proprietary model that consolidates all existing knowledge in the company from the FCC area, incorporating technological innovations such as cracking of residues and others.

Currently there is an ongoing project that intends to integrate this model with a mathematical solver, to make a real-time optimization (RTO) in a Fluid Catalytic Cracking unit that uses atmospheric residue as feed (RFCC). It is expected to achieve a good financial return.

6. Conclusions

Actually, PETROX has shown to be an efficient computational tool to simulate several complex plants, as well as to aid process engineers in operating, controlling and designing process units. Some important features of commercial simulators have been included in its code in order to make it useful to the Engineering environment in Petrobras. Besides, it has a multi-disciplinary team that provides support and develops state-of-the-art applications required by users, based on either Petrobras' proprietary technologies which could not be feasible with commercial simulators or would be much more difficult and complex.
It is anticipated that real time tools will be very important to determine the best operating conditions in Petrobras refineries.
Finally, development of an in-house process simulator, besides being a competitive advantage, is strategic to protect and disseminate the technological innovations in the whole company.

Abstract

This work presents a two-layered decomposition methodology aimed at the resolution of difficult batch scheduling problems arising in chemical production facilities. The method relies on partial relaxation and aggregation of a detailed discrete time-indexed scheduling model, effectively transforming it into a computationally tractable approximate scheduling problem. The output of the approximate model forms the basis of an order-based decomposition scheme, within which scheduling sub-problems are resolved with the aid of the detailed scheduling model. Computational results are shown for several instances of the well-known "Westenberger-Kallrath" batch scheduling benchmark, which represents a typical multi-purpose multi-product batch chemical process.

Keywords: scheduling, decomposition, batch plants, MILP.

1. Introduction

The batch chemical production scheduling problem, consists in determining the optimal allocation of a number of resources (processing units, raw materials, utilities, manpower, etc.) over time to a number of processing tasks transforming raw materials into a number of desired final products. The extent of each processing task (total amount of materials consumed/produced by the task) is constrained by minimum and maximum batch sizes. Interactions between resources and processing tasks are discrete, i.e. occurring at fixed time intervals relative to the tasks' starting times. The problem is NP-hard in the strong sense, and even simplified versions of it are NP-hard too (Burkard et al., 2000). Accordingly, a number of approaches have been developed in order to maintain computational tractability in systems of industrial relevance; including rigorous and heuristic time-based decomposition of detailed scheduling models, mixed-integer linear programming, heuristics, local search, methods relating to project scheduling, and combined batching/scheduling techniques. The later have been shown to yield good solutions to realistic short-term production scheduling problems with reduced computational cost.

2. Motivation: The ''Westenberger-Kallrath'' process

The "Westenberger-Kallrath" (WK) benchmark represents a typical multi-purpose, multi-product batch chemical process. A thorough description of the process can be found in the literature (Kallrath, 2002).

The WK example consists of 17 distinct processing tasks (T1-T17) that can take place in 9 multi-purpose units, and 19 material states (S1-S19) with 5 desired products (S15-S19). The process features convergent, divergent, and cyclic production flows, constituting a sophisticated scheduling problem. Fig.1 depicts the State-Task-Network (STN) representation (Kondili et al., 1993) of the WK process flow.

The process involves a number of perishable products, for which both initial and maximum inventory levels are zero. It is worth mentioning that two main issues complicating scheduling considerations in the WK process are: (i) the existence of one processing task (T2) with flexible output proportions, and (ii) the need for sequence-independent batch setup times. For task T2, the first output state (S3) can be produced in amounts ranging from 20 to 70% of the task's batch size. Consequently, the second output state (S4) can be produced in amounts ranging from 80 to 30% of the task's batch size.

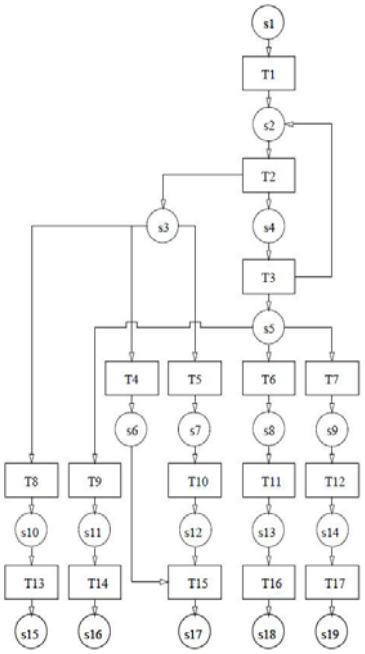

Figure 1. WK STN representation

For each processing unit, cleaning must be performed whenever production switches between two different task types. For a given set of final product demands, the scheduling objective is the minimisation of makespan subject to a number of operational constraints.

3. Detailed problem formulation

The detailed scheduling problem (DSP) formulation is based on the STN process representation. Let S denote the set of material states in the process (raw materials, intermediates, final products), U the set of available processing units, and I the set of processing tasks. For each material state $s \in S$, there is an initial inventory R_s^0, a maximum inventory level R_s^{max} and an external demand d_s. For each processing task $i \in I$, there exist minimum and maximum allowable batch sizes; B_i^{min} and B_i^{max}, respectively. For each processing unit $u \in U$, there is a set of production tasks $I_u \subset I$ that can be executed in the unit with integer processing times p_{iu}. Finally, for each material state $s \in S$, there is a set of consumption tasks I_s^c with consumption coefficients $\alpha_{is} \leq 0$, and a set of production tasks I_s^p with production coefficients $\alpha_{is} \geq 0$. These coefficients are expressed as fractions of the total batch size of task i.

Let T denote the total scheduling horizon, B_{iut} the batch size of task i starting in unit u at time $t \subset T$, and R_{st} the amount of state s at time t. Binary variable x_{iut} equals to one if task i starts in unit u at time t; otherwise, it is set to zero. To continue with, let $I^F \subset I$ denote the set of processing tasks with variable production coefficients. For each state s and processing task $i \in (I^F \cup I_s^p)$, there exist minimum and maximum production coefficients; α_{is}^{min} and α_{is}^{max}, respectively. Finally, b_{isut} denotes the amount of state s processed by task i in unit u at time t. It follows the DSP mathematical model.

$$B_i^{min}\, x_{iut} \le B_{iut} \le B_i^{max}\, x_{iut} \qquad \forall u \in U, i \in I_u, t \in T \tag{1}$$

$$\alpha_{is}^{min}\, B_{iut} \le b_{isut} \le \alpha_{is}^{max}\, B_{iut} \qquad \forall u \in U, s \in S, i \in (I_u \cup I^f \cup I_s^p), t \in T \tag{2}$$

$$\sum_{s \in I_s^p} b_{isut} = B_{iut} \qquad \forall u \in U, i \in I_u, t \in T \tag{3}$$

$$\begin{aligned} R_{st} = R_{st-1} + \sum_u \sum_{i \in (I_u \cup I_s^c)} \alpha_{is} B_{iut} + \sum_u \sum_{i \in (I_u \cup I_s^p \cap I^f)} \alpha_{is} B_{iut-p_{iu}} \\ + \sum_u \sum_{i \in (I_u \cup I_s^p \cup I^f)} b_{isut-p_{iu}} - d_s \qquad \forall s \in S, t \in T \end{aligned} \tag{4}$$

$$R_{st} \le R_s^{max} \qquad \forall s \in S, t \in T \tag{5}$$

$$\sum_{i \in I_u} \sum_{t'=t-p_{iu}+1}^{t'=t} x_{iut} \le 1 \qquad \forall u \in U, t \in T \tag{6}$$

$$\sum_{i' \in I_u, i' \ne i} \sum_{t'=t+p_{iu}}^{t'=t+p_{iu}+c_{iu}-1} x_{iut} \le \lceil \frac{p_{iu} + c_{i,u}}{\min(p_{i'u})} \rceil (1 - x_{iut}) \qquad \forall u \in U, i \in I_u, t \in T \tag{7}$$

$$t \sum_{i \in I_u} x_{iut}\, (p_{iu} + c_{i,u}) \le C_{max} \qquad \forall u \in U \tag{8}$$

Batch size constraints are expressed by eqs.(1)-(3). Flexible production recipes are taken into account by incorporating eqs.(2)-(3). Eqs.(4)-(5) correspond to material balance constraints. Eq.(6) forbids any two tasks to be performed in the same unit concurrently, and eq.(7) enforces unit unavailability during changeovers from any task *i* to a different task *i'*. Eq.(8) is only related to the makespan (C_{max}) objective.

4. Approximate scheduling model

The approximate scheduling model is derived from the detailed scheduling formulation (DSP) with the following modifications. First, alternative processing units for the same production task are aggregated based on a mean processing time. Second, the computationally expensive unit allocation constraints are partially relaxed. The functional form of all other constraints is retained. In effect, the suggested approximate model concentrates on ordering the production steps within the process relative to each other, without explicitly considering scheduling details at the unit level. Afterwards, let U_i denote the set of alternative processing units for task *i*, and $\overline{p}_i$ its mean processing time. Moreover, let z_{it} denote the number of batches for task *i* starting at time *t*, Q_{it} the cumulative batch size of task *i* starting at time *t*, and q_{ist} the cumulative amount of state *s* being processed by task *i* at time *t*. Finally, let *I'* denote any non-empty set of tasks that can be performed in at least one common unit. The approximate model constraints are summarised below.

$$B_i^{min} z_{it} \le Q_{it} \le B_i^{max} z_{it} \qquad \forall i \in I, t \in T \tag{9}$$

$$\alpha_{is}^{min} Q_{it} \le q_{ist} \le \alpha_{is}^{max} Q_{it} \qquad \forall s \in S, i \in (I \cup I^f \cup I_s^p), t \in T \tag{10}$$

$$\sum_{s \in I_z^p} q_{ist} = Q_{it} \qquad \forall i \in I, t \in T \tag{11}$$
