$$R_{st} = R_{st-1} + \sum_{i \in I_s^c} \alpha_{is} Q_{it} + \sum_{i \in (I_s^p \cap I^f)} \alpha_{is} Q_{it-\bar{p}_i} + \sum_{i \in (I_s^p \cup I^f)} q_{ist-\bar{p}_i} - d_s \qquad \forall s \in S, t \in T \tag{12}$$

$$z_{it} \leq |U_i| \qquad \forall i \in I, t \in T \tag{13}$$

Eqs.(9)-(12) are the aggregated form of eqs.(1)-(4) in the DSP formulation, and eq.(13) is the approximate form of eq.(6) in DSP. Changeovers are ignored in the approximate model, thus makespan cannot be meaningfully related to the approximate model either.

5. Decomposition

The total number of batches required to satisfy demand is known by solving ASP. This information can be utilised to split the detailed scheduling problem into a number of tractable sub-problems. Hence, if Z_k is the (constant) number of batches to be scheduled at each iteration k, then the total number of sub-problems to be solved will be at most $\sum_i \sum_t z_{it} / Z_k$. In practice, an adaptive adjustment of Z_k can be employed based on the makespan achieved at the previous sub-problem.

The iterative procedure examines the solution of ASP problem sequentially starting from the first time period. When the desired number of batches Z_k has been reached (let t^* denote the corresponding time period in ASP), model DSP is solved by adding the following cuts:

$$\sum_{u \in U_i} \sum_t x_{iut} \geq \sum_{t' \leq t^*} z_{it'} \qquad \forall i \in I \tag{14}$$

$$\sum_{u \in U_i} \sum_t B_{iut} \geq \sum_{t' \leq t^*} Q_{it'} \qquad \forall i \in I \tag{15}$$

Let us refer to this sub-problem as DSP-k. The solution to DSP-k will be used in the next iteration in two ways: (i) the makespan achieved in DSP-k will provide a lower bound for the makespan of DSP-*(k+1)*, and (ii) the timings of scheduled batches from DSP-k will be fixed and provided as input to DSP-*(k+1)*. In practice, the timings obtained by DSP-k can be fixed only partially, i.e. with the exception of the last batch of each task i scheduled in DSP-k, so that feasibility of next sub-problem DSP-*(k+1)* is facilitated. For each sub-problem *DSP-k*, the choice of an appropriate upper bound on makespan is critical in the computational performance of the algorithm. In this study, a greedy heuristic has been employed, which schedules all batches in Z_k with two simple dispatching rules: (i) batches starting earlier in ASP are scheduled first, and, (ii) each batch is scheduled on the available unit with the earliest completion time.

6. Experimental results

Two sets of computational experiments are considered; one ignoring and the other considering cleaning times. Consequently, the solutions of 22 problem instances of the WK example are compared with publicly available results in order to shed light on the advantages of the proposed approach.

Comparisons are attempted with the Time-Grid Heuristic (TGH) methodology (Blömer and Günther, 1998; Blömer and Günther, 2000) and the Batching/Batch Scheduling (B+BS) approach (Neumann et al., 2002). TGH employs relax-and-fix as well as dive-and-fix heuristics for the resolution of the detailed scheduling model (Wolsey, 1998). B+BS methodology employs a simple batching model in combination with resource-constrained project scheduling algorithms. ASP is used here as an acronym for our combined bi-level approach.

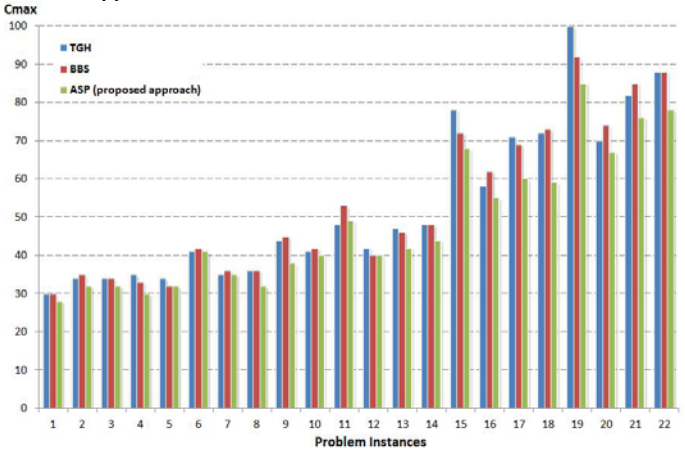

Figure 2. Experimental results for the case without cleaning times (Cmax in hours).

For the computational experiments without cleaning times (see Fig.2), equal or better solutions than TGH are obtained in 21 out of 22 cases, with an average makespan improvement of 8%. Compared to B+BS, ASP finds equal or better makespans in all 22 cases, with an average improvement of 8.16%. For the computational experiments with cleaning times (see Fig.3), ASP manages to find equal or better solutions than TGH in all cases, with an average improvement of 15.5%. Compared to B+BS, equal or better solutions are obtained in 20 cases with an average improvement of 9.3%.

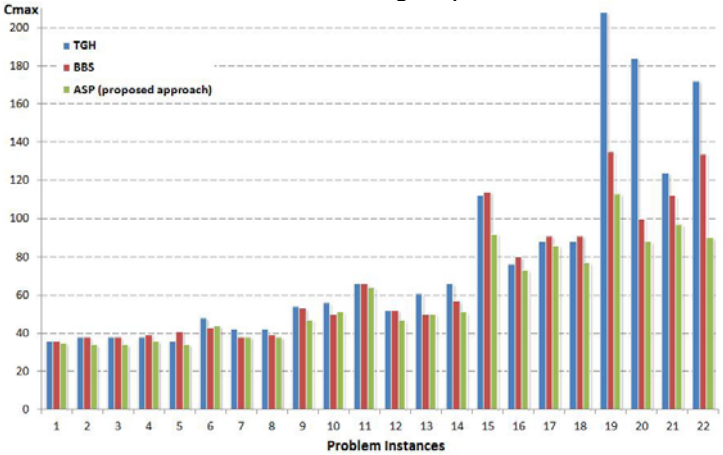

Figure 3. Experimental results for the case with cleaning times (Cmax in hours).

The results indicate that ASP manages to find good quality solutions in reasonable computational time (see Table 1). Problem ASP and all DSP sub-problems were

resolved with the aid of CPLEX 6.6 solver via a GAMS (Brooke et al. 1998) interface on a single 400 MHz Unix processor. The number of DSP sub-problems was determined dynamically for each problem instance, so that at least 20 batches were scheduled in every DSP iteration. For completeness, it is noted that TGH results were obtained on a single 266 MHz PC and B+BS results were obtained on an 800 MHz PC.

Table 1. CPU times (in seconds) for the cases with (a) and without (b) cleaning times.

7. Final considerations

A decomposition approach has been developed for the resolution of large-size batch process scheduling problems. The method has been tested on several published instances of a benchmark batch process scheduling problem with good results; particularly, for the larger problem instances. Comparisons between the decomposition approach and the full scheduling model in terms of quality solution and CPU effort will show the effectiveness of the proposed approach. To conclude, it is pointed out that as it is not certain that the minimum number of batches corresponds to a schedule of minimum length, the theoretical determination of a performance guarantee for the decomposition approach presents a challenging direction for future research.

Acknowledgments

Financial support received from the Spanish Ministry of Education and Innovation (FPU grant) is fully appreciated.

Generating Portable, High-level Process Models and Stand-Alone, Special-Purpose Simulators

Heinz A Preisig, Tore Haug-Warberg

Department of Chemical Engineering, NTNU, Trondheim, Norway

Abstract

The concepts behind a computer-aided modelling environment are being presented.

Keywords: modelling simulation, CAD, software

1. The Scene

Models are a core commodity in process systems engineering. If it is design or any operation activity, models are being used in one or the other form. The models being used are tailored for the application, because it is the performance of the application of the model that determines the measure of quality. Different people will have a different view on what constitutes a model. Thus the term *mode*l is used in many different contexts such as a physical, scaled replica, a set of equations or a computed trajectory. The PSE community most commonly uses the term *model* for a set of equations representing the behaviour of the modelled physical-chemical-biological system and not any derived products, such as computer code, which is also the view we take here.
Traditionally flowsheeting packages represent the state-of-the-art in terms of the common practice. Tools to construct models are limited to providing 'pick, insert and combine" library models. The linking of the sub-models may be done graphically using fixed connector definitions. The commercial side of the business has taken an approach that appears monolithic from the outside. The interior of these systems is increasingly protected in terms of accessibility and providing a view on the "inside". Whilst the vision of tools generating models based on fundamental principle has been around as long as the flowsheeting effort, the realization has been inhibited successfully based on either commercial arguments or it is seen as to large of a task, too abstract and too complex. Academic efforts approaching the problem by defining languages for capturing the information have failed to make a curb. Reviews on the subject are available in abundance (Tu:2006, Cameron:2008). Also the software providers do have little interest in supporting the exchange of models and it is only the pressure excerpted by industry that made the CAPE-OPEN effort to become a partial success.

2. The View

What one would want is a graphical representation of the process, possibly providing different modes on how to look at it. The components of these representations should give access to the model that represents its behaviour including all the assumptions that have been made to get there. Editing the structure should be supported so as to handle complexity and multiplicity of possible underlying behaviours. Thus it should allow defining different models for the same plant. The definition of the models should be built on a theoretical framework that is as generic as possible and enforces the basic concepts. Thus for first-principle rules should be implemented as hard facts. The repre-

sentation should be based on what one considers canonical in the respective sciences, in particular thermodynamics, geometry and kinetics. The fundamental concepts should be handled analytically, thus the basic concepts like energy, entropy functions and their derivatives should be available to any order analytically. Engines should exist that generate code for structure-tailored solvers, for any of the user's favourite solver, for the generation of the stand-alone, special-purpose solvers; an engine that ensures completeness and structural integrity of the models on the background of the theory; an engine that handles commonly made assumptions and eliminates the consequent mathematical problems in the model; an engine that generates stand-alone models, which can be wrapped and match an appropriate solver environment. Engines/software components that are connected by pipelines enabling the replacement of any of the software components and the need for servers should not be a must but one should have the option of inheriting all the required information down to the resulting application.
The thinking thus goes towards a kind of factory in contrast to an integrated computing environment.

3. The Modelling Process

3.1. The Model

The process of modelling a plant can be captured in Fig 1: The first domain, on the top left, is to map the process into a model, which requires two major operations: the first being an abstraction, breaking the overall process down into a set of interacting control volumes and a second being the description of each control volume and each interaction. Since one may have more than one alternative in terms of theories for the individual parts, one may be able to generate several different alternative representations using a set of combinations of available theories.

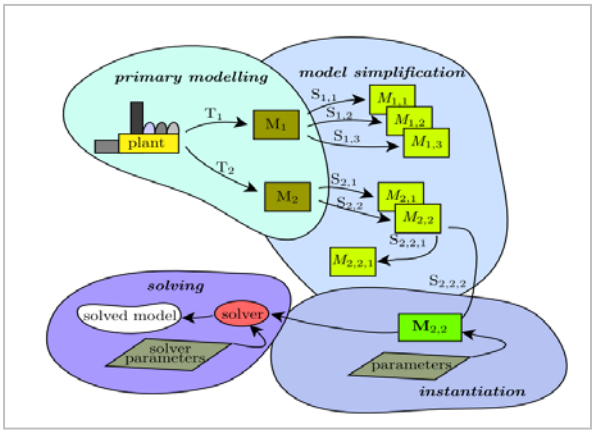

Figure 1: *Modelling overview: three major domains 1. primary modelling: maps the world into a mathematical object using theory T 2. model simplification: simplifies to match use of model using simplification S 3. model instantiation: define parameters characterizing the specific plant and solve the defined problem using the problem-specific method settings*

3.1.1. Example 1:

A distillation can be seen as a tower of dynamic flashes, where each flash consists of two phases enclose in a fixed volume. Three flashes are special, the feed splitting the column into a rectifying and stripping section, the boiler, where energy is added in form of heat and the condenser, where the heat is again removed. The mathematical description of a generic flash is shown in Figure 2

3.2. Simplifications

The second domain, on the right, is a set of simplifications and approximations. This may be done recursively, thus a simplification may be followed by another one, etc. This results in the possible generation of several models all of which represent the same plant but with an emphasis on different characteristics.

3.3. Instantiation

In the third domain the process model is instantiated with parameters making it complete and ready for simulation or other mathematical problem solvers. The transition to the solver incorporates also adding information that is specific to the solver being used.

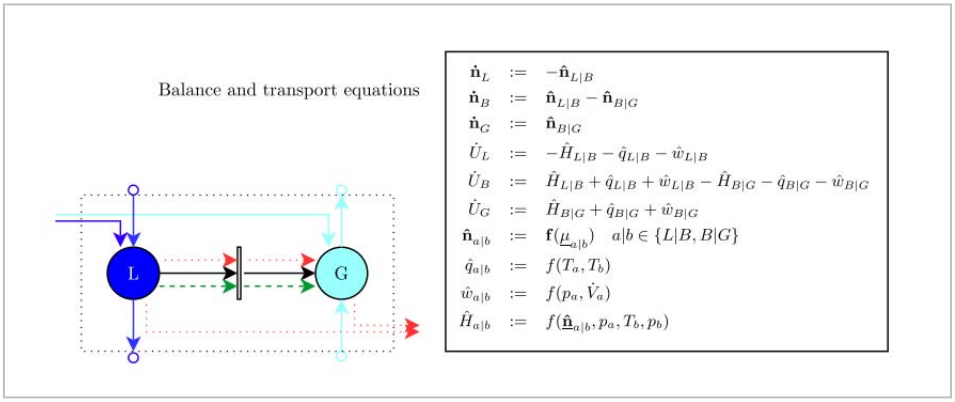

Figure 2: *A possible abstraction of a tray consisting of a lump for each phase communicating heat, work and component mass through the three connections. Heat may be exchanged with the environment and material may enter each of the lumps.*

3.4. Solving

The fourth domain solves the mathematical problem specified. In the figure a simulation is implied, which is indeed underlying many problems, including optimisation.

4. The Structures

The *abstraction* results in a network of capacities and connections, which can be very large depending on the granularity of the model and the size of the plant being modelled. This complexity can only be handled by overlaying a hierarchy. Mathematically seen a hierarchical graph is generated in which the arcs representing the connections are defined between leave nodes, with the leave nodes being the primitive capacities. Defining a graph as a set of nodes and arcs with the nodes being graphs ***G*** on the next lower level connected by a set of arcs, and defining the bottom out rule that on level 0 is a simple node ***N***, one has a hierarchical graph.

The connections on any level represent connections between pairs of primitive nodes each of which belongs to two parts of the tree on the respective level.

What one requires thus is a way of generating and manipulating a graph consisting of nodes and arcs and a tree, thus a *hierarchical graph tool*. The graph manipulation requires a number of operations: add, delete and move node, add arc, connect two nodes, delete and move an end of an arc to a new node. In order to support the hierarchy a number of operations are required such as zoom into a graph, group nodes/graphs to form a new graph (obviously including the connections), and the opposite, namely exploding a graph. These operations can be done on an abstract object that generates a set of identifiers. There is no need to make the objects anything special. The actual interpretation of the graphs' components can simply be identified using the identifiers by the graph tool. Thus this component can be designed completely independently.

If one chooses for a graphical handling of the graph generating and manipulation, the graph tool need only to generate the events for accessing the identifier-handling module.

One could also choose to generate a language for the definition of the hierarchical graph. This then would have some ways of defining the hierarchy and the underlying graph with syntax implementing adding nodes and arcs, and refining commands. In terms of algebra, one requires a tree and an incidence list for the description of the two key components, namely the tree and the underlying graph.
Depending on the application, the nodes and the arcs may be consistently typed. For example in Figure 2 we clearly have different types of connections namely mass, heat and work. This can easily be implemented as attributes to the graphs, nodes and arcs.
The individual components in the underlying graph, namely the nodes and the arcs must be given an interpretation. The *theory* for their representation can be generated separately (Hackenberg:2005). So in the chemical engineering domain one will have nodes representing physical-chemical-biological systems being of the class of 0, 1, 2, 3-D distributed systems, but it may also be an information processing system, which is used for the representation of controllers, for example. The *theory* for each component can be generated separately. The application then is only choosing the combination of *theories* appropriate for hers/his application. Using the state-concept, the *theories* for physical-chemical-biological systems implements the respective basic laws, in particular the conservation principles being the dynamic part of the description.

4.1.1. Example 2

These include the graph in typed form, explicitly the typed incidence matrices of the graph, which provide the hard link to the graph representation. Next the introduced flows and reaction/transposition parts must be extended applying the transport phenomena concepts. Transport is in turn driven by the intensive properties being the conjugates to the various fields: chemical potential, temperature and pressure, to mention the main ones. Latter are derived from the thermodynamic part of the model including a material model in the form of Helmholtz surfaces as a function of the canonical variables. Legendre transformations provide the necessary connection to the basic state variables being the conserved quantities. Providing the ability to differentiate the thermodynamic models provides access to any of the required variables.

$$
\begin{aligned}
U &:= A + T\,S \\
A &:= A(T, V, \underline{\mathbf{n}}) \\
\underline{\mu} &:= \frac{\partial A}{\partial \underline{\mathbf{n}}} \\
p &:= \frac{\partial A}{\partial V} \\
H &:= U + p\,V := U + \frac{\partial A}{\partial V}\,V \\
&:= U + \frac{\partial A}{\partial V}\,V
\end{aligned}
$$

It is absolutely feasible to *split the definition of the "theory" into different parts* and use different means for their definition, as long as the internal representation is providing the necessary link. For example it seems natural to split off the thermodynamics and possibly even the transport and kinetic part and define them as separate model components. In nearly all cases one requires a language capable of capturing equations representing specific phenomena. The equations themselves are composed of usually rather straightforward algebraic expression for which it is easy to define a simple language and generate a respective parser. The main problem really is in providing a powerful indexing procedure, which resolves the internal broadcasting at the time the equations are being instantiated. Equations consist of two expressions one for each side. An expression can be captured in an abstract syntax tree making it easy to later generate target code as desired. This applies to all sub-domains transport, thermo, etc. Each of these implementations must provide consistent equations. Those variables that are not defined by one module must be provided by one of the other modules forming an overall bipartite network. Providing alternative models defines a *super*-structure. As part of the specific model definition all choices must be made in a given super-structure reducing it

to an internally consistent set of equations[1]. All the consistency checks can be done on this level. Providing "clean" connections of the models automatically guarantees consistent process models. Thus we use the term *model synthesis* for this last stage though the sequence of the synthesis is user-controlled by either an input file or an interactive extension of the graph editor.
The internal representation of a model consists of sets of: typed nodes and arcs, typed incidence matrices, theory components representing nodes and arcs as consistent sets of equations, index maps (nodes, arcs, species, reactions, etc.) and plant-characterizing parameters. Since the equations are given as abstract syntax trees, it is straightforward to define various sets of templates for the different target languages and the available operations. These templates are then instantiated with the respective components from the abstract syntax and written to a file.

5. The Components

The Graph Tool generates and manipulates graphs. It imports the information on how its interface behaves, which enables the implementation of rules guaranteeing application-consistent graphs, such as connections must be done between primitive systems, leave nodes, in the hierarchical graph. The connection to the next layer is provided through an interface for a plug-in ***the Typing Tool*** plugs into the graph tool providing a well defined interface to perform the typing of the graph component. The typing tool imports its knowledge labelled "theory" from ***the Theory User Tool*** which provides an interface to the defined *theory* being the super-bi-partite graph of the equations representing the behaviour of the individual nodes and arcs. Here the choices reducing the super-graph into a simple equation set is performed and the index maps for the broadcasting operation in the final code are prepared. This tool may also implement model simplifications (Preisig:2009). **The Instantiation Tool** is used to instantiate the model's parameters, conditions and inputs. Intrinsically this specifies the type of mathematical problem to be solved. For example knowing the initial conditions, the model parameters and the inputs, defines a simulation problem. ***The Code Generation Tool*** computes first the final index maps (Preisig:2009) and then generates the compiled code for the selected model components using a template engine (Parr:2004). Finally this code is spliced into the solver-specific interface generating the final code being written to a target file. Later operation can also be solved with a template machine. Providing different sets of templates for the primitive operations and the external functions to be embedded, provides the means to generate code for the respective different target solvers. Target language and target solvers may be split for obvious practical reasons. ***The Theory Definition Tool*** may be split into several parts each specific to any of the sub-fields mass, energy, transport, thermo, etc. (Loevfall:2008). Each must though provide a consistent model; that is a set of equations that have a well defined set of input variables from, which a set of output variables are defined all of which is consistent with the applied theory. The set of equations must be well determined, though may have a superstructure imposed. Any of those tools must perform the possible structural check to the extent possible. For example physical units in connection with any mathematical operation must be checked etc. The tool should also provide analytical derivatives of the equations it generates. So as to enable transformations as briefly touched upon in Example 2.

[1] Consistency is defined as having zero degrees of freedom once the parameters and initial conditions of a simulation problem have been defined.

6. Conclusions

The concept of a software/solver structure has been introduced and, which mirrors the outlined step-wise modelling process. The core is a communicating network of components forming a factory for generating all kind of tools, including stand-alone simulators, code for legacy solvers, simulation languages, optimisation environments etc. The resulting components provide a dense checking on structures being generated thereby essentially eliminating the structural problems one experiences using the traditional tools (Szyperski:1998). The generation of internal code enables automatic analytical differentiation of any of the expressions appearing in the theory. The making of order-of-magnitude assumptions can be implemented including the reconciliation of the introduced mathematical problems, as shown in (Preisig:2009, Preisig:2008)

The generation of such a software environment: is a truly interdisciplinary activity, with information processing being the common "glue". Essential for the decomposition of the overall problem is the definition of well defined, small, highly structured, easy digestible pieces, which utilize *very few* concepts. For example the thermo module uses essentially only 3 principle ways of combining objects.

The paper addresses six different types of subjects all lying in different domains but also all of which must be resolved in order to generate an integrated modelling environment. 1) Graphical user interface for easy handling of hierarchical graphs. 2) Template engine, a technique to generate target code recursively. 3) Small languages that are tailored to capture individual components such as mathematical expressions and equations for the representation of the theory for the components represented in the respective graphs; latter being process models (capacities and extensive quantity transfer, reactions) or expressions, representing mathematical operations, or thermodynamic models, or geometry. 4) Solvers for well defined mathematical problems, including integrators, root solvers, symbolic differentiation. 5) Theory knowledge, including physical chemistry in particular thermodynamics, but also mathematical system theory, control etc. 6) Communications, that enable and support the interaction of the different programs using communication frameworks such as .COM or .NET environments.

The concept of a graph appears in different contexts: The graphical representation of a hierarchical decomposition of the processes' control volume; the representation of an equation, an expression as an abstract syntax tree; the representation of equation sets as bi-partite graphs; the GUI-controlling automaton as a state-graph.

Abstract

PID controllers are widely used in the process control industry due to their simplicity and ease of re-tuning on-line. A software package has been developed for system identification and PID control loop tuning by a partnership between UFCG and CENPES-PETROBRAS. This system implements literature and industry standard PID tuning algorithms and developed in UFCG. Application results of tuning software tools in a petrochemical plant, at PETROBRAS' are presented in this paper

Keywords: System Identification, PID Tuning, Relay Experiments, Industrial Application.

1. Introduction

The use of PID (proportional-integral-derivative) control loops is common in a large number of industrial processes (Aström and Hägglund, 2006). It is estimated that over 90% of industrial controllers are implemented based around PID algorithms, particularly at regulatory level. Its wide application has motivated the development of various PID tuning techniques and tuning software tools (Ang et al., 2005). A research effort has been made to improve system identification techniques and PID tuning using operational plant data.

The PETROBRAS (Brazilian Petroleum Company), through your Research Center - CENPES, invested in developing PID tuning software package tools during partnership with Federal University of Campina Grande (UFCG). In this manner, the academic and industry competence was combined. These software tools are named BR-TUNING.

The BR-TUNING software tool implements literature and industry standard PID tuning algorithms as well the algorithms developed at UFCG. Open and closed-loop identification techniques are implemented. In this paper, descriptions of implemented algorithms are presented. The main objective of this paper is present application results of the BR-TUNING in a natural gas processing plant (PETROBRAS' UN-RNCE in Guamaré–RN-Brazil).

This paper is organized as follows: Initially, the algorithms for identification and PID tuning implemented in BR-TUNING are presented (Sections 2, 3 and 4). In the section 5, the application results are presented and, finally, conclusions are presented in section 6.

2. Open-Loop Identification and PID Tuning

In this section, step response and relay-based open-loop identification techniques are presented. For each identification technique, a set of standard PID tuning are available in BR-TUNING.

2.1. Identification of FOPDT model from a step excitation and model-based PID Tuning

In the BR-TUNING it is implemented an identification technique of FOPDT model from open-loop step response. This technique was presented in (Wang et al., 2000). Consider the open-loop shown in Figure 1. It applies a step excitation signal (MV input) and store the PV signal. The FOPDT model is given by $\hat{G}(s) = \frac{b}{s+a} e^{-L_d s}$.

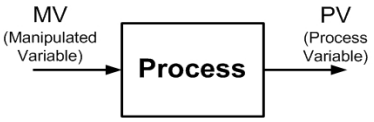

Figure 1: Open-Loop Process

The process is assumed to be in steady-state at $t = 0$ so that, $MV(t) = 0$ for $t < 0$ and zero initial conditions are assumed. For $t \geq L_d$ the process is assumed to satisfy $PV(t) = -a\int_0^t PV(\tau)d\tau + bht - bhL_d$, where h is the amplitude of step excitation.

From which a regression model can be obtained on model parameters $\{a, b, bL_d\}$. The parameters can be computed in one step using the least-squares method, and a model-based PID tuning method can be used. Several methods can be found in literature (O'DWYER, 2006). The following techniques: Ziegler-Nichols, Cohen-Cohn, Chien-Hrones-Reswick-Load-0% (CHR-Load-0%), CHR-Load-20%, CHR-Setpoint-0%, CHR-Setpoint-20%, IMC - First Order and SIMC are implemented in BR-TUNING.

2.2. Relay-based Identification and PID Tuning

The standard relay feedback experiment (see Figure 2) was introduced in (Åström and Hägglund, 1984). The theory for analyzing the plant under relay feedback was based on the well knows describing function analysis, which also contributed to make the method widely accepted. With this experiment, a single point of process frequency response, the critical point (phase angle –180°), can be estimated. Applying the relay experiment, the output, for most systems, has a limit cycle which occurs near the critical frequency. The values of critical gain (K_c) and critical frequency (ω_c) are estimated using DFT (Discrete Fourier Transform) of input-output process data (MV and PV signals).

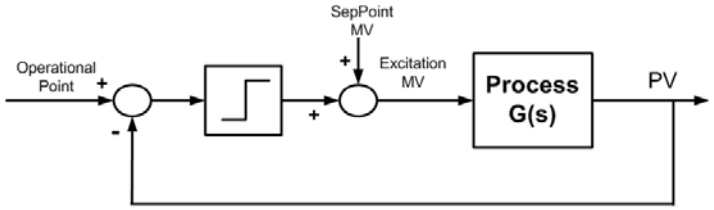

Figure 2: Relay Feedback Experiment

With the critical point, it is possible to design a PID controller. The BR-TUNING implements following techniques: Ziegler-Nichols, Clair, Tyreus-Luyben, With Some Overshoot and No Overshoot, for details about these techniques a good reference is (O'DWYER, 2006).

3. Relay-Based Closed-Loop Evaluation

In this section, modified relay experiments are presented to evaluate the closed-loop gain and phase margins. Consider the closed-loop shown in Figure 3. The unknown process transfer function is given by $G(s)$ while the controller is given by $C(s)$.

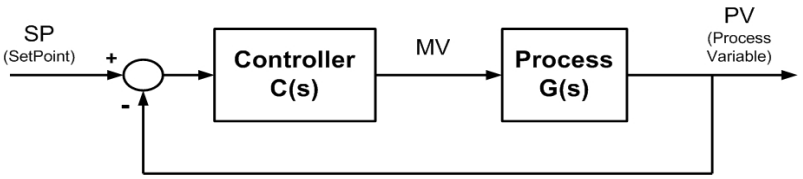

Figure 3: Closed-Loop Process

The closed-loop transfer function from setpoint signal SP to PV signal is given by

$$\frac{\mathrm{PV(s)}}{\mathrm{SP(s)}} = \frac{G(s)C(s)}{1+G(s)C(s)} = T(s)$$

The gain margin (GM) can be estimated with the relay structure, as shown in Figure 4 (See (Schei, 1992)), applied to the closed-loop T(s). Applying a relay with amplitude d to the closed-loop yields a limit cycle near the critical frequency (ω_u) of the loop transfer function. The loop gain at that frequency can be computed as

$$L(j\omega) = G(j\omega)C(j\omega) \cong \frac{m}{1-m},$$

where $m = \frac{-\pi a}{4d}$ and a is the closed-loop output amplitude.

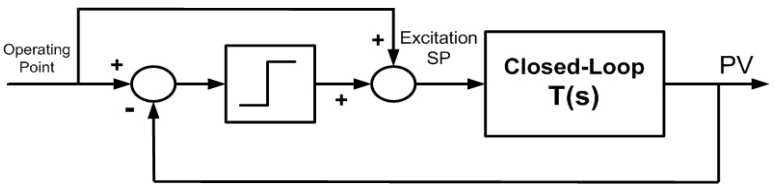

Figure 4: The Gain Margin Relay Test Structure

In BR-TUNING, a more refined algorithm to estimate closed-loop critical frequency information is implemented. This algorithm using DFT (Discrete Fourier Transform) of the SP and PV signals to define ω_u and $T(j\omega_u)$. With this, we can define $L(j\omega_u)$ as

$L(j\omega_u) = \frac{T(j\omega_u)}{1-T(j\omega_u)}$, and the gain margin is defined as $GM = \frac{1}{|L(j\omega_u)|}$.

The closed-loop phase margin can be obtained using the relay structure shown in Figure 5. This structure was introduced in (Schei, 1992) and generalized in (Arruda and Barros, 2003a).

Estimate the crossover frequency (ω_g), $T(j\omega_g)$ and $L(j\omega_g)$ in the same way using DFT. The phase margin is defined as $PM = \pi + \angle L(j\omega_g)$.

For more details about the algorithm to estimate closed-loop margins using DFT and relay tests structures can be found in (Arruda and Barros, 2003a).

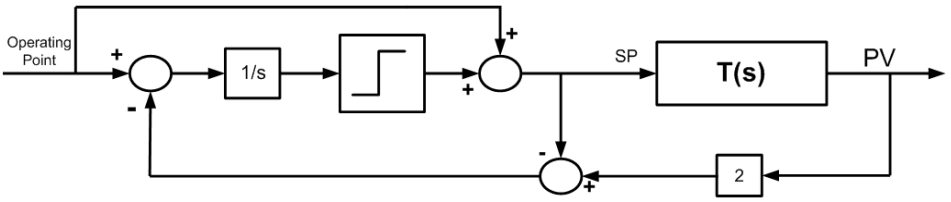

Figure 5: The Phase Margin Relay Test Structure

4. PI Controller Iterative Redesign

Consider the closed-loop shown in Figure 2 and gain and phase margins specifications given by A_m and φ_m respectively. For the desired specifications the controller must be designed to satisfy the following set of equations:

$$\angle G(j\omega_u)C(j\omega_u) = -\pi\,, \quad |G(j\omega_u)C(j\omega_u)| = \frac{1}{A_m}\,,$$

$$|G(j\omega_g)C(j\omega_g)| = 1 \text{ and } \angle G(j\omega_g)C(j\omega_g) = -\pi + \varphi_m$$

If $G(j\omega)$ is known, the PI controller design requires the solution of the set of equations for K_p, T_i, ω_u and ω_g a total of four unknowns and four equations and it is a non-linear problem. In (Arruda and Barros, 2003), an iterative algorithm is used which requires the estimation of the frequencies ω_u and ω_g and the gain and phase margins at each iteration. After each relay test the controller is updated to correct for the gain or phase margin. The scheme can be interrupted whenever a both specifications are met within tolerated limits. The design procedure, presented in details and with safety considerations, in (Arruda and Barros, 2003) is as follows: At each iteration assume an existing controller $C^0(s)$, with parameters $K_p{}^0$, $T_i{}^0$.

4.1. Gain Margin Redesign

Estimate GM and frequency ω_u, and redesign the controller for Gain Margin using

$$K_p = \frac{K_p{}^0 GM}{A_m}\,, \quad \text{so that the new controller is } C(s) = K_p\left(\frac{s+1/T_i}{s}\right).$$

4.2. Phase Margin Redesign

Estimate PM and the gain crossover frequency ω_g:

a) Compute the integral time $$T_i = \frac{\tan\left(-\pi - \varphi_m - PM + \tan^{-1}\left(\omega_g T_i{}^0\right)\right)}{\omega_g}.$$

b) Adjust the proportional gain. $$K_p = K_p{}^0 \frac{\sqrt{\left(1/T_i{}^0\right)^2 + \omega_g{}^2}}{\sqrt{\left(1/T_i\right)^2 + \omega_g{}^2}}.$$

5. The Experimental Results

In this section, application results of the BR-TUNING in PETROBRAS' UN-RNCE are presented.

5.1. Temperature Control Loop TIC_29051 – Open-Loop Example

The first loop is a temperature control named TIC_29051. An open-loop step excitation was applied. The FOPDT model estimated using BR-Tuning is $\hat{G}(s) = \frac{0.925}{93.62s+1} e^{-18s}$.

In Figure 6, the step responses of open-loop process (blue curve) and estimated model are shown. The mean-squared error computed for estimated model was 0.008. The PID controller was designed using IMC technique with filter time constant 93.6 sec.

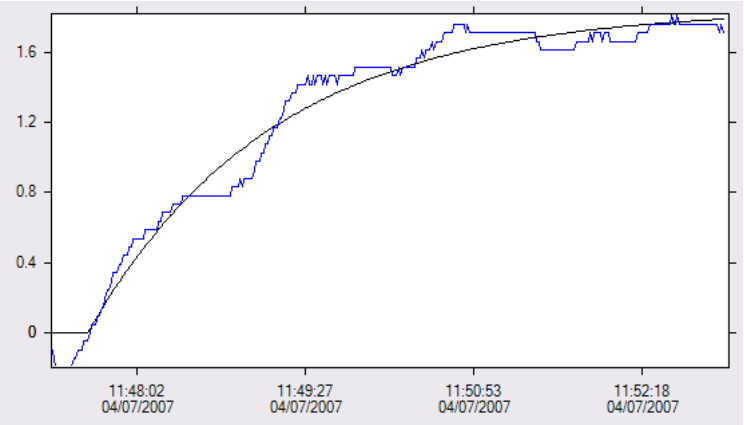

Figure 6: BR-TUNING Window – Open-Loop Identification

The designed controller is $C(s) = 0.99\left(1 + \frac{1}{1026.1s} + 8.2s\right)$. The control loop performances of TIC_29051 with the older and the new controller are shown in Figure 7.

5.2. Flow Control Loop FIC_29020 – Closed-Loop Example

The second loop is a flow control named FIC_29020. In this loop, relay tests for closed-loop gain and phase margins evaluation are performed. The estimated gain and phase margins are $GM = 1.104$ and $PM = 49.36°$. This is very aggressive from the gain and phase margins side. The gain margin specification $A_m = 2$ yields a controller gain $K_p{}^1 = 0.25$ and $T_i{}^1 = 0.05\,\text{sec}$, while a redesign for a phase margin $\varphi_m = 70°$ results in a controller with com $K_p{}^1 = 0.633$ and $T_i^1 = 0.0336\,\text{sec}$. The objective is to achieve a more stable control loop, the chosen controller was the phase margin with the gain from the gain margin:

$$C(s) = 0.25\left(1 + \frac{1}{0.0336s}\right).$$

The control loop performance for SP signal step changes of FIC_29020 with older and new controller is shown in Figure 8a and 8b respectively. Note that the response with new controller is less aggressive when compared with the response with older.

6. Conclusion

In this paper application results of the BR-TUNING in a petrochemical plant was presented. Moreover, the algorithms for identification and PID tuning implemented in BR-TUNING were reviewed. The obtained results showed the properties of the algorithms and these practical effectiveness.

Abstract

The present work is concerned with a dynamic optimization problem involving the methyl methacrylate (MMA) free-radical batch solution polymerization reaction to produce poly-methyl methacrylate (PMMA). Ethyl acetate is used as solvent and benzoyl peroxide (BPO) as the reaction initiator. A dynamic model that represents the batch reaction process is presented. The model equations are solved in order to maximize the performance index defined as MMA conversion rate (X_m). The optimization process will indicate the trajectories for the reactor temperature (T), the cooling water flow rate (F_{cw}) and the heating power (Q) supplied to the reactor through an on/off switch system. X_m is optimized in accordance with the experimental reactor operation and safety conditions. The reaction time of 350 minutes is divided in discretized intervals. The reactor temperature and the control variables (F_{cw} and Q) are assumed piecewise constant in each time interval. To perform the optimization a program based on the Iterative Dynamic Programming (IDP) technique is successfully developed. The optimization results demonstrated that IDP technique is suitable for the optimal control of MMA-PMMA system, and probably for other batch polymerization processes with high complexity and nonlinearity.

Keywords: Batch Reactor, Dynamic Programming, Optimization, IDP, MMA.

1. Introduction

In this work, the MMA batch polymerization reaction was chosen as case-study. MMA polymerization process in batch reactors has been largely studied in the last decades. Important contributions on MMA polymerization can be found in the specialized literature (Ellis et al. (1988); Mutha et al. (1997); Soroush e Kravaris (1992); Rho et al. (1998); Jeong e Rhee (2000); Ahn et al. (1998), Chang e Liao (1999); Chae et al. (2000); Rafizadeh (2001)). By nature batch reactors are transient and are modeled by a combination of Differential and Algebraic Equations (DAEs) of distinct levels of complexity. To solve these equations important techniques have been used as Pontryagin's Maximum Principle (Zeybek et al. (2004)), Genetic Algorithms (Upreti et al. (2005)), Control Vector Parameterization (CVP) (Ekpo and Mujtaba, 2007), and IDP (Luus, 1991) chosen for this work. In the IDP approach, a piecewise constant control policy is found by employing dynamic programming in an iterative fashion. It uses a contraction of the region over which allowable values of the control are taken randomly (Palanki & Vemure, 2005). The choice of random values was proposed by Bojkov & Luus (1992) to overcome the difficulty of dealing with control vectors of high dimensionality presenting faster convergence to optimum. This strategy has been

applied in a variety of batch applications (Luus, 1993a; Luus, 1993b). Sayer et al. (2001) applied IDP to compute optimal monomer and chain transfer agent feed profiles to produce polymer with specified copolymer composition and molecular weight distribution. More recently, Sayer et al. (2006) implemented IDP strategy to optimize the off line optimal trajectories for the less reactive feed flow rate and for the reactor set-point temperature. In the present study, the IDP technique is applied to optimize X_m and obtain the optimal trajectories of T, F_{cw} and Q, for the system MMA-PMMA.

2. Mathematical Modeling

The same experimental reactor scheme initially designed by Pedrosa et al. (2001) and used by Antunes et al. (2005) is considered for the IDP off line optimization. The reaction is supposed to be carried out inside a jacket glass batch reactor (Figure 1). The feed of F_{cw} for the jacket is regulated by a control valve, and monitored in terms of inlet and outlet temperatures. The system is equipped with two electrical heaters of 0.075 and 0.045 kJ/s, respectively. The first one remains on during the reaction time while the second is hypothetically controlled by an on/off basis, which occurs respectively, when the temperature deviates –4 or +4 ºC from set-point of 63ºC (336.2 K). These conditions for T were defined by Antunes et al. (2005), according to the real reactor characteristics, and operation/safety conditions, which are considered as the basis of this study. To represent the MMA solution polymerization reaction in the batch reactor, it was chosen the principle model studied by Ray et al. (1995) as well as Seth and Gupta (1995), which considers the mass balance and moments of the live and dead polymer concentrations distributions. Chakravarthy (1997) improved this model by introducing the gel, cage and glass effects. According to Gosh et al. (1998), predictions of this model demonstrated a perfect agreement when compared to their experimental results and with those reported earlier in the literature. Once the conditions adopted in the present study for MMA polymerization reaction are close to those used by Gosh et al. (1998), the model was considered reliable and was not experimentally validated. The following DAEs for the model are presented below:

BPO initiator consumption:

$$\frac{dI}{dt} = -k_d I + R_{Ii}(t) \tag{1}$$

Mass balance to the primary radical:

$$\frac{dR}{dt} = 2fk_d I - k_i \frac{RM}{V_l} \tag{2}$$

Monomer consumption:

$$\frac{dM}{dt} = -(k_p + k_f)\frac{\lambda_o M}{V_i} - k_i \frac{RM}{V_l} - k_s S \frac{\lambda_0}{V_l} + R_{Im}(t) - R_{vm}(t) \tag{3}$$

Solvent consumption:

$$\frac{dS}{dt} = R_{Is}(t) - R_{vs}(t) \tag{4}$$

Moments of the live polymer concentrations distributions, λ_i:

$$\frac{d\lambda_0}{dt} = k_i \frac{RM}{V_l} - k_t \frac{\lambda_0^2}{V_l} \tag{5}$$

$$\frac{d\lambda_1}{dt} = k_i \frac{RM}{V_l} + k_p M \frac{\lambda_0}{V_l} - k_t \frac{\lambda_0 \lambda_1}{V_l} + \left(k_s S + k_f M\right)\frac{\left(\lambda_0 - \lambda_1\right)}{V_l} \tag{6}$$

$$\frac{d\lambda_2}{dt} = k_i \frac{RM}{V_l} + k_p M \frac{(\lambda_0 + 2\lambda_1)}{V_l} - k_t \frac{\lambda_0 \lambda_2}{V_l} + (k_s S + k_f M)\frac{(\lambda_0 - \lambda_2)}{V_l} \quad (7)$$

Moments of the dead polymer concentration distributions, μ_i:

$$\frac{d\mu_0}{dt} = \left(\frac{1}{2} ktc + k_{td}\right)\frac{\lambda_0^2}{V_l} + (k_f M + k_s S)\frac{\lambda_0}{V_l} \quad (8)$$

$$\frac{d\mu_1}{dt} = k_t \frac{\lambda_0 \lambda_1}{V_l} + (k_f M + k_s S)\frac{\lambda_1}{V_l} \quad (9)$$

$$\frac{d\mu_2}{dt} = k_{tc} \frac{\lambda_1^2}{V_l} + k_t \frac{\lambda_0 \lambda_2}{V_l} + (k_f M + k_s S)\frac{\lambda_2}{V_l} \quad (10)$$

Variables to account addition and vaporization of monomer after time t = 0, kmol/m^3:

$$\frac{d\zeta_m}{dt} = R_{lm}(t) - R_{vm}(t) \quad (11)$$

$$\frac{d\zeta_{ml}}{dt} = R_{lm}(t) \quad (12)$$

Volume of reacting mixture at time t, m^3:

$$V_l = \frac{S(MW_s)}{\rho_s} + \frac{M(MW_m)}{\rho_m} + \frac{(\zeta_m - M)(MW_m)}{\rho_p} \quad (13)$$

Energy balance in the reactor:

$$\rho\, c\, \frac{dT}{dt} = (-\Delta H_P) k_P M \lambda_0 + U\, A\, (T_j - T) \quad (14)$$

Energy balance in the jacket:

$$\rho_w c_w \frac{dT_j}{dt} = UA(T - T_j) + U_\infty A_\infty (T_\infty - T_j) + [Q - F_{cw}\rho_w c_w (T_j - T_{cw})] \quad (15)$$

Luus (2000) describes that the best way of dealing with difficult equality constraints is the use of a quadratic penalty function incorporating a shifting term. Then, to complete the model equations, X_m is used as an augmented performance index as follow:

$$I = X_m + \theta(X_m - s)^2 = \left(1 - \frac{M}{\zeta_{m1}}\right) + \theta\left[\left(1 - \frac{M}{\zeta_{m1}}\right) - s\right]^2 \quad (16)$$

where θ is a positive penalty function factor and the shifiting term is inittialy put to zero and then, after every pass q, updated by:

$$s^{q+1} = s^q - X_m \quad (17)$$

The state vector $\boldsymbol{x}$ can be generically expressed as:

$$x = [I, M, R, S, \lambda_0, \lambda_1, \lambda_2, \mu_0, \mu_1, \mu_2, \zeta_m, \zeta_{m1}, T, T_j, I_{pf}]^T \quad (18)$$

Additional equations and values for cage, gel and glass effects, besides other parameters used in this work are found in the sources: Achilias et al. (1992), Chakravarty et al. (1997); Ellis et al. (1988); Gosh et al. (1998); Soroush e Kravaris (1992).

3. Optimal Control Technique

To optimize X_m, a program in Matlab for the IDP technique implementation was developed. As all the steps involving the IDP algorithm are very well documented in the literature, they are not described in details in this work. To implement IDP, it was necessary to create a program subdivided in main routine and additional subroutines. To solve the model equations, Matlab's ode23tb function was inserted as a subroutine in

the IDP main program. It is suitable for solving stiff differential equations as in the case of MMA polymerization. The developed program permits to divide the time interval [0, *tf*] into *P* [0, 20] stages of equal time length *L*. To choose the values for the control variable $\boldsymbol{u}$ (F_{cw}) and the number of $\boldsymbol{x}$-grid points *N*, the Matlab's function *rand* (an *N*-by-*N* matrix with random entries) was used to generate random values to accelerate the convergence process (Luus, 2000). To assure the random values inside the region permitted for control (in agreement with reactor operation and safety conditions), the clipping technique was used:

For the control variable: $F_{cw} = 26.7x10^{-5}\, m^3/s \quad if \quad F_{cw} \geq 26.7x10^{-5}\, m^3/s$ *(20)*

$F_{cw} = 8x10^{-6} \quad if \quad F_{cw} \leq 0$ *(21)*

For the state variable: $T = 340.2\, K \quad if \quad T \geq 340.2\, K$ *(22)*

$T = 332.2\, K \quad if \quad T \leq 332.2\, K$ *(23)*

It is important to emphasize that the clipping rules are used only to supply the lower and upper limits for the IDP comparisons, but are not used as constrains during the integration process. The heating system was composed by two on/off electrical heaters following the clipping rules:

Both heaters on: $Q = 0.12\, kJ/s \quad if \quad T \leq 332.2K$ *(24)*

Only one heater on: $Q = 0.075\, kJ/s \quad if \quad T \geq 340.2K$ *(25)*

Figure 2 (Schröder and Mendes, 1999) illustrates an example for the optimal trajectory obtained for $\boldsymbol{x}$ at the end of the first IDP iteration. The configuration used was *P* = 10 stages (vertical lines) and **N** = 5 $\boldsymbol{x}$-grid points (black dots). The solid line from stage 1 to *P* is the trajectory for each stage obtained during the integrations for the first iteration. All the lines at the stages *P* and *P* – 1 represent the partial results obtained by the integrations using different *N* $\boldsymbol{x}$-grid points and *R* random values for **u** control variables.

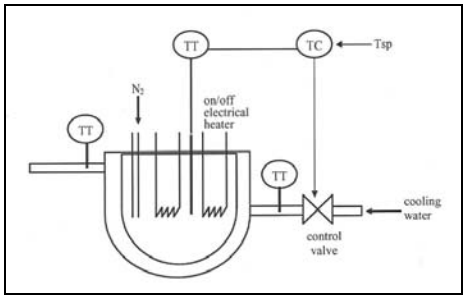

Figure 1 – Batch Reactor Scheme for MMA polymerization (Antunes, 2005)

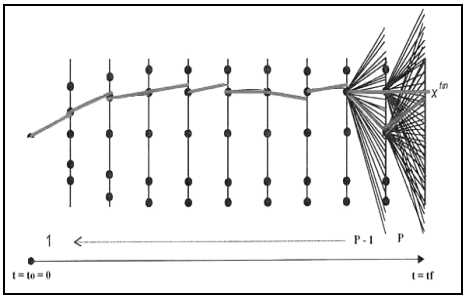

Figure 2 – Optimal Trajectory for $\boldsymbol{x}$-Grid Points in the First Iteration

4. Results

During the optimization process several IDP configurations for *N* $\boldsymbol{x}$-grid points and *R* random values for F_{cw} were tested. The best results for X_m were obtained by an IDP configuration with *P* = 20, *N* = 20 and *R* = 20 (Figure 3). The trajectories for *T*, F_{cw} and *Q*, are shown in Figures 4 to 6. The optimization result of 0.5322 for X_m is 33.05% higher than 0.4 obtained experimentally by Antunes (2005) using a fixed *T* set point of 336.2 K tracked by a PID controller. Probably this improvement on the value of X_m is due to *T* trajectory obtained by the IDP off line optimization, which suggests the use of different set points for each time interval (Figure 4), instead of a fixed set point.

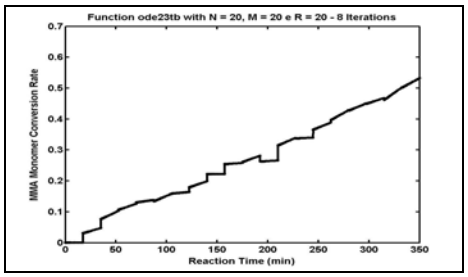

Figure 3 – MMA Conversion Rate

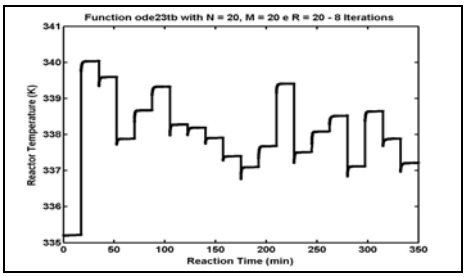

Figure 4 – Reactor Temperature

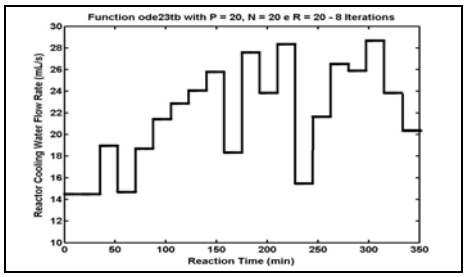

Figure 5 – Cooling Water Flow Rate

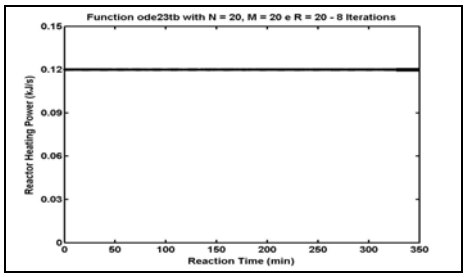

Figure 6 – Reactor Heating Power

The behavior of T, F_{cw} and Q (Figures 4 to 6) are in accordance with the reactor operation and safety conditions. At the second stage in Figure 4, T reached the superior permissible limit and F_{cw} was increased to balance the system, while the two heaters kept switched on during the reaction time (Figures 5 and 6). At 200 minutes, X_m calculated by the model has a small decrease (Figure 3) of about 0.02, which is naturally unfeasible. Additionally, the data between some of the discretization intervals apparently shows a pseudo discontinuity in X_m trajectory. However, both observations can be explained by the IDP methodology. For example, when the system equations are integrated from $tf - 2L$ to $tf - L$, it is unlikely that the state $\boldsymbol{x}(tf - L)$ will be exactly one of the $\boldsymbol{x}$-grid points at stage P. This problem of not hitting an $\boldsymbol{x}$-grid point exactly is overcame by taking the optimal control policy corresponding to the $\boldsymbol{x}$-grid point that is closest to the state $\boldsymbol{x}(tf - L)$. As has been shown by DeTremblay and Luus (1989), this gives a good approximation if a sufficiently large number of $\boldsymbol{x}$-grid points and of allowable values for control are used. Figure 4 shows that T increases and decreases very fast. Although it is well known that U changes considerably with X_m, it was not taken into account by the model. It is reasonable due to the high dilution used in this work (S = 8.833 kmol/m^3 and M = 2.413 kmol/m^3). For this dilution condition U does not change significantly. Naturally T affects the characteristics of PMMA produced. For example, the number average molecular weight (Mn=Mm[$(\mu_1+\lambda_1)/(\mu_0+\lambda_0)$]) is different when T is constant and when T varies. The experimental value obtained by Antunes et al. (2005) after the runs by the gel permeation chromatography technique was 4.1x10^5 kg/kmol for Mn, while the IDP optimization results indicated 4.9x10^5 kg/kmol for Mn. As a matter of fact, Mn will be the major concern as performance index in future works and this justifies not using a maximum constant T during the MMA polymerization to maximize X_m.

5. Conclusions

The present work is concerned with the optimization of MMA batch solution polymerization reaction. It was successfully developed a program in Matlab to perform an off line optimization through IDP technique. The control variables used were F_{cw} and

Q, and the model equations were reliable to predict the polymerization reaction behavior. The choice of IDP technique and X_m as performance index supplied relevant subsidies on the trajectories for T, F_{cw} and Q, which can be used in future for experimental works in order to improve the reactor performance and PMMA production. These subsidies showed that the definition of different set points for T at each time interval affects positively the process, and contributes to achieve better results for X_m in comparison with the use of a fixed set point for the whole reaction time. In the experimental reactor of Figure 1, the T profile obtained from IDP procedure (Figure 4) would be implemented as set point tracking using a conventional or advanced temperature controller. Regarding the relevance and power of IDP, for future works the reactor performance should be evaluated in terms of optimum global efficiency and PMMA characteristics. An augmented perform index could be created by unifying the properties *Mn*, *Mw* (number average molecular weight) and X_m, (Upreti, 2005).

Nomenclature

A, $A\infty$	Reactor-jacket and surrounding-jacket heat transfer surface areas, m^2
c, c_w	heat capacity of reacting mixture and water, kJ/kg.K
f_o, f	initiator initial efficiency and at any time t
k_d, k_i, k_f, k_p,k_s, k_{tc}, k_{td}	rate constants for the equations 1 to 10 at any time t (s^{-1} or $m^3.mol^{-1}.s^{-1}$)
I, I_{pf}	concentration of initiator, $kmol/m^3$; or performance index, dimensionless
M	concentration of monomer, $kmol/m^3$
MW_I, MW_m, MW_s	molecular weight of pure initiator, monomer and solvent, kg/mol
R_{li}, R_{lm}, R_{ls}	primary radical of initiator, monomer and solvent in liquid phase, $kmol/m^3$
R_{vm}, R_{vs}	primary radical of monomer and solvent in vapor phase, $kmol/m^3$
S, s	concentration of solvent, $kmol/m^3$, and shifting term for the penalty function
T, T_{cw}, T_j, T_∞	temperature of reactor, inlet cooling water, jacket and room respectively, K
$\boldsymbol{u}$	control variable vector
U, U_∞	overall heat-transfer coefficients of reactor-jacket and jacket-surrounding, $kJ/m^2.s.K$
$\boldsymbol{x}$, X_m	state variable and monomer conversion rate
ΔH_p	heat of propagation reactions, kJ/kmol
ρ, ρ_{cw}, ρ_s, ρ_m, ρ_p	density of reacting mixture, water, MMA liquid, polymer or solvent respectively, kg/m^3

Abstract

Pultrusion is a continuous polymeric manufacture process for producing composite parts with constant cross-sectional profiles. In this process, the fiber/resin mixture is continuously pulled through a heated die at constant speed. As the fiber/resin system goes through the die cavity, a cure reaction occurs and this reaction releases a considerable amount of energy. But initially, the die needs to be heated in order to start the cure reaction. For this objective, electrical heaters are generally used on die surface to provide enough energy to start the polymerization reaction. The heating power must be carefully designed to achieve a minimum degree of cure. In this present work, an "I" beam geometry using a configuration with internal heaters was simulated by Finite Volume Method, based on a computational fluid dynamics package. Thus, a sum of all heating power was considered as the objective function in order to find the minimal energy consumption. This process heating overall cost was minimized applying a stochastic algorithm, the so-called particle swarm optimization (PSO) algorithm. The hybrid nature of the developed computational program evolves CFD tools to simulate the process allied with a PSO algorithm to optimize it. The obtained results showed that the heat flux spent to cure the resin-fiber system may be considerably reduced producing a significant decrease in process cost. The superior quality of the results was characterized by their comparison with reported literature values. At the same time, the developed methodology was always capable to find an optimum design of pultrusion process.

Keywords: cure reaction, computational fluid dynamics, optimization, particle swarm.

1. Introduction

Pultrusion is a continuous polymeric manufacture process for producing composite parts with constant cross-sectional profiles. In this process, the fiber and resin mixture is continuously pulled through heated die at a constant speed. As the fiber/resin system goes through the die, a cure reaction occurs and this reaction causes the change of composite physical properties besides a considerable energy production, because of the reaction exothermic characteristic (Pagano *et al*. 2006). A schematic diagram of pultrusion is shown in Fig. 1.

Some studies have been conducted in order to gain an understanding of the pultrusion optimization. Li *et al*. (1999) optimized the pultrusion process based on the uniformity of the degree of cure at the die exit. The optimization procedure has been applied in

order to obtain a part characterized by a good quality, i.e. a uniform distribution of the degree of cure with a satisfactory mean value, at the exit of the forming die. This procedure was based on an iterative procedure by using the Steepest Descent coupled to finite element method. Carlone *et al*. (2007) used a hybrid method based on genetic algorithms and simplex method for minimizing the same function proposed by Jianhua *et al*. (2001). However, these researchers failed to provide methods that regard economic objectives. Coelho and Calado (2001) proposed an economical objective function with the aim to find the optimal temperature profile using the Simulating Annealing Method. Srinivasagupta *et al*. (2003) used a multi-objective optimization which involves control, environmental and quality aspects for injected pultrusion optimization. The approach was successful in determining optimal values of the processing parameters such as heating zone temperatures, as well as the equipment specifications (die dimensions and heater) that satisfy the multiple objectives. However, it was seen that the economic objective did not coincide with quality aspects objectives and a tradeoff becomes necessary.

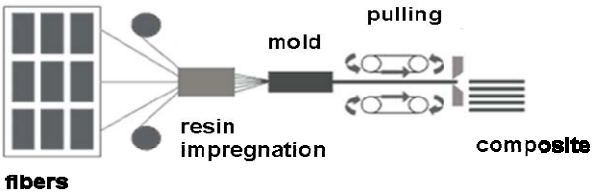

Figure 1. Schematic diagram of pultrusion process.

In the present investigation, a numerical procedure based on CFD technique and a stochastic optimization algorithm is developed. Our strategy is to join the desirable characteristics of CFD tools and Particle Swarm Optimization (PSO) algorithm (Kennedy and Eberhart) to result in an efficient optimization procedure. The aim is to minimize the process cost, represented by an objective function. The application of this technique on pultrusion process has not been explored yet.

2. Mathematical model

2.1. Equations

The mathematical model of the steady state pultrusion process is composed by the energy balance and the kinetic cure reaction. These equations can be written as:

$$\rho_c \; C_{pC}\left(u_i \nabla T\right) = k_c \nabla^2 T + c_{in}(1-\phi)\left(-\Delta H\right)R_a \tag{1}$$

$$\frac{d\alpha}{dz} = R_a = \left(Ae^{\left(\frac{-Ea}{RT}\right)} \right)(\alpha)^m (1-\alpha)^n \tag{2}$$

where T is temperature, u velocity vector, C_c specific heat of the composite, k_c thermal conductivity of the composite, ($-\Delta H$) total heat generated, ρ_c the density of the composite, R_a resin reaction rate, ϕ fiber volume fraction, c_{in} resin initial concentration, α degree of cure, A frequency factor, E activation energy, and m, n is the reaction order. In this work, the degree of cure was assumed to be zero *(α = 0)* before the fiber-resin system entering into the die, and the inlet temperature was

considered as 298 K. In order to compare our results with the results presented by Liu X.L (2001) the same physical and kinetic parameters were considered here, shown in Table 1.

Table 1. Physical and Kinetic Parameters

Fiber fraction ***(Φ)***	0.55

Order of reaction ***(n+m)***	2
Universal constant of gases ***(R)***	1.98 (cal/mol. K)
Heat generated ***(ΔH)***	398 (J/g)

2.2. Optimization procedure

In order to propose the pultrusion process optimization it was used an objective function similar to that proposed by Coelho and Calado (2001), which represents the process profit per unit time:

$$F = Q_{spent}.P_e \tag{3}$$

where Q_{spent} is the total heat rate spent to cure the system and P_e is the price of energy consumed.

The constrained non-linear optimization problem is written as:

$$\min_{\theta,\alpha\in\Re^n} F(q,\alpha) \tag{4}$$

subjected to:

$$g(\theta) = \alpha_{\min} - \alpha$$

where $\alpha_{\min}$ is the minimum desired value of degree of cure.

The problem is formulated as a new unconstrained optimization problem by adding a quadratic penalty function:

$$F(q,\alpha) = F + \psi.[\max(0, g(\theta))]^2 \tag{5}$$

where ψ is the penalty parameter.

The optimization procedure method applied to minimize the objective function was PSO (Kennedy and Eberhart). This method allows a global minimization in a predefined search region, without the need of initialization parameter guesses and without differentiation of the objective function. In this method, a set of points, nominated particles, is configured to find the optimal value of objective function.

CFD packages enable to model engineering problems in a realistic geometry with good mesh resolution. The software used here is the Ansys CFX^{TM}, a CFD package

based on finite volume method. In this technique, the region of interest is divided into small sub-regions, called control volumes. The equations are discretized and solved iteratively for each control volume. However, it is not provided of optimization tools. Our strategy is to compound characteristics of CFD tools with a PSO algorithm to design optimal heating strategies of the process. In the proposed strategy, PSO estimates heat flux values and transfers these values to a management algorithm that starts the CFD package. At the end of simulation, the algorithm reads the final value of degree of cure. According to simulation results, PSO estimates new values of heat flux and starts the same procedure until the convergence, as illustrated in Fig. 3.

In a previous paper, Liu *et al.* (2001) used a three-dimensional model for simulating the pultrusion of vinyl-ester-fiberglass I-beam composite. The procedure is successful in predicting the temperature and curing profiles in the pultruded material under different process conditions. The temperature predictions were verified by comparing to the experimental results published in the literature.

Assuming this fact, our methodology is to decrease the superficial area of heaters intended to minimize the energy consumption used in the process. We believe that the typical heater configuration, suggested by Liu *et al.* (2001), is not efficient because it spends high amount of thermal energy. We proposed a heat configuration consisted of five cylindrical heaters inside an insulated die. This configuration increases algorithm possibilities to find optimal heat arrangements.

Pultrusion was conducted using an insulated steel die of 1020 mm in length. Heater dimension is 5 cm of diameter and 14 cm of length. Adopted mesh consists of 170617 nodes and 888242 elements. Using symmetry, only a quarter of pultrusion tool should be considered in the numerical model.

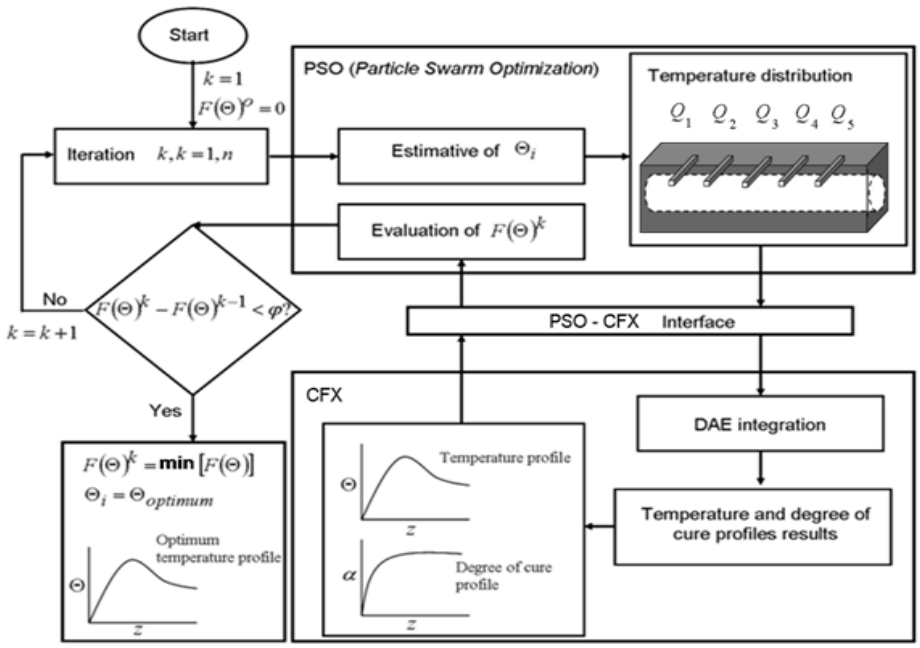

Fig.3. Illustration of optimization procedure.

3. Results

Optimization results of composite and die are shown in the following figures.

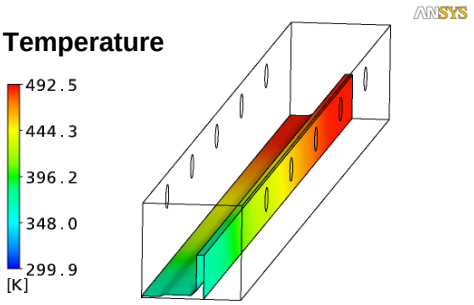

Fig. 4. Composite temperature profile.

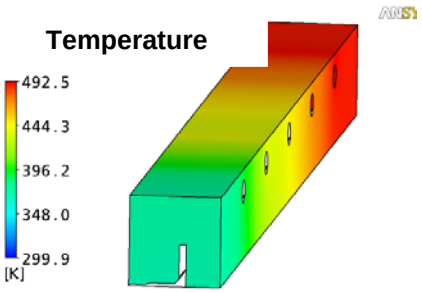

Fig.5. Die temperature profile.

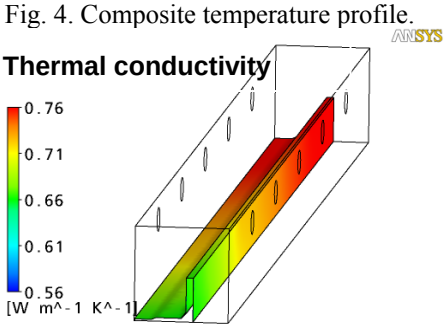

Fig.6. Thermal conductivity.

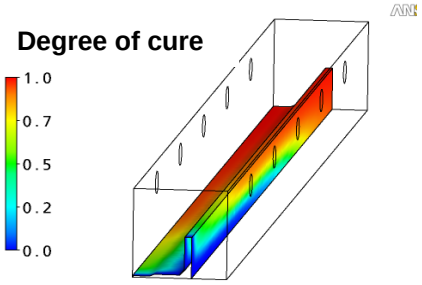

Fig.7. Degree of cure profile.

Temperature distribution of composite and die part are shown in Fig. 4 and 5. When the exothermic reaction starts, released heat raises the composite temperature until 492 K. Fig 6 shows that thermal conductivity increases with temperature and degree of cure. Fig.7 shows that the degree of cure achieves its maximum value at die exit; this figure clearly demonstrates that the die was adequately heated providing complete cure of the resin.

Optimization results are shown in Table 2. At each iterative step, PSO estimates heat flux values of each heater. Efficiency of the algorithm is well characterized in Table 2 through the value reduction of heat rate in successive iterations. Based on the obtained results, energy used to cure the resin/fiber system may be considerably reduced. The results show that the best choice is to use only the third heater with a heat flux of 67.69 $kW \cdot m^{-2}$ or 446 K. This arrangement results in a total heat rate of 6.7 kW while Liu *et al.* (2001) used 9.2 kW, meaning that there is the possibility to cure the material with lower energy consumption and our configuration is approximately 26% more economic.

Table 2. Optimization results

Iteration	q_1 ($kW.m^{-2}$)	q_2 ($kW.m^{-2}$)	q_3 ($kW.m^{-2}$)	q_4 ($kW.m^{-2}$)	q_5 ($kW.m^{-2}$)	Total heat rate *(kW)*
1	23.35	62.15	42,05	26,42	32,41	18.24
2	18.87	4.70	53.72	48.98	32.10	15.84
3	0.00	0.00	38.30	37.69	18.19	16.66
4	0.00	0.00	47.98	33.80	0.00	8.17
5	4.24	5.32	45.07	22.63	1.26	7.85
6	0.83	0.00	38.54	38.91	0.00	7.82
7	3.18	0.00	42.29	31.89	0.00	7.73
8	0.00	0.00	67.69	0.00	0.00	**6.77**

4. Conclusions

In the present paper, it was verified that smaller energy consumption can be obtained with the suggested heat strategy in a pultrusion process. This economy was verified by the reduction of the surface area of the heaters causing a significant decrease of the energy consumption. This present heat configuration seems to be a good alternative to improve global thermal efficiency of the process.

PSO algorithm coupled to CFD code was successful in finding an optimal temperature profile resulting in a minimal process cost. Our results showed that the algorithm converges to the minimal value of heat rate. Furthermore, the solution did not violate the constrained region defined in the mathematical formulation. This characteristic guarantees the efficiency of PSO in finding the optimal solution. The results obtained herein suggest that new studies about heater arrangements of the pultrusion process must be made.

Abstract

Optimization technique for the solid-liquid equilibrium calculation of binary fat mixtures with natural origin was used with the software GAMS. The calculation of phase equilibrium is based on the minimization of Gibbs free energy of the system. For the thermodynamic representation of mixtures Margules and the Slaughter & Doherty Model were used the former referring to the liquid phase and the latter for the solid one. The mixtures studied are composed by saturated, insaturated fat acids and triglycerids. The models developed in this work are written in a convex nonlinear programming, so that the optimal solution found is the global optimum. Therefore, the results found are the equilibrium points.

Keywords: Solid-Liquid Equilibrium, Gibbs free energy, eutectic and peritectic points, convexity analysis, Global minimization.

1. Introduction

The solid-liquid equilibrium data have an important hole in separation process, like extraction, distillation, absorption, and others, they are also used in foods, pharmaceutical, chemical, and recently in bio-diesel industry. Then (tenta evitar o so), the reliable determination of phase equilibrium is necessary for the correct prediction of phase formation and their composition [1].

Thus, for theoretical determinations by computational programs it is necessary to improve the thermodynamic models that could represent the behavior of the solid and liquid phases, particularly the solid phase, due to the existence of the peritectic point [2,3,4] since most of the available models are able to represent only the eutectic point [4,5,6].

The solid-liquid equilibrium can be calculated in many different ways. In the present work, the minimization of Gibbs free energy was chosen for its calculation. This technique is considered sufficient whereas it guarantees that the equilibrium point was found if the global minimum is too [7,8]. The thermodynamic representation of the solid and liquid phases was made using specific models for each phase. The liquid phase was modeled using Margules 2-sufix equation [2,4]. The solid phase was modeled using a modification of the activity model described by Slaughter & Doherty [9,4], using a mathematical limit. The final equations obtained resulted in an expression for Gibbs free energy.

Oils and fats, which are composed of mixtures of fatty acids, are the main compounds in this work [10]. Three of these mixtures were studied: myristic - palmitic acids, oleic - capric acid and palmitic acid – triestearin. Their Diagram phases could be determinate by the technique developed here.

In this context, the main objective of this work was obtained points which can represent the solid liquid equilibrium of fatty mixtures using mathematical models associated a computational programs by the minimization of Gibbs free energy, using GAMS software, where the convexity analysis guarantee the global minimum, consecutively the equilibrium state.

2. Mathematical model

2.1. *Fundamentals of Minimization of Gibbs free energy technique*

The phase equilibrium could be obtained by Minimization of Gibbs free energy given by [1]:

$$G = \sum_{i=1}^{NC} \sum_{j=1}^{NF} n_{ij} m_{ij} \tag{1}$$

Subject by:

$$n_{ij} \geq 0\,, \quad i = 1,..., NC; \quad j = 1,..., NF \tag{2}$$

That represents the non negativity of mol numbers, and:

$$\sum_{j=1}^{NF} n_{ij} = n_i\,, \qquad i = 1,..., NC \tag{3}$$

That represents the mass balance without chemical reaction.

2.2. Thermodynamics models – Solid and liquid phases

The solid-liquid equilibrium is described by the ratio of fugacities, given by [7]:

$$\ln \frac{f_i^{l,o}}{f_i^{s,o}} = \frac{\Delta h_{f\,i}}{R \cdot T_{t\,i}} \cdot \left(\frac{T_{t\,i}}{T} - 1 \right) - \frac{\Delta c_{p\,i}}{R} \cdot \left(\frac{T_{t\,i}}{T} - 1 \right) + \frac{\Delta c_{p\,i}}{R} \cdot \ln \frac{T_{t\,i}}{T} \tag{4}$$

In equation 4, two simplifications are necessary: the fusion temperature is used instead of the triple temperature and the variation of heat capacity can be neglected The equation is approximated by:

$$\ln \frac{f_i^{l,o}}{f_i^{s,o}} = \frac{\Delta h_f}{R \cdot T_f} \cdot \left(\frac{T_f}{T} - 1 \right) \tag{5}$$

Defining the parameter B_i as:

$$B_i = \ln \frac{f_i^{l,o}}{f_i^{s,o}} = \frac{\Delta h_f}{R \cdot T_f} \cdot \left(\frac{T_f}{T} - 1 \right) \tag{6}$$

For the liquid phase, the equation used to describe the comportment was Margules – 2 suffix, given by:

$$\underline{G}^{ex} = R \cdot T \cdot \sum_{i=1}^{NC} x_i \cdot \ln g_i = \frac{1}{2} \cdot \sum_{i=1}^{NC} \sum_{j=1}^{NC} A_{ij} \cdot x_i \cdot x_j \tag{7}$$

On the other hand, the solid phase was described for an approximation of Slaughter and Doherty [9], given by:

$$g_i^s = \frac{1}{x_i^s + e} \tag{8}$$

The parameter ε in equation 7, was used by Slaughter and Doherty to avoid some numerical problems in the calculation of the equilibrium constant [9]. However, in this

work it is used a different approach for the equilibrium calculation, it can use the limit of $e \to 0$ in the Gibbs free energy.

In this work, the model for the solid phase was considered to be one that obeys the Gibbs-Duhem equation and that has the following properties:

$$g_i^s \cdot x_i^s = 1 \qquad \text{for} \qquad 0 < x_i^s \le 1 \tag{9}$$

$$g_i^s \cdot x_i^s = 0 \qquad \text{for} \qquad x_i^s = 0 \tag{10}$$

$$\lim_{x_i^s \to 0} \left(x_i^s \cdot \ln\left(g_i^s \cdot x_i^s \right) \right) = 0 \tag{11}$$

2.3. *Minimization Problem*

Associating the thermodynamics model for the liquid and solid phases, the Gibbs free energy can be written as:

$$G = \sum_{i=1}^{NC} n_i^0 \cdot m_i^{s,o} - n_p^0 \cdot \Delta G_R^o + n_p^s \cdot \Delta G_R^o + R \cdot T \cdot \sum_{i=1}^{NC} n_i^l \cdot \left[B_i + \ln n_i^l - \ln \sum_{j=1}^{NC} n_j^l \right] + \frac{\sum_{i<j}^{NC} A_{ij} \cdot n_i^l \cdot n_j^l}{\sum_{j=1}^{NC} n_j^l} \tag{12}$$

and satisfying the restrictions:

$$n_i^s + n_i^l = n_i^0 + n_i \cdot \left(n_p^s - n_p^0 \right) \qquad i = 1, \mathrm{K}, NC \qquad i \neq p \tag{13}$$

$$n_i^s \ge 0 \qquad i = 1, \mathrm{K}, NC \tag{14}$$

$$n_i^l \ge 0 \qquad i = 1, \mathrm{K}, NC \qquad i \neq p \tag{15}$$

$$n_p^l = 0 \tag{16}$$

The equilibrium composition is then calculated by minimizing G, given by equation (12), with respect to the variables n_i^l and n_i^s, satisfying the restrictions (14) – (16), at constant T and P. Other quantities that are also kept constant during the minimization are n_i^0, n_i, B_i, A_{ij}, ΔG_R^o, and $m_i^{s,o}$.

3. Algorithm for Optimization

Considering the mathematical problem proposed, the solution was an algorithm applied in GAMS, using the Gibbs free energy minimization with the global minimization, based on the equations developed in the previous section.

The necessaries parameters to obtain the phase diagrams were taken from Rolemberg [2]. The parameters are physical properties of pure compounds, such as melting temperatures (T_f), enthalpy variation at the melting point (Δh_f), the interaction phase parameter of Margules equation (A_{12}), and the Gibbs free energy of reaction (ΔG_R^o).

In mixtures where the formation of the intermediate compound (characterized by the peritectic point) does not occur, the parameter ΔG_R^o can assume any positive value or zero.

Other initial parameters were necessary, the atmospheric pressure *P* = 1.00 atm and the universal gas constant *R* = 1,9872 *cal/mol.K*

After the parameters and models implementation in GAMS, using CONOPT solver, that used GRG solving method, can be possible to obtain diagrams phase of the mixtures studied.

4. Case studies and Numerical Results

In this work, three case studies are considered: myristic acid – palmitic acid, oleic acid - capric acid, palmitic acid - triestearin. These examples and the necessaries parameters were taken from Rolemberg [2], and are presented in Table 1.

Table 1: Parameters for the solid-liquid equilibrium [2]

Compound	T_f (K)	Δh_f (kcal/mol)	A_{12} (cal/mol)	ΔG_R^o (cal/mol)
Myristic acid	327.07	10.800	-297.2904	-308.0957
Palmitic acid	335.02	13.100		
Oleic acid	286.59	9.460	-648.5496	≥ 0
Capric acid	303.98	6.690		
Palmitic acid	335.02	13.100	44.8203	≥ 0
Tristearin	345.27	48.580		

The determination of solid-liquid phase equilibrium can be done by minimization of gibbs free energy method, for the three fatty binary systems. The mathematical model presented resulted in a convex NLP, applied in GAMS, using CONOPT solver.

4.1. Case Study 1 – myristic acid – palmitic acid

The solid-liquid phase diagram for this mixture is the set of points (x_1, T), where compound 1 is myristic acid and compound 2 is palmitic acid.

Figure 1 shows the calculated values for the equilibrium temperatures at different molar fractions of myristic acid, where the calculated curve is compared with the experimental points from Rolemberg [2]. It can be seen a good agreement between the calculated and the experimental data. Both eutectic and peritectic points are shown in the phase diagram, where the presence of the intermediate solid compound occurs for x_1 between 0.5 and 0.7.

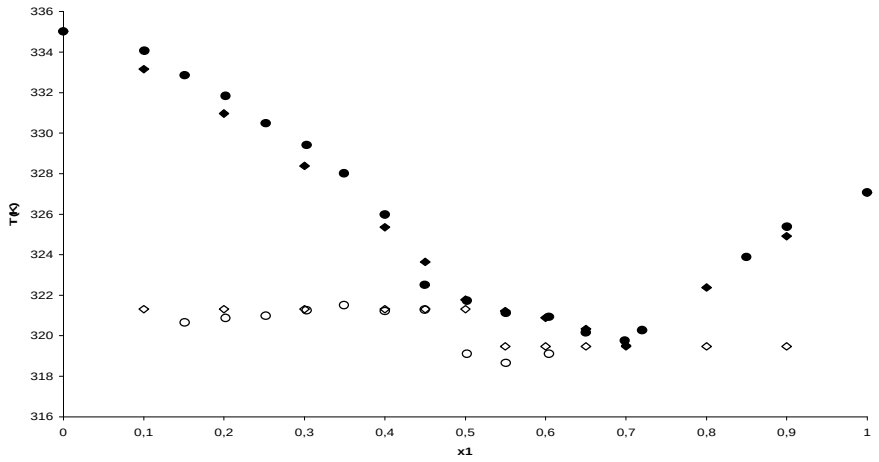

Figure 1: Phase Diagram for myristic (1) – palmitic (2) acids: ♦ fusion temperature - calculated; ◊ transition temperature – calculated; ? fusion temperature – experimental; ? transition temperature - experimental.

4.2. Case Study 2 – oleic acid – capric acid

The solid-liquid phase diagram for this mixture is the set of points (x_1, T), where compound 1 is oleic acid and compound 2 is capric acid.

Figure 2 shows the calculated values for the equilibrium temperatures at different molar fractions of oleic acid, where the calculated curve is compared with the experimental points from Rolemberg [2]. It can be seen that the calculated data have a good agreement with the experimental ones. Only the eutectic point is shown in the phase diagram, where there is not presence of the intermediate compound.

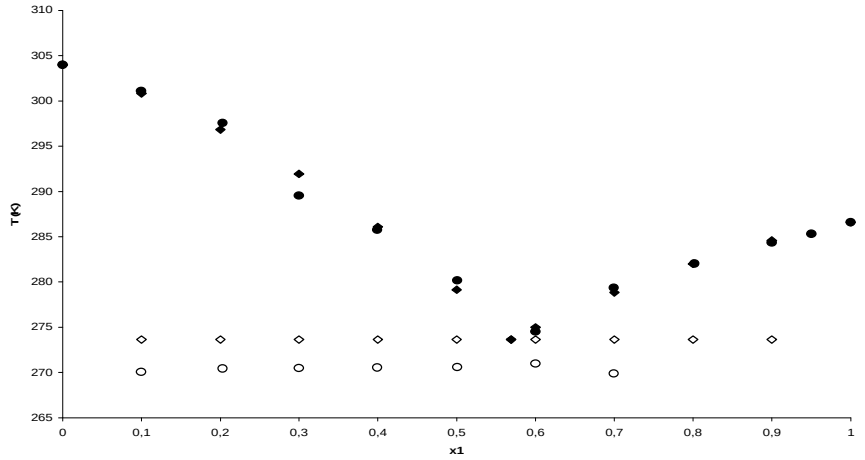

Figure 2: Phase Diagram for oleic (1) – capric (2) acids: ♦ fusion temperature - calculated; ◊ transition temperature – calculated; ? fusion temperature – experimental; ? transition temperature - experimental.

4.3. Case Study 3 – palmitic acid – tristearin

This case study is a mixture composed of a saturated fatty acid and a triglyceride, with palmitic acid ($C_{16}H_{32}O_2$) and tristearin ($C_{57}H_{110}O_6$), respectively.

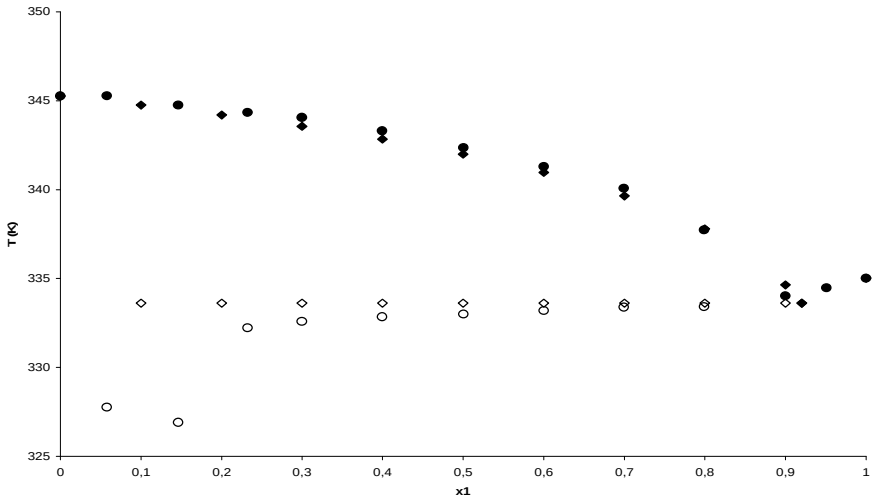

Figure 3: Phase Diagram for palmitic acid (1) – Tristearin (2): ♦ fusion temperature - calculated; ◊ transition temperature – calculated; ? fusion temperature – experimental; ? transition temperature - experimental.

Figure 3 shows the calculated values for the equilibrium temperatures at different molar fractions of palmitic acid, where the calculated curve is compared with the experimental points from Rolemberg [2]. It can be seen that there are a good agreement between the calculated and the experimental data. Only the eutectic point is shown in the phase diagram, where there is not presence of the intermediate compound.

5. Conclusion

This study deals with an optimization of the solid-liquid equilibrium point of binary fatty mixtures. The phase diagrams were determinate for satured, insatured and triglycerids binary fatty mixtures. The results obtained by the methodology developed in this work shows good agreement with the experimental data of Rolemberg [2]. The software GAMS shows to be an important tool for optimization, because of its implementation facility of the mathematical model. This new developed technique is capable to detect the intermediate compound, characterized by peritectic point in any temperature that this point could exist, including the perfect identification of the eutectic point. This work shows good results in determining the solid-equilibrium point of fatty mixtures.

Optimal production scheduling for the sausage industry

Paulo Eduardo Polon[a], Cid Marcos Andrade Gonçalves[a], Luiz Mario de Matos Jorge[a], Paulo Roberto Paraiso[a].

[a]*Department of Chemical Engineering, State University of Maringá (UEM) On Colombo avenue, at 5790, Edifice D90, Zip Code 87020-900, Maringá – PR, Brazil Phone: (0-XX-44) 3261-4752 – Fax: (0-XX-44) 3261-4792.*

Abstract

The increased consumption of processed foods, as well as a greater variety of products offered by the food industry has required for greater flexibility and the most efficient coordination in the allocation of existing resources. The sausage industry in particular in recent years had an increase in consumption, and this has led to a search for a more efficient use of available resources to achieve increased productivity, cost reduction, reliability in attendance and reduction of lead times. These aspects of production and management can be achieved more easily through tools of programming production. The sausage production is a batch process. The process can be divided into two main stages, the first refers to the preparation, the mixture of raw materials and stuffing; the second stage refers to the cooking of products that were stuffed in the first stage. A variety of types of products are obtained in the sausage industry. Most of these products do not have an exclusive line and therefore, there is a dispute between equipment and intermediate states. The products are classified as perishable, and it is recommended that production should not exceed the demand under the risk of keeping products in stock and overcome the shelf life validity of the product. The objective of this paper was to optimize the production for the sausage industry using values of demands for each product. The proposed approach states the problem as a model of mixed integer linear programming (MILP) to represent the decisions involved and was solved using the GAMS (General Algebraic Modelling System) language. The model was applied to the problem of production scheduling with real-world operational data from an industry and was able to generate better results than those used by industry. Thus, the model proved to be appropriate to support the decisions of production scheduling in the sausage industry.

Keywords: scheduling, sausage manufacture, mixed integer linear programming

1. Introduction

The increased consumption of processed foods and greater variety of products offered by the sausage industry has required for greater flexibility and efficient coordination in the allocation of existing resources.

The scheduling has attracted the attention of both academia and industry. The reason for this is the pressure on industries to improve productivity and reduce costs and also the substantial progress related to the models and techniques of solution and the rapid growth of computational power. The problem of interest is to determine the most

efficient way to produce a set of products in a time horizon, given a set of limited resources and production recipes. The activities of scheduling generally take place in multiproduct or multipurpose plants, in which a variety of different products can be manufactured via the same or different recipes sharing of limited resources such as equipment, material, and time.

Mathematical programming, especially Mixed Integer Linear Programming (MILP) because of its flexibility and extensive modeling, has become one of the most exploited for scheduling problems. Applications of MILP based scheduling methods range from the simplest single-stage single-unit multiproduct processes to the most general multipurpose processes. These planning processes scheduling problems are inherently combinatorial in nature because of the many discrete decisions, such as equipment assignment and tasks allocation over time (Floudas and Lin, 2005).

Production recipes in chemical processes can be very complex. For scheduling, the representation in networks has been developed to represent the proceeds of production unambiguously. Kondili, Pantelides and Sargent (1993) proposed a general structure State Task Network (STN). The STN representation of a process is a direct graph with two distinct types of nodes: state nodes represented by a circle, representing raw materials, intermediate products and final products, and tasks nodes represented by a rectangle, representing a physical or chemical operation, as reaction, mixing, heating.

According to Mendez et al. (2006) to formulate a mathematical model for any problem scheduling, the first major issue that arises is how to represent the time. This article used to the discrete time model, where a time horizon of interest is divided into a number of time intervals of uniform durations. The start/end of a task and other important event are associated with the boundaries of these time intervals.

Kondili, Pantelides and Sargent (1993) and Shah, Pantelides and Sargent (1993) proposed a discrete-time formulation for short term scheduling of batch operations, based on the STN representation that was used with some adjustments in this article.

The use of models of MILP programming to represent the decisions involved and resolve them using the GAMS software is used frequently for the optimization of production of real-world industries (Araujo, Arenales and Clark, 2004, Toso and Morabito, 2005 and Dogan and Sarimveis, 2008).

2. Production Process

This work is based on case study of the sausage industry. This industry produces 8 different types of sausage, such as: fresh sausage, cooked sausage, hotdog sausage, bologna and ham. The process production consists of two steps. In the first step of the process production meat products are selected and then cut into pieces small sufficiently to pass easily by the mouthpiece of grinder machine, for each type of sausage use an appropriate degree of comminution. To work with the meat close to freezing point it is recommended, this facilitates the cut operations, reduces the abrasion of the equipment and mainly minimizes the contamination. After grind, the meat is placed in appropriate containers and stored in refrigerated room. Additives and spices are carefully weighed and well blended. Then this blend is added to the grind meat, these materials are mixed in a mixer until they form a compact mass and well homogenized, to avoid formation of air bubbles during the stuffing (Rocco, 1996). Before the stuffing some products are cured, the process, which is the development of characteristics of color, flavor and texture of each product, depending on the product this process can vary from 8 to 24 hours. Natural and artificial casings are used as forms and containers for sausages.

In the process of stuffing the emulsion prepared is placed on top of the stuffer machine, it is compressed by a piston electric drive, the force to leave the equipment in a stuffing tube, of various sizes, according to type of product being stuffing. After stuffing the products are placed in special cooking cabinets or rods.
In a second step, the products are cooked in smokehouses or tanks of cooking. After cooking the products are cooled, packaged and transported to storage or shipment.
The real process analysed, is composed of 7 stuffing proper for stuffing 8 different products, the production capacity of stuffers varies from 700 kg/h to 3000kg/h according to the product being produced. The stuffers 1 and 2 are suitable for stuffing the following products: ham, hamlike, bologna type 1 and bologna type 2. The stuffers 3, 4 and 5 are suitable for stuffing the following products: fresh sausage, cooked sausage cooked sausage type 1 and type 2 and stuffers 6 and 7 are suitable for stuffing the hotdog sausage. The process of cooking in smokehouse has 6 smokehouse with capacity ranging from 3,200 kg to 1,600 kg and the cooking time varies from 2 hours for hotdog sausage until to 8 hours for bologna type 1. The process of cooking in tanks with hot water suitable for cooking the ham and hamlike products has 3 cooking tanks, 2 heat shock tanks and 5 cooling tanks, each tank has a capacity of 1,500 kg of material and processing time is 4 hours for cooking, 1 hour for the shock heat and 6 hours for cooling.

3. Methodology

Primarily, an examination of the industrial production of sausage was making. To facilitate the implementation of the model, divided the process into two sections according to the scheme of work seen in the industry under study. In the first stage, which the products are stuffed, the production time is 18 hours. In the second stage, which the products earlier stuffed are cooked in a smokehouses or in tank of cooking, the production time is 24 hours. Although the production process of sausage is in various stages, any these stages not require to be scheduled because the equipment to work with idle time, such as grinders, mixers and tanks of cure, so the main bottlenecks of production are the stuffed and cooked sections.
To develop the model, the representation of the production process in the STN as shown in Figure 1 was made. The production of sausage has three production lines distinct: (a) Fresh sausage, (b) sausage cooked in a smokehouses and (c) sausage cooked in tanks of cooking.

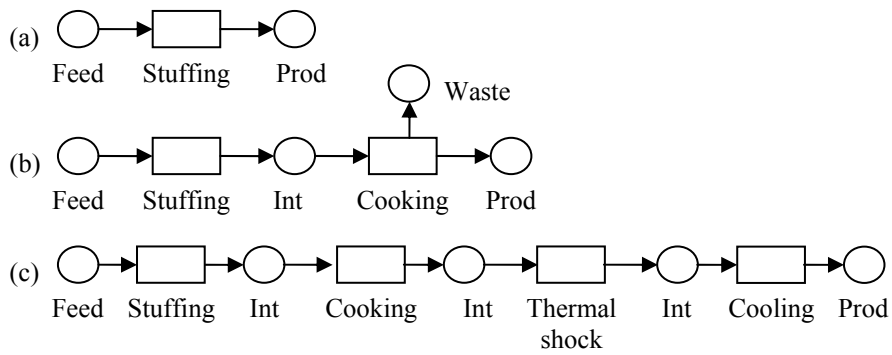

Figure 1 STN representation for production of sausage.

In addition to STN, the set, the equipment available for processing of each task, the intermediate storage policy, the production requirements and a time horizon of interest are defined. The objective is to determine a program that includes the sequence of tasks to be performed in each piece of equipment and the amount of material to be processed by each task.
The production process has two stages, so the solution of the problem was conducted in two modules, one for the processing time of 18 hours (Stuffing step) and another for the processing time of 24 hours (cooking step). The results will be obtained in stuffing step serve as input to the cooking step. It considered in this model there is full availability of raw materials and labour.
The criteria of performance were used to maximize the plant overall production. The production demand is not seasonal, with historical data obtained from industry, the average production of each product is estimated. Due to the perishable nature of products in this work used minimum and maximum production demands.
The model used was adapted and modified the MILP problem presented by Kondili, Pantelides and Sargent (1993) and Shah, Pantelides and Sargent (1993) and resolved by the modeling language GAMS.

4. Results

The optimal schedule is shown in Figure 2 and Figure 3 for the production time of 18 hours and production time of 24 hours respectively. The number above each bar is the tasks, while the number below the bar denotes the amount of material being processed.
The optimal combined global production for the Product was 145,828 kg; this result was 19.53% above the production industrial.

Table 1 Production

Product	Industrial Production (kg)	Scheduling Production (kg)
Ham	4500	4500
Hamlike	11200	12000
Bologna 1	2200	2880
Bologna 2	14800	15040
Fresh sausage	15100	21600
Cooked sausage 1	12000	12240
Cooked sausage 2	5000	13056
Hotdog sausage	57200	64512
Total	122000	145828

Table 1 shows a comparison between the results obtained in the optimization and the results of the industry. Three products (fresh sausage, cooked sausage 2 and hotdog sausage) obtained very best production that the industrial production.

5. Conclusions

This paper presented the optimization of production to a sausage industry, using a general formulation adapted to the problem that considers both the sequencing and scheduling of production. A comparison between the production manufactures by industry and the production obtained by the program, the efficiency of the method was verified and the using the method in the industry achieve better utilization of equipment and the plant productivity was improved.

Development of a Morphological Population Balance Model in Principal Component Space

Cai Y Ma and Xue Z Wang*

Institute of Particle Science and Engineering, University of Leeds, Leeds LS2 9JT, UK
** Correspondence author: Xue Z Wang. Email: X.Z.Wang@leeds.ac.uk*

Abstract

Multi-dimensional and morphological population balance models for crystallization processes can simulate the dynamic evolution of particle shape as well as particle size distribution. These models however can become computationally expensive when the crystal has a large number of independent faces, and are not applicable to non-crystalline, irregularly shaped particles such as those encountered in granulation and milling. This paper addresses these challenges by introducing principal component analysis (PCA) to morphological population balance modeling. PCA transforms the shape description of a particle from a high dimensional domain to a lower dimensional, principal component space. Morphological population balance models can then be built in this latent variable space, greatly reducing the computational complexity. It also makes it possible to model non-crystalline irregularly shaped particles. The original particle shape at any time can be reconstructed from the principal components. The methodology is demonstrated via modeling the cooling crystallization of potash alum.
Keywords: Principal Component analysis; Morphological population balance; Multidimensional population balance; Crystal shape; Model reduction

1. Introduction

Population balance (PB) models have been widely used in engineering for modelling the dynamic evolution of particle size distribution (PSD). However, in these models, the size of a particle is often defined as the diameter of a sphere having the same volume as the particle, missing important information about particle shape. Motivated by this observation, research has been carried out to introduce particle shape information into PB simulation, and multi-dimensional PB models were proposed for crystallization processes. The models can predict the evolution of PSD in more than one size dimension [1-4] but the majority of efforts have been limited to using two characteristic size dimensions, e.g. the length and width distributions of plate-like crystals. Multidimensional PB models in literature are not always able to fully reconstruct the particle shape unless for very specific situations such as plate like crystals. Ma et al. [5, 6] proposed a morphological PB model for crystallization processes. It defines the shape and size of a crystal as a function of the normal distances of all its faces to the geometrical centre, and predicts the dynamic evolution of size distribution of every face for the population of crystals. Morphological PB model emphasizes the capability of full reconstruction of the particle shape in high fidelity at any moment of the simulation. Since a morphological PB model is able to retain the particle shape, it provides an effective multi-scale modelling tool, linking single particle simulation e.g. single crystal morphology prediction, with a process model about the behaviour of the particle population in a processing vessel.

In principle, the morphological PB model has no limit on the number of faces for the modelled crystals, i.e., the number of size dimensions. But with the increase in the number of size dimensions, solution of the PB equations becomes computationally too expensive, resulting in unacceptably long CPU time. In applying the morphological PB model to the case studies [5, 6], symmetrical faces were treated as having identical growth behaviour, which effectively reduced the size dimensions, and so the CPU time.

The application of multi-dimensional PB models to processes such as granulation and milling that produce irregularly shaped particles has not been attempted. This does not imply that particle shape is not important for these processes but do indicate the difficulties to accurately define the shape of these irregular particles. Therefore, the way to apply multi-dimensional PB models to these processes is not obvious.

The purpose of this study is to develop a new methodology for carrying out shape based PB modeling that uses only a small number of size dimensions, but misses little shape information. Based on principal component analysis (PCA), the method uses principal components (*PC*s) to describe the particle shape so that PB modeling can be carried out in a transformed, latent variable domain or *PC* space. The *PC*s are calculated directly from the original multiple size dimensions of particles but the number of *PC*s can be much smaller than that of the original size dimensions. At any time, the real particle shape can be reconstructed from the latent *PC*s using the PCA model.

2. Shape Description in Principal Component Space

2.1. Principal component analysis

Given a data set consisting of m observations for n variables, $x_1, x_2, \ldots x_n$, PCA calculates a new variable y_1 that accounts for the variation in the n original variables. The first *PC*, y_1, is the linear combination of the n variables, i.e., $y_1 = w_{11} x_1 + w_{12} x_2 + \ldots + w_{1n} x_n$. The sample variance is greatest for all of the coefficients, $w_{11}, w_{12}, \ldots w_{1n}$ (written as a vector $\boldsymbol{w_1}$) with a constraint, $\boldsymbol{w'_1 w_1} = 1$. The second *PC*, y_2, is also given by the linear combination of the n original variables as, $y_2 = w_{21} x_1 + w_{22} x_2 + \ldots + w_{2n} x_n$ or $\boldsymbol{y_2} = \boldsymbol{w'_2 x}$, which has the greatest variance subject to two conditions, $\boldsymbol{w'_2 w_2} = 1$ and $\boldsymbol{w'_2 w_1} = 0$ (so that y_1 and y_2 are uncorrelated). Similarly the jth *PC* can be calculated as $y_j = \boldsymbol{w'_j x}$, which has greatest variance subject to $\boldsymbol{w'_j w_j} = 1$, $\boldsymbol{w'_j w_i} = 0$ $(i < j)$.

The coefficients defining the first *PC*, i.e. the elements of $\boldsymbol{w_1}$ can be determined by maximizing the variance of y_1 subject to a constraint, $\boldsymbol{w'_1 w_1} = 1$. The solution of $\boldsymbol{w_1}$ to maximize the variance y_1 is the eigenvector of variance-covariance matrix, **S**, corresponding to the largest eigenvalue. The eigenvalues of **S** are roots of the equation,

$$||S - \lambda I| = 0 \tag{1}$$

By arranging the eigenvalues, $\lambda_1, \lambda_2, \ldots \lambda_n$ in descending order, the top d eigenvectors, $d << n$, are the *PC*s that capture most of the variance of the original data while the remaining *PC*s can be mainly considered as noise. Hence the data is reduced from n dimensions to a much smaller dimension of d with loss of mainly the noise information.

The operation can be described in matrix algebra as follows:

$$[y]_{m\times n} = [x]_{m\times n}[w]_{m\times n} \qquad \text{and} \qquad [y]_{m\times d} \approx [x]_{m\times n}[w]_{m\times d} \tag{2}$$

Then the original variables can be re-constructed by the following operation:

$$[x]_{m\times n} \approx [y]_{m\times d}[w_{m\times d}]^T \tag{3}$$

2.2. Shape and size description in principal component space

For a crystalline particle, such as a potash alum crystal having 26 faces, its shape and size can be represented by the normal distance of each face to the geometrical centre [5, 6]. Using the same method to define the shape and size of a non-crystalline, irregularly shaped particle in two-dimension (2D), the distance of every pixel at the edge to the geometric centre is required. To describe the shape and size of the same object in three-dimension (3D), it requires the distances to the geometric centre from all the points on the particle surface. In summary, the shape and size of a single particulate object in 2D or 3D, either a structured crystal or an irregularly shaped particle, can be described by a finite number of sizes, namely, x_1, x_2, …, x_n. To consider a population of m particles, each with n size descriptors, a matrix is formed as shown in (E-1).

	x_1	x_2	----	x_n
particle - *1*				
⋮				
particle - *m*				

(E-1)

Applying PCA to this matrix and selecting d *PC*s, $d < n$, leads to a new matrix with the same number of columns but d rows of *PC*s which represent the new latent size dimensions with each being calculated by the linear combination of all the original sizes x_1, x_2, …, x_n. To conduct multi-dimensional PB modelling in the original space, one has to consider all the n dimensions. The idea of multi-dimensional PB modelling in a *PC* space is to model size distribution evolution in each of the *PC* directions, *PC1*, *PC2*, …, *PCd*, via solving d ($<< n$) dimensional PB equations without compromising much on the shape information. At any time of simulation, shape and size of particles represented by x_1, x_2, …, x_n, can be reconstructed from the selected *PC*s using eq (3).

3. Morphological PB Modeling of Potash Alum Crystallization in *PC* Space

A case study of a seeded potash alum crystallization process is presented here to demonstrate that morphological PB modeling can be carried out in *PC* space. The crystal morphology of potash alum crystals is dominated by the large face {111} and two smaller faces {100} and {110}. In this study, secondary nucleation, crystal breakage and aggregation are excluded [6]. Therefore, all needed to carry out morphological PB modelling in the *PC* space are the initial size distributions of the selected *PC*s, and the growth rate in each *PC* direction as a function of operating conditions.

time	particles	x_1	x_2	----	x_{26}
t_1	particle - *1*				
	⋮				
	particle - *m*				
⋮	⋮				
t_T	particle - *1*				
	⋮				
	particle - *m*				

(E-2)

3.1. Calculation of initial PC size distributions and growth rates in PC directions

The simulated results [6] based on three independent faces was used to generate data for the other 23 faces. The obtained data is arranged into a matrix (E-2). The columns, x_1, x_2, …, x_{26}, represent the sizes of the 26 faces. The rows are divided into sections, t_1, t_2, …, t_T, representing the time points of simulation. At a given time point, there are m rows, representing m particles, particle-*1*, …, particle-*m*. So the data matrix shown in (E-2) is of the size $(m \times T) \times 26$.

For each time point of t_1, t_2, …, t_T, however, there would be too many rows due to too many particles (in this study, $m = 2.2 \times 10^7$). As a result, only a limited number of representative particles of different shape and size were selected (3375 in this study). The simulated time span was 3300s for 57 time steps. So the matrix (E-2) has elements

of (3375×57)×26. PCA was applied to the matrix (E-2). Three *PC*s were selected based on the slope of variance vs. *PC* number. A new matrix with three columns and the same number of rows were formed. The new matrix was then used to estimate the growth rates in each *PC* direction as follows:

$$G_1=1.05\times10^{-5}\sigma^{1.24}\times Size_{PC1}{}^{0.16};G_2=6.28\times10^{-7}\sigma-5.84\times10^{-8};G^3=-1.50\times10^{-8}\sigma+1.22\times10^{-9} \quad (4)$$

3.2. PB model in the PC space

The PCA-based three dimensional PB equation can be written as follows:

$$\frac{1}{V_T(t)}\frac{\partial}{\partial t}[\psi(PC1,PC2,PC3,t)V_T(t)]+\frac{\partial}{\partial PC1}[G_1(PC1,t)\psi(PC1,PC2,PC3,t)] \quad (5)$$
$$+\frac{\partial}{\partial PC2}[G_2(PC2,t)\psi(PC1,PC2,PC3,t)]+\frac{\partial}{\partial PC3}[G_3(PC3,t)\psi(PC1,PC2,PC3,t)]=0$$

where ψ is the number population density function, G_1, G_2 and G_3 are the growth rates in three *PC* directions, and V_T is the total volume of the suspension in the reactor.

To solve Eq. (5), the initial distributions of crystal population in 26 dimensions were converted to new distributions in the three *PC* dimensions, which were curve-fitted using a Gaussian function. The PCA-based PB equation (Eq. 5) can be solved using a discretisation method, moment of classes, which is only briefly described here with its detailed description to be found in literature [1, 5].

The 3D size domain was equally discretised into n_1, n_2, n_3 classes, which form a set of $n_1\times n_2\times n_3$ ordinary differential equations:

$$\frac{1}{V_T(t)}\frac{d}{dt}\left[N_{i,j,k}(t)V_T(t)\right]+[FX^{O}_{i,j,k}(t)-FX^{I}_{i,j,k}(t)]+[FY^{O}_{i,j,k}(t)-FY^{I}_{i,j,k}(t)]+[FZ^{O}_{i,j,k}(t)-FZ^{I}_{i,j,k}(t)]=0 \quad (6)$$

where $N_{i,j,k}(t)$ is the number of crystals in the class $Cl_{i,j,k}$, and *FX*, *FY* and *FZ* are the crystal flow fluxes in three PC directions with the superscripts, *O* and *I*, denoting the crystal flowing outletting from and inletting into the $Cl_{i,j,k}$ class [5, 6].

The discretised PCA-based PB equations (Eq. (6)), together with the initial size distribution and boundary conditions, were solved simultaneously using the Runge-Kutta-Fehlbergh solver [7] in the mesh ranges of 22~114μm, -24~51μm and -26~79μm in *PC1*, *PC2* and *PC3* directions, respectively, with the classe sizes being 100×100×100. For a crystal with known values for *PC1*, *PC2* and *PC3*, the reconstruction of its values of x_1, x_2, ...x_{26} can be easily performed using equation (3).

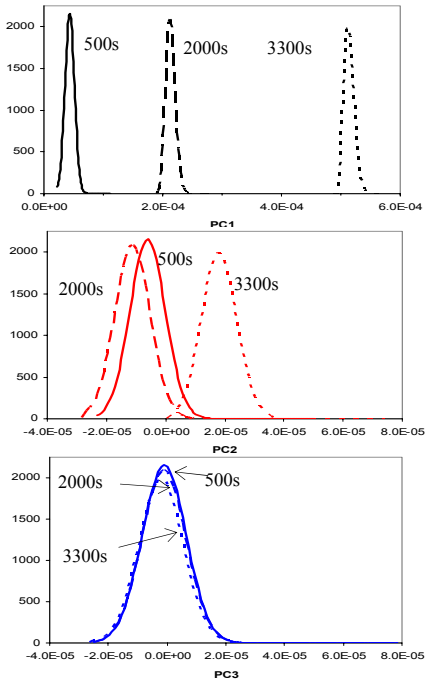

Figure 1. Typical size distributions for individual PCs.

4. Results and Discussions

Figure 1 shows typical size distributions of three *PC*s at 500th, 2000th and 3300th second. The most significant *PC*, *PC1*, grew much faster with time, while the second significant *PC*, *PC2*, was firstly decreasing with time, then increasing after 2150th second. The third *PC*, *PC3*, did not show obvious change during crystallization. Using the PCA reconstruction technique, the size distributions of

the 26 faces were obtained. Three typical distributions in x_1, x_9 and x_{15} face directions, representing {111}, {100} and {110} faces, were illustrated in Figure 2. Also plotted in Figure 2 are size distributions in x_1, x_9 and x_{15} obtained from the original morphological PB model [6]. Figure 2 shows that PCA reconstruction produced size distributions very close to that of the original simulation.

Since the sizes for the 26 faces can be reconstructed from *PC*s, the shape of crystals can be drawn at any time during crystallization process. Figure 3 shows the shape evolution of a crystal. At 3300s, both the crystal shape reconstructed from *PC*s and the original shape from the original simulation were drawn.

Figure 4 shows comparison between simulated evolution trajectories of the {110} boundary sector using PCA approach and and the origianl morphological PB model [6].

The case study proved the principle that morphological PB modeling can be effectively performed in the transformed, latent variable space. The real particle shape at any time of simulation can be reconstructed with high fidelity from only a few *PC*s. It also brings about a question: how can the methodological PB be used in practice? It clearly cannot be expected that the original data of crystal size distributions of all 26 faces over the time span is always available for other processes.

The PCA based morphological PB modeling technique can be used in various ways, and is open for future exploration. Below we look at one example. We still consider a seeded cooling crystallization process with the assumptions that secondary nucleation, aggregation and breakage can be ignored. The seed particles can be characterized to get data of the shape and size. The data can be arranged into a matrix in the form of (E-1). Applying PCA to the matrix and then selecting *d* number of *PC*s will produce a new matrix in the form of (E-2). The size distribution for each of the *d PC*s can be estimated. The above procedure produces: 1) the number of *PCs*, *d*, for which population balance simulation will be carried out; 2) the initial size distributions for the selected *d* principal components; and 3) a transformation matrix containing the loadings that can be used at any time of the simulation to reconstruct the original *n* variables (original shape descriptors) from the values of the *d PCs*.

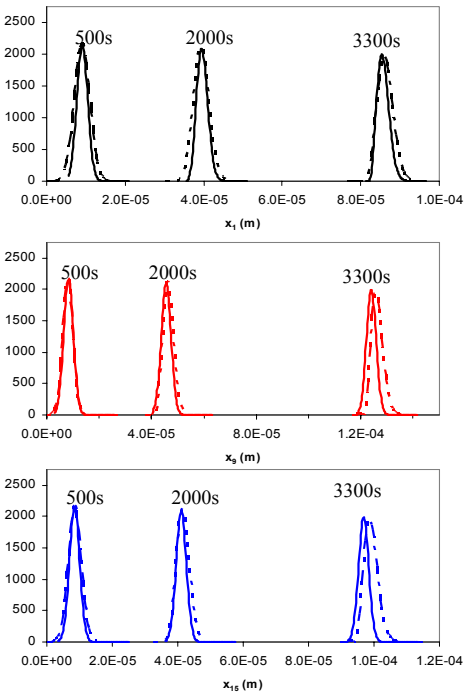

Figure 2. Size distributions of individual faces: solid curves (reconstructed from PCs); dotted curves (original simulation).

The only missing item prior to PCA based morphological PB simulation is the growth rate of each *PC* as a function of supersaturation (σ) and its size:

$$G_{PCi} = f(\sigma, \text{size of } PC_i, \text{parameters}) \quad (7)$$

Suppose the structure of equation (7) is known, the PCA based PB equations can be formulated with its parameter values to be determined via model identification using data from a real crystallization experiment.

A real cooling crystallization experiment can be carried out using the characterized seeds with operating conditions, e.g. temperature and supersaturation being continuously recorded. The product at the end should be characterized in the same way as for seeds. The product characterization data can then be used as the targets in model identification [3] for determining the parameters in eq (7). PCA based morphological PB models can thus be built to simulate the crystallization process of the same chemical in other operating conditions and varied seed crystal shape and size.

Abstract

Synthesis of large-scale heat exchanger networks has attracted increasing attention but it is still a very difficult task because of the geometrically increasing of the design parameters to be optimized. In such cases, even long computing time were used, the result would usually not converge to the global optimum. In order to overcome this disadvantage, a monogenetic algorithm based on the optimization of sub-networks (functional groups) was proposed to improve the initial design obtained by the hybrid genetic algorithm. In this new procedure, the first search was carried out by the use of the hybrid genetic algorithm under a small population size and limited number of evolution generations so that the first design could be finished in relatively short time. Then, the sub-networks undergo recombinations and are further optimized with the hybrid genetic algorithm, in which a large population size and more evolution generations are used for the optimization of the sub-networks to ensure that the optimal solution of each sub-network can be found. An example from literature was calculated with this new method which yields a better network construction.

Keywords: large-scale heat exchanger network, hybrid genetic algorithm, monogenetic algorithm, optimization.

1. Introduction

The optimal design of large-scale process systems is a difficult task not only due to its non linear characteristics but also due to a number of local optima in its solution space. A typical example is the synthesis of a heat exchanger network (HEN) used for heat recovery. In refineries the amount of the streams to be heated up and cooled down could be up to 100. However, most of existing targeting techniques, particularly those from Pinch Technology (Linnhoff and Hindmarsh, 1983), are suitable only for small HENs. In recent years the genetic

algorithm was also applied to the HEN synthesis (Lewin, Wang and Shalev, 1998; Lewin, 1998; Chen et al., 2007), but it is not efficient for the synthesis of large-scale HENs. In such cases, even a large population size and long computing time were used, the result would usually not converge to the global optimum. Björk and Pettersson (2003) and Pettersson (2005) developed a genetic algorithm with sub-networks as genes which seems effective for synthesis of large-scale HENs.

In the present work the monogenetic algorithm is proposed which is based on the idea that any improvements in sub-networks (functional groups) will yield an improvement in the whole network. Since a sub-network usually contains less process streams, it is easy to find its optimal network structure. The recombination operation will stochastically applied to the sub-networks to form new sub-networks. An example from literature was used to illustrate the procedure and a better design was found.

2. Mathematical model for HEN synthesis

The HEN synthesis problem can be stated as follows: Given are N_h hot process streams, N_c cold process streams, N_{hu} hot utilities HU and N_{cu} cold utilities CU. Specified are heat capacity flow rates and the supply and target temperatures of each stream. Given also are the temperature levels and costs of the hot and cold utilities, the costs and overall heat transfer coefficients of heat exchangers, heaters and coolers. Determine the configuration of the HEN and the values of heat transfer areas and thermal flow rates of each heat exchanger in the HEN which bring the total annual cost of the HEN to the minimum.

The problem is solved basically by means of the hybrid genetic algorithm developed in our early work (Chen et al., 2007; Luo et al. 2009). It is assumed that the HEN has a stage-wise superstructure proposed by Yee et al. (1990), of which one restriction is that at each branch in a stage there is only one heat exchanger. However, the restriction of isothermal mixing used in their model is rescinded in the present analytical solution of stream temperature. The variables to be optimized are $(UA)_{ijk}$ and heat capacity flow rates $\dot{W}_{h,ijk}$ and $\dot{W}_{c,ijk}$, in which U is overall heat transfer coefficient, A is heat transfer area, and the subscripts i, j, and k denote the structure stage, hot stream, and cold stream, respectively. For a given set of $(UA)_{ijk}$, $\dot{W}_{h,ijk}$ and $\dot{W}_{c,ijk}$, the stream temperatures in the HEN can be explicitly obtained. To avoid the use of binary variables, we stipulate that a non-positive value of $(UA)_{ijk}$ means no heat exchanger at the position (i, j, k). With this stipulation, the cost of a heat exchanger in the HEN can be calculated by

$$C_{E,ijk} = \begin{cases} a + bA_{ijk}^{c}, & (UA)_{ijk} > 0 \\ 0, & (UA)_{ijk} \le 0 \end{cases} \tag{1}$$

in which a, b and c are known parameters for the calculation of heat exchanger cost.

In order to heat or cool the streams to their target temperatures, the strategy of excessive use of utilities (Lewin et al., 1998) is adopted. If the exit temperature of stream n, t_n'', is higher than the upper bound of its target value $t_{\mathrm{OUT},n}^{+}$, a cold utility should be used. Similarly, if t_n'' is lower than the lower bound of its target value $t_{\mathrm{OUT},n}^{-}$, it should be heated by a hot utility, no matter whether it is a hot stream or a cold one. Thus, the sum of utility cost for stream n (hot stream: n = 1, 2, …, N_h; cold stream: $n = N_\mathrm{h} + 1, N_\mathrm{h} + 2, \ldots, N_\mathrm{h} + N_\mathrm{c}$) and the cost of corresponding heater or cooler can be expressed as

$$C_{\mathrm{U},n} = \begin{cases} \min\{C_{\mathrm{HU},p}\dot{W}_n(t_{\mathrm{OUT},n}^{-} - t_n'') + a_p + b_p A_{\mathrm{HU},n}^{c_p};\ p = 1,2,\cdots,N_{\mathrm{hu}}\}, & t_n'' < t_{\mathrm{OUT},n}^{-} \\ 0, & t_{\mathrm{OUT},n}^{-} < t_n'' < t_{\mathrm{OUT},n}^{+} \\ \min\{C_{\mathrm{CU},q}\dot{W}_n(t_n'' - t_{\mathrm{OUT},n}^{+}) + a_q + b_q A_{\mathrm{CU},n}^{c_q};\ q = 1,2,\cdots,N_{\mathrm{cu}}\}, & t_n'' > t_{\mathrm{OUT},n}^{+} \end{cases} \tag{2}$$

$$A_{\mathrm{CU},n} = \frac{\dot{W}_n(t_n'' - t_{\mathrm{OUT},n}^{+})}{U_{\mathrm{CU},n}\Delta t_{m\mathrm{CU},n}} \tag{3}$$

$$A_{\mathrm{HU},n} = \frac{\dot{W}_n(t_{\mathrm{OUT},n}^{-} - t_n'')}{U_{\mathrm{HU},n}\Delta t_{m\mathrm{HU},n}} \tag{4}$$

in which $n = 1, 2, \cdots, N_\mathrm{h} + N_\mathrm{c}$ and Δt_m is the logarithmic mean temperature difference.

The objective function is the sum of heat exchanger costs, utility costs and costs of heaters and coolers calculated by Eqs. (1) and (2). Thus, the HEN synthesis problem becomes to find the values of $(UA)_{ijk}$, $\dot{W}_{\mathrm{h},ijk}$ and $\dot{W}_{\mathrm{c},ijk}$ so that the total annual cost reaches the minimum,

$$\min\ C(\mathbf{x}) = \sum_{n=1}^{N_\mathrm{h}+N_\mathrm{c}} C_{\mathrm{U},n} + \sum_{i=1}^{N_\mathrm{s}}\sum_{j=1}^{N_\mathrm{h}}\sum_{k=1}^{N_\mathrm{c}} C_{\mathrm{E},ijk}$$
$$x \in \{(UA)_{ijk}, \dot{W}_{\mathrm{h},ijk}, \dot{W}_{\mathrm{c},ijk} \mid i = 1,2,\cdots,N_\mathrm{s};\ j = 1,2,\cdots,N_\mathrm{h};\ k = 1,2,\cdots,N_\mathrm{c}\} \tag{5}$$

This problem is solved by means of the hybrid genetic algorithm. The values of $(UA)_{ijk}$, $\dot{W}_{\mathrm{h},ijk}$ and $\dot{W}_{\mathrm{c},ijk}$ are restricted in the regions of $[(UA)_{\min}, (UA)_{\max}]$, $[0, \dot{W}_{\mathrm{h},j}]$ and $[0, \dot{W}_{\mathrm{c},k}]$, respectively, with an empiric value of

$$(UA)_{\min} = -3(UA)_{\max} \tag{6}$$

and the physical restriction: If $(UA)_{ijk} \le 0$, then $\dot{W}_{\mathrm{h},ijk} = \dot{W}_{\mathrm{c},ijk} = 0$. The fitness of a HEN (individual) used in the hybrid genetic algorithm is evaluated with the reciprocal of its total annual cost and is adjusted with a commonly used linear transform,

$$f = \frac{C^{-1} + C_{\min}^{-1} - 2(C^{-1})_{\mathrm{avg}}}{C_{\min}^{-1} - (C^{-1})_{\mathrm{avg}}} \tag{7}$$

in which C is the total annual cost of the individual (See Eq. (5)), $C_{\min}$ the minimum total annual cost in the population, and $(C^{-1})_{\text{avg}}$ the average value of the reciprocal of total annual cost of the population.

3. Monogenetic algorithm

For a large-scale HEN, there might be more than ten thousand design parameters, and even the hybrid genetic algorithm often yields the solution to an unexpected local optimum. This is due to the probabilistic characteristics of the algorithm. The more the possible heat exchangers in a network exist, the less the possibility to obtain an optimal design. In practice a large-scale HEN usually consists of some functional groups. In traditional genetic algorithms the probability that such functional groups appear simultaneously in a HEN is so small that in fact it would never appears.

The new method for the large-scale HEN synthesis consists two optimization levels. At the upper level the evolution is carried out among the functional groups of a HEN, i.e. the functional groups are taken as individuals. Meanwhile, the functional groups themselves are optimized at the lower level with the hybrid genetic algorithm. Because of their small size, the optimization of the functional groups is usually easy to be performed. The sub-networks of the HEN can be taken as such functional groups. The sub-network is defined as a part of the HEN in which the streams have no thermal relation with the streams outside the sub-network. If a HEN can be divided into two or more sub-networks, then, these sub-networks are independent from each other. Therefore, any improvement in a sub-network will bring an improvement in the whole network at the same time.

The procedures are as follows: (1) Apply the hybrid genetic algorithm to the whole network with small individual number and small evolution generations to obtain an initial set of sub-networks. (2) Recombine two or more sub-networks stochastically to form a new sub-network. (3) Apply the hybrid genetic algorithm to this sub-network. If the new sub-network is better than the original parent sub-networks, this new sub-network replaces its parent sub-networks and will be decomposed into new sub-networks if possible. Otherwise, the original parent sub-networks will remain in the HEN. (4) Repeat steps (2)-(4) until no improvements can be found. More details can be found in our recent work (Fieg, Luo and Jezowski, 2009).

4. Case study

An example taken from Björk and Pettersson (2003) is used to illustrate the procedure. The problem data are given in Table 1. The annual cost of heat exchanger is $8000 + 800A^{0.8}$\$/yr where A is the area given in m^2. The hot utility cost is 70\$/kWyr and the cold utility cost is 10\$/kWyr. Their best design has an total annual cost of 2.073M\$/yr. A new design was obtained by Pettersson (2005) with the total annual cost of 1.998M\$/yr.

Table 1 Problem data

Hot streams	t' °C	t_{OUT} °C	$\dot{W}$ kW/K	h kW/m^{2}K	Cold streams	t' °C	t_{OUT} °C	$\dot{W}$ kW/K	h kW/m^{2}K
H1	180	75	30	2	C1	40	230	20	1.5

H7	170	45	30	2	C7	40	150	20	2
H8	180	50	30	2	C8	120	210	35	2.5
H9	280	90	15	2	C9	40	130	35	2.5
H10	180	60	30	2	C10	60	120	30	2.5
H11	120	45	30	2	C11	50	150	10	3
H12	220	120	25	2	C12	40	130	20	1
H13	180	55	10	2	C13	120	160	35	1
H14	140	45	20	2	C14	40	90	35	1.75
H15	140	60	70	2	C15	50	90	30	1.5
H16	220	50	15	2.5	C16	50	150	30	2
H17	220	60	10	2.5	C17	30	150	50	2
H18	150	70	20	2	HU	325	325	-	1
H19	140	80	70	2	CU	25	40	-	2
H20	220	50	35	2					
H21	180	60	10	2					
H22	150	45	20	2.5					

In the present work, an initial solution was obtained by hybrid genetic algorithm with 100 individuals and 1000 generations, which has the total annual cost of 2.062M$/yr. The initial HEN can be divided into 11 sub-networks. These sub-networks are further optimized with the hybrid genetic algorithm, which yields a better structure with 2.012M$/yr. Then, the monogenetic algorithm was applied to the sub-networks. After recombination, the new sub-networks will be improved and evaluated. This operation is repeated until no improvement can be further obtained. The total annual cost of the whole HEN reduces to 1.965M$/yr. The structure of the HEN is shown in Fig. 1, which has 44 units.

5. Conclusions

A new method for solving large-scale HEN synthesis problems is proposed as the monogenetic algorithm. In this method, the genetic algorithm is applied to the sub-networks of a HEN rather than the population of HENs. The monogenetic algorithm uses the sub-networks of a HEN as individuals. Since the sub-networks are small, they can be optimized with the hybrid genetic algorithm more efficiently. A case study was conducted and a better design than that in literature is obtained.

Acknowledgments

The present research was supported by Innovation Program of Shanghai Municipal Education Commission (No. 07ZZ89).

Simulation of distillation process in the bioethanol production using nonequilibrium stage model

Tassia L. Junqueira,[a] Rubens Maciel Filho,[a] Maria R. W. Maciel[a]

[a] *School of Chemical Engineering, State University of Campinas – UNICAMP, P.O. Box 6066, Campinas, SP 13083-970, Brazil*

Abstract

Most models available for simulation of multicomponent separation processes are based on the idealized concept of equilibrium or theoretical stages. However, accuracy of the predictions can be highly enhanced if a nonequilibrium stage model is taken into account. In this work, hydrous bioethanol production process was simulated using Aspen Plus® considering three calculation methods: equilibrium, equilibrium with constant plate efficiency and nonequilibrium stage models. Comparison of nonequilibrium and equilibrium model simulations, assuming the same number of stages, showed that energy consumption calculated is much larger when nonequilibrium model is considered and that column specifications have to be adapted in order to achieve bioethanol specification. Equilibrium model with efficiency of 70% presented a satisfactory agreement with nonequilibrium model.

Keywords: simulation, bioethanol, nonequilibrium model, distillation process

1. Introduction

Bioethanol has been increasingly used as substitute or additive to gasoline, since it is a renewable fuel and its combustion discharges less greenhouse gases when compared to fossil-derived fuels. In Brazil, second largest producer in the world, it is typically produced through fermentation of sugars derived from sugarcane.

In order to be used as a fuel, wine obtained from fermentation must be concentrated to about 93 wt% of ethanol (hydrous bioethanol), which requires distillation process. Besides, for bioethanol being used as gasoline additive, further processes are necessary, since water and ethanol form an azeotrope with 95.6 wt% ethanol at 1 atm. Thus, conventional distillation can not achieve anhydrous bioethanol specification (approximately 99.5 wt%). Azeotropic distillation with cyclohexane as entrainer, extractive distillation with monoethyleneglycol as solvent and adsorption onto molecular sieves are possible and usual alternatives for bioethanol dehydration.

Usually, simulations of distillation process consider the equilibrium stage model, although, in practice, columns rarely operate under thermodynamic equilibrium conditions. In 1985, Krishnamurty and Taylor described the nonequilibrium stage model of multicomponent separation processes and observed that equilibrium and nonequilibrium model provided results quite different from each other. In the nonequilibrium model, conservation equations are written for each phase independently and solved together with transport equations that describe mass and energy transfers in multicomponent mixtures; also it is assumed that equilibrium occurs only in the vapor-liquid interface. Besides, in this way, the empirical correcting factors, such as efficiencies used in the equilibrium model, are no longer necessary (Pescarini, 1996).

Several works have been developed regarding comparison between nonequilibrium stage model and experiments. For instance, Springer et al. (2002) realized experiments in a bubble cap distillation column with the system water – ethanol – methylacetate and also developed the nonequilibrium model, their comparison showed excellent agreement between the results. In adition, Eckert & Vaněk (2001) modelled three-phase distillation columns for ethanol dehydration with cyclohexane and observed that nonequilibrium model provided results in good agreement with experiments. Repke et al. (2004) carried out the validation of the developed nonequilibrium model in a pilot packed column and concluded that nonequilibrium model describes the experimental data with a good accuracy.

In view of the fact that distillation operations require a significant amount of energy and have a great importance in bioethanol production, the simulation of this unit operation has to be as representative as possible. In this work, simulations of distillation process in bioethanol production were carried out in Aspen Plus®, considering equilibrium model, equilibrium model with constant plate efficiency and nonequilibrium model.

2. Traditional distillation process

The distillation process simulated was based on the traditional Brazilian biorefineries configuration employed to produce hydrous bioethanol. Distillation takes place in a set of five columns, divided into distillation (A, A1 and D, each one at the top of each other) and rectification columns (B and B1). Columns B and B1 are located one above the other and have the same diameter, so they were simulated as a single column (46 stages). Since columns A (19 stages), A1 (8 stages) and D (6 stages) have different diameters, they were simulated detached. This configuration is depicted in Figure 1.

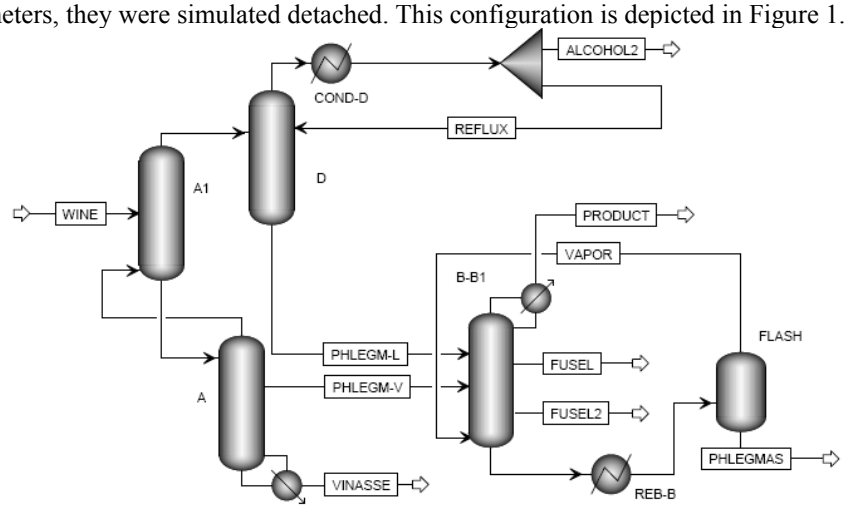

Figure 1. Configuration of the distillation process.

Wine, produced in the fermentation stage, is fed to column A1. Column D is responsible for removing volatile contaminants at the top, while a large amount of water (vinasse) is obtained in the bottom of column A. Vapour phlegm produced near to the top of column A and liquid phlegm obtained at the bottom of column D are sent to rectification columns. The task of the rectification consists on the concentration of the phlegms to 93 wt% ethanol (hydrous bioethanol). Phlegmasse, which has high contents of water, is produced in the bottom of column B-B1. Pressure drop in the columns was considered,

top/bottom pressures (kPa) adopted were 139.3/152.5, 136.3/139.3, 133.8/136.3 and 116.0/135.7 in columns A, A1, D and B, respectively.

3. Simulation procedure

Thermodynamic models adequacy to represent the system was evaluated by comparison between vapor-liquid equilibrium results given by Aspen Plus® and available experimental data (Gmehling and Onken, 1977). Aspen Plus® simulator supplies binary parameters from its databank and uses them automatically. This study analyzed NRTL and UNIQUAC activity coefficient models, PSRK equation of state and the UNIFAC method. NRTL was the model that provided better predictions, for this reason it was used to calculate the activity coefficients for the liquid phase.

Wine compositions, flow rate and temperature, given in Table 1, were based on biorefinery data. This data showed that other components, such as acetaldehyde, acetone, acetal, n-propanol, isobutanol, n-butanol and acetic acid, are also present in the wine, however they represent less than 0.1% in the composition and were disregarded in this work.

Table 1. Specification of wine fed to distillation process.

Variable	Value
Water (wt%)	92.0
Ethanol (wt%)	7.3
Glycerol (wt%)	0.4
Isoamyl alcohol (wt%)	0.2
Glucose (wt%)	0.1
Total mass flow rate (t/h)	206.9
Temperature (°C)	81.0

PHLEGMA-L and PHLEGMA-V inlet stages were the only feed positions that could be varied, since the other streams are fed to the first or last stage to substitute a missing condenser or reboiler, respectively. Therefore, optimization process was carried out in order to determine the best inlet stages concerning energy consumption. Three different approaches were used in the simulation of this distillation process regarding to column calculations: equilibrium model (EQ), which assumes as efficiency of 100%, equilibrium model with constant plate efficiency (EQ55, EQ70 and EQ85) and nonequilibrium model (NEQ). All simulations considered condenser and reboiler as an equilibrium stage.

In order to perform equilibrium model simulations, RadFrac model in Aspen Plus® simulator is used and its specification is quite simple, since number of stages and feed inlet positions are the only column design parameters required. In the equilibrium model with constant plate efficiency, RadFrac model is also utilized and a additional especification is introduced: plate efficiency. Therefore, it was specified that all stages have the same Murphree efficiency of 55, 70 and 85% in simulations EQ55, EQ70 and EQ85, respectively.

In the nonequilibrium model, which is a more rigorous calculation, software Aspen Plus® makes available RateFrac model. This model calculates the product of the binary mass transfer coefficients and interfacial areas using the correlations developed by Grester et al.; the vapor phase and liquid phase heat transfer coefficients are determined

using the Chilton-Colburn analogy. In general, these quantities depend on column diameter and operating parameters. Tray type was defined as bubble cap and column diameter was calculated by the simulator, which sizes the column based on the approach to flooding on the stage where it is most critical. Parameters used in calculations, such as vapor and liquid flows, densities, viscosities, surface tension of liquid, vapor and liquid phase binary diffusion coefficients, are all estimated by the simulator.

4. Simulation results and discussion

In order to obtain hydrous bioethanol (93 wt% ethanol), distillate rate on column A and vapor fraction on column B reboiler were manipulated. Equilibrium and nonequilibrium models had different values on these variables, since results using same specification are significantly different. Equilibrium with plate efficiency and nonequilibrium models assumed same values, since the purpose was to determine the efficiency value that most approximates nonequilibrium model predicitions.

Temperature profile in column B-B1 was analyzed aiming comparison between results given by the models. This column was chosen for this study because it has larger number of stages, thus it is the most influenced column in this process.

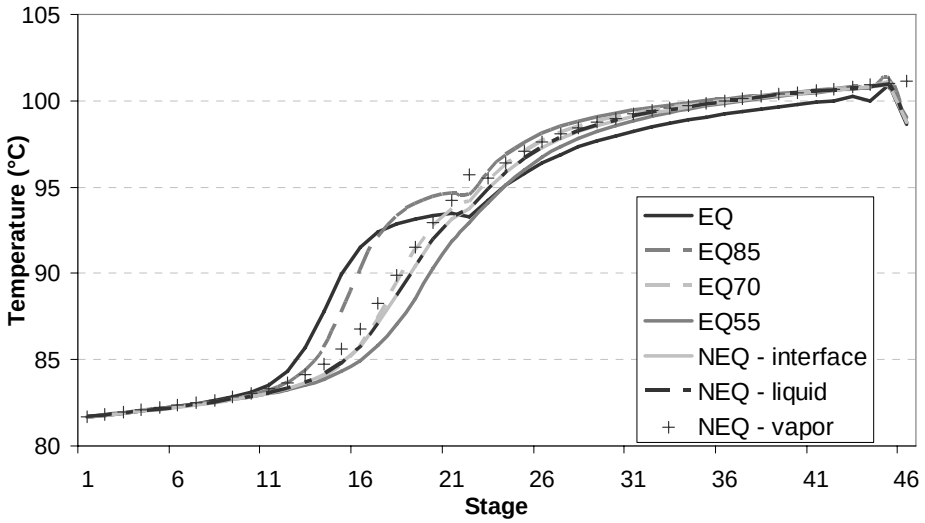

Figure 2. Temperature profiles for column B-B1.

Temperature profiles, depicted in Figure 2, showed that EQ results deviate considerably from the curves given by NEQ. Liquid and interface temperature profiles obtained in the NEQ model were coincident, indicating that there is no resistance to energy transfer between interface and liquid phase. However, vapor temperatures calculated by NEQ slightly diverged from the other temperatures, which means that vapor phase controls energy transfer in the system. Besides, analysing temperatures given by equilibrium model with constant plate efficiency (EQ55, EQ70 and EQ85), it can be observed that temperatures are higher for the superior efficiency (85%), since it means that system behavior is closer to ideal. Among simulations considering plate efficiency, taking NEQ simulation as base, EQ70 predicted better results since its curve is between vapor and liquid temperature profiles calculated by NEQ, which is an indicative that the value 70% is reasonable for efficiency in this process.

Main stream results for EQ, NEQ and EQ70 are displayed on Tables 2-4. It was verified that, in all simulations, hydrous bioethanol production was 16,100 kg/h and its concentration was around 93 wt% ethanol. Other streams also showed similar flow and composition in the simulations. It was also observed that ethanol losses on vinasse and phlegmasse are not significant in all simulations.

Table 2. Stream results for equilibrium stage model.

Stream	VINASSE	PHLEGMAS	ALCOHOL2	PRODUCT

Energy demand on columns reboilers for each simulation is shown in Table 5. It can be seen that equilibrium model calculates lower energy consumption when compared with

other calculation methods, because it assumes that vapor and liquid phases leave stages in equilibrium. Once mass and energy transfers or efficiency are considered, as in NEQ and EQ70 simulations, more stages and energy are required to achieve the same separation. It was also observed that energy demand was similar in EQ70 and NEQ, so 70% may be a good estimate for total efficiency in this process. In addition, values displayed in Table 5 indicate that the reboiler of column A required larger amount of energy than column B-B1, since column A operates with larger flows.

Table 5. Energy demand on hydrous bioethanol production.

Model	EQ	EQ70	NEQ
Column A reboiler (kJ/kg Product)	4503	4712	4723
Column B-B1 reboiler (kJ/kg Product)	1150	2252	2259
Total energy consumption (kJ/kg Product)	5653	6964	6982

5. Conclusions

Simulations of bioethanol production process were carried out considering equilibrium, equilibrium with plate efficiency and nonequilibrium models. Regarding to energy consumption and temperature profiles, equilibrium model gave different predictions from the other models studied. Equilibrium model with efficiency of 70% showed a satisfactory agreement with results obtained with nonequilibrium model, which is a rigorous calculation. It was also observed, from temperature profiles, that in the nonequilibrium model, liquid phase presents no resistance to energy transfer and vapor phase controls this process. In conclusion, nonequilibrium model simulation revealed to be a useful tool to predict column performance and to provide more accurate results.
Literature review showed that nonequilibrium model predicts results in good agreement with experimental results, however, further studies including experiments are recommended to validate nonequilibrium model for bioethanol production process.

Abstract

Oxidation processes can be used to treat industrial wastewater containing non-biodegradable organic compounds. However, the presence of dissolved salts may inhibit or retard the treatment process. In this study, wastewater desalination by electrodialysis (ED) associated with an advanced oxidation process (photo-Fenton) was applied to a NaCl in water solution containing phenol. The influence of process variables on the on the demineralization factor was investigated for ED in pilot scale. A phenomenological approach was used to relate the phenol, salt and water fluxes with the driving force. The oxidation process was investigated in a laboratory batch reactor and a model based on artificial neural networks was developed by fitting the experimental data describing the reaction rate as a function of the input variables. With the experimental parameters of both processes, a dynamic model was developed to ED and a continuous model, using a plug flow reactor approach, to the oxidation process. Finally, the hybrid resulting simulation could validate different scenarios of the integrated system and can be used for further optimization.

Keywords: process integration, modeling, electrodialysis, advanced oxidation process, wastewater

1. Introduction

Recalcitrant organic pollutants, like phenol and phenolic compounds, common contaminants in industrial wastewater, have been recognized as an issue of growing importance in recent years. Conventional wastewater treatments are hardly capable of removing such pollutants and oxidation processes are used for its degradation. However, the presence of ionic compounds, like sodium chloride, NaCl, normally associated with these pollutants in wastewater, may retard the process (Maciel, 2004). In this context, the possibility of integrating electrodialysis (ED) and advanced oxidation processes (AOP) for the treatment of a saline aqueous solution containing phenol has been investigated.

ED is an electrochemical separation process based on selective transport of ions from one solution to another through ion-exchange membranes under the driving forces of an electrochemical potential gradient. Typical ED equipment consists of a series of anion and cation-exchange membranes, that allow the selective passage of anion and cation,

respectively, arranged in an alternating pattern between an anode and a cathode. When ionic solutions are pumped through the cell the ion concentration increase in alternate compartments (*diluate*), while the other compartments become depleted (*concentrate*) (Strathmann, 2004). In particular, an aqueous saline solution containing phenol and water can be treated by ED resulting in a demineralized solution and a saline wastewater. In this manner, the salt can be removed prior to the wastewater treatment by oxidation processes as shown in Figure 1.

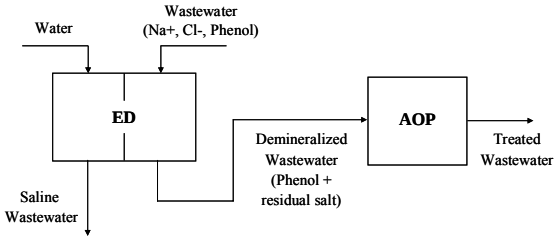

Figure 1 – Process integration schematic representation

AOP is considered a promising remediation of wastewaters containing recalcitrant compound like phenol. The processes involve the production of reactive hydroxyl radicals that can mineralize organic compounds. One of the most used AOP is the photo-Fenton process, which combines peroxide, usually hydrogen peroxide, iron ion and UV light irradiation (Esplugas, 2001).

The objective of this paper was to develop and study a hybrid model using the phenomenological parameters obtained experimentally for the demineralization and oxidation processes. Experiments were performed with synthetic saline solutions, with a concentration range of sodium chloride (NaCl) normally found in phenolic wastewater. The model will be used for further optimization.

2. Model Approach

2.1. Electrodialysis

The investigation of the desalination of water containing phenol and sodium chloride by ED was previously reported by Borges et al., 2008. Experiments were carried out in pilot equipment and a phenomenological approach was used to relate the phenol, salt and water fluxes with the driving forces (concentration and electric potential gradients) in the ED cell. Experiments were carried out at constant current, in a range between 75 and 275 A m^{-2}; the concentration of the salt and phenol in the *diluate* ranged from 0 to 55 kg m^{-3} and from 100 to 400 ppm C, respectively. Table 1 presents the flux equations and parameters obtained.

Table 1. Flux equations and overall transport coefficients obtained in the experiments with the ED system (Borges et al., 2008).

Water transport	**Salt transport**	**Phenol transport**	
$J_w = \alpha.i$	$J_s = \beta.i$	$J_p = P_p.\Delta C_p^0 + (1-\sigma).C_{pd}^0.J_w$	
α x10^{-6} (m^3 h^{-1} A^{-1})	β x 10^{-3} (kg s^{-1} A^{-1})	P_p x 10^{-4}(m h^{-1})	σ
3.74	1.98	3.02	0.24
S_1 = 0.4 m^2	S_2 = 0.2 m^2	S_1 = 0.4 m^2	

where J_W is the water flux (m h^{-1}); J_p and J_s, phenol and salt flux respectively (kg m^{-2} h^{-1}); α, electro osmotic coefficient (m^3 h^{-1} A^{-1}); β, current coefficient (kg h^{-1} A^{-1}); i, current density (A m^{-2}); S, membrane transfer area; P_p, phenol permeability coefficient (m h^{-1}); ΔC_p^0, initial phenol concentration difference between compartments, and C_{pd}^0, the initial phenol concentration in the feed (kg m^{-3}).

Salt and water transport were related to the current density applied. For the neutral solute, phenol, a convective contribution due to water flux was pointed out besides the expected diffusion contribution. The fitting of the parameters of the transport equations resulted in good agreement with the experimental results over the range of conditions investigated.

The equations presented in Table 1, which describe the flux within the ED cell, can be combined with mass balance and 10 ordinary differential equations to describe the system presented in Figure 2.

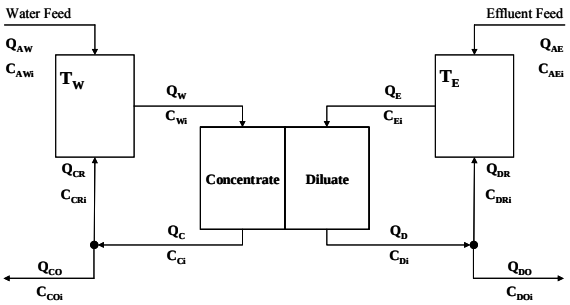

Figure 2 – Schematic representation of the ED system modeled; Q and C represent the different flow and concentration for the streams; subscript i: phenol and salt.

R_C and R_D represent the recycle fraction of Q_C and Q_D, as the following equations:

$$Q_{CR} = R_C Q_C \quad (1)$$

$$Q_{DR} = R_D Q_D \quad (2)$$

The phenol flux equation was simplified for the pilot experimental conditions; for this generic model, the former equation can be used as presented in equation (3) once the phenol concentration difference between compartments, ΔC_p, can be significant and calculated over time in this case.

$$J_p = P_p.\Delta C_p + (1-\sigma).\Delta C_p.J_w \quad (3)$$

For the second flux contribution, the original mean solute concentration on either side of the membrane was considered equal to ΔC_p.

The dynamic model can simulate the system flow, salt and phenol concentrations over time, and a steady state approach was obtained from this model.

2.2. Photochemical

Photo-Fenton oxidation processes were experimentally investigated using a laboratory batch reactor for the degradation of phenol in saline media. Experiments were carried in an annular photochemical reactor (1 L) connected to a well stirred jacketed gall

reservoir (1 L). The lamp (250W Philips medium-pressure mercury vapor lamp) was protected by a water-cooled quartz immersion well. The system was feed with a 100 ppm C of phenol saline solution and ferrous sulfate heptahydrate (Fe^{2+}). The solution was circulated through the reactor at a flow rate of about 1.5 L min^{-1} by means of a centrifugal pump. The reaction was initiated with the irradiation and onset addition of hydrogen peroxide (H_2O_2) solution at a rate of 0.83 mL min^{-1}. The pH was maintained at 3.0 and temperature at $30^oC \pm 2^oC$. Samples were withdrawn at appropriate time intervals. The organic concentration was determined by total Organic Carbon (TOC) analysis.

An experimental design based on the Doehlert model (De Aguiar et al., 1998) with three variables was used to study the effect of NaCl, H_2O_2 and Fe^{2+} concentrations on phenol degradation (variables ranges between 0 to 50 kg m^{-3}, 10 to 80 mM and 0.1 to 0.5 mM, respectively). These ranges were chosen from preliminary studies in the domain of interest.

As expected, the results confirm the negative effect of the salt concentration on the phenol removal efficiency by oxidation. Moreover, this effect was not found to be linear concerning salt concentration and degradation rate. Due to the complexity of these reaction systems, a model based on artificial neural networks has been developed to fit the experimental data (Gob et al., 1999). This model describes the evolution of the pollutant concentration i.e. phenol, by means of a reaction rate, during irradiation time under various operating conditions.

Figure 3 shows a diagram representation of the model used to obtain the reaction rate in function of the salt, Fe^{2+}, H_2O_2 concentration and TOC/TOC_0; where TOC_0 is the initial TOC value.

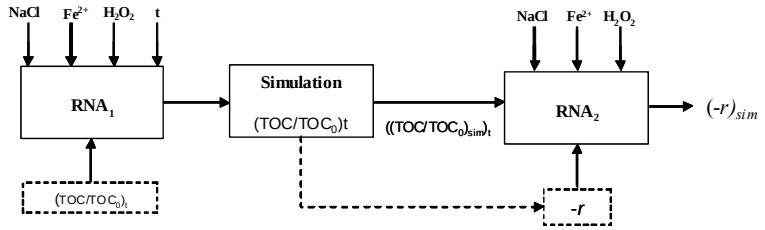

Figure 3 – Diagram representing the reaction rate mathematical model

Two artificial neural networks were used (RNA_1 and RNA_2). RNA_1 models the values of TOC/TOC_0 at a given time and condition, and RNA_2 calculates the reaction rate in function of TOC/TOC_0 value, NaCl, Fe^{2+} and H_2O_2 concentrations. The model obtained was in good agreement with experimental data.

A plug flow reactor was modeled using the reaction rate obtained by RNA_2, r, in an ordinary differential equation:

$$\frac{dTOC_{(z)}}{dV} = -\frac{r}{q} \tag{4}$$

where V is the reactor volume, z the distance down the tube from the inlet and q the flow.

The model can describe the TOC variation in a plug flow reactor in function of its volume and operation conditions, i.e. NaCl, Fe^{2+} and H_2O_2 concentrations.

3. Results and discussion

The process integration was carried out by setting the ED salt and phenol concentration output (C_{DO_S} and C_{DO_P} (Figure 2)) as the photochemical input. Several scenarios have been studied with the proposed hybrid model and some of the results obtained are summarized below.

Concerning the desalination, the model represents a generic ED system to study different configurations of the process. Firstly, the accuracy of the simulation prediction was validated comparing experimental results with a pilot configuration of the system; i.e. feed and outlet stream equal to zero (total recycle).

In terms of optimal operation conditions for the ED step, the objective is to minimize phenol loss in the saline wastewater, i.e. the concentrated stream, and minimize the cost of operation, related to energy and membrane area required. Figure 4 shows an example of how the phenol loss and the membrane area depend on the current density for 80 % demineralization of the effluent feed (Figure 4).

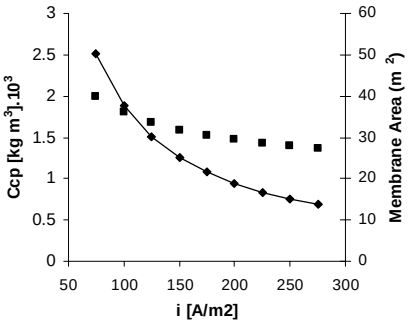

Figure 4 – Phenol loss (■) and membrane area (◆) vs. current density for 80% demineralization; C_{D_S} = 10 kg m^{-3}; C_{AE_P} =0.18 kg m^{-3}, C_{AE_S} =50kg m^{-3}, C_{AW_P} =0, C_{AWs} =0

As expected, for lower current density higher membrane area is required and higher phenol loss (C_{CO_P}) in the *concentrate* occurs in order to achieve a given amount of demineralization. The change in membrane area is more pronounced for lower current densities. The phenol loss is less sensitive to the current density than the membrane area.

On the other hand, the optimal condition for the photochemical step operation is related to the cost to demineralize the effluent to a certain level of salt concentration. The total cost is mainly the sum of reagents, energy and investment cost, in which energy is the most significant factor. Therefore, the cost can be associated directly with the reactor volume and its variation for different conditions can be obtained by the model. Figure 5 shows the reactor volume *versus* NaCl concentration for different values of H_2O_2 concentration for 70% removal of the initial TOC.

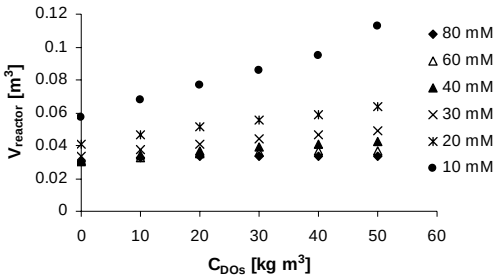

Figure 5 – Photochemical reactor volume vs. salt concentration feed for different H_2O_2 concentrations to 70% degradation; TOC_0= 0.1 kg m^{-3}; i = 275 A m^{-2}.

As can be observed for the conditions studied, the H_2O_2 concentration has an important effect on the process. The best oxidation conditions were attained when more than 30 mM H_2O_2 was added. Although values larger than 40 mM do not affect the degradation considerably, a mitigation of the NaCl negative effect can be observed for concentration above 30 kg m^{-3}. For 40 mM, the increase from 0 to 50 kg m^{-3} in salt concentration increases the reactor volume by ca. 40%, which negative significant information in economic feasibility studies.

4. Conclusions

A hybrid model in agreement with experimental data was obtained for the ED and photochemical processes. Simulations based on the model have been performed in order to estimate the behavior of the system under different conditions. The model constitutes an important tool in further studies aimed at assessing the feasibility of integrated effluent treatment processes, in which the costs of the ED and photochemical steps must be coupled in order to achieve a given level of demineralization and degradation.

Evolutionary Multi-objective Optimization of an Activated Sludge Process

Rosana Kazuko Tomita[a], Song Won Park[a]

[a] *Department of Chemical Engineering - USP Av. Prof. Luciano Gualberto, n. 380, trav. 3, CEP 05508-900, São Paulo - SP, Brazil.sonwpark@usp.br*

Abstract

Many real problems involve multiple objectives that are often conflicting and non comparable. Rare are the problems in which the objectives to be achieved (maximized or minimized) are single. Such problems are not adequately solved by using single objective function optimization techniques. Non comparable solutions are associated to the multi-objective optimization problems that represent the tradeoff among objectives. These solutions are named Pareto optimal solutions. In this work, a general review about different methods that deal with multi-objective optimization problems is presented. Special attention is given to evolutionary methods, detailing the NSGA II algorithm. This algorithm was implemented in Matlab to deal with crossover and mutation applied directly to real variables and constrained optimization problems. This method of evolutionary multi-objective optimization was applied in an activated sludge wastewater treatment system, in which effluent quality and operational cost are optimized. For this purpose, set-points of nitrate and dissolved oxygen concentrations were used as decision variables. The Pareto curves obtained at the end of 50 generations were analyzed. Finally, for illustration, one point in the Pareto curve was chosen to demonstrate the optimal set of values. In this study, the results obtained show the ability of the algorithm to achieve Pareto optimal solutions.

Keywords: NSGA II, Evolutionary Multi-Objective Optimization, Activated Sludge.

1. Introduction

Many real problems involve multiple objectives that are often conflicting and non comparable, and their solutions are associated to the multi-objective optimization problems, that represent the trade-off among the objectives, named Pareto optimal solutions. Most techniques to solve these problems comprise two phases: a multi-objective phase, which is more mathematical, and a subjective phase, namely decision-makers problem.

There are many methods to solve multi-objective problems. Very recently, the heuristic methods, such as those based on genetic algorithms, show increased application. Evolutionary algorithms are becoming an alternative to the classical optimization methods, because they permit to work with great search spaces, can generate the best compromise solution among several objectives using an unique run of optimization algorithm, besides not needing extra information, as function derivative. The evolutionary algorithms reproduce the natural evolution principles to drive the search towards an optimal solution. Such algorithms refer to a class of stochastic optimization methods that simulate the natural evolution process. According to Deb [1], the ability of an evolutionary algorithm to find multiple optimal solutions in one single simulation

run makes an evolutionary algorithm unique in solving multi-objective optimization problems. The first implementation of a multi-objective evolutionary algorithm occurred in the mid 1980s with the J. Schaffer studies, but only in the mid-1990s that the evolutionary multi-objective optimization take shape, with the development of several important algorithms [2]. Among them, the multiobjective genetic algorithm (MOGA), developed by Fonseca and Fleming [3]; non-dominated sorting genetic algorithm (NSGA), by Srinivas and Deb [4]; and the niched Pareto genetic algorithm (NPGA) elaborated by Horn et al. [5]. Also Deb et al. [6] proposed the elitist non dominated sorting genetic algorithm (NSGA II) so as to alleviate three principal criticisms of the NSGA: computational complexity, non-elitist approach and the need of specifying a sharing parameter.

2. Evolutionary Multi-Objective Method

The elitist non dominated sorting genetic algorithm, denoted as NSGA II, incorporates the concept of elitism and use an explicit diversity preserving mechanism to make it more powerful than the previous NSGA algorithm. The NSGA II was proposed to alleviate three difficulties presented in NSGA: computational complexity, non-elitist approach, and the need for specifying a sharing parameter. The flowchart for NSGA II used here is shown in Figure 1. The blocks on right of this figure indicate our Matlab functions implemented for this work.

SBX – *Simulated Binary Crossover*

Create two solutions $x_i^{(1,t+1)} = 0{,}5\left[\left(1+\beta_{qi}\right)x_i^{(1,t)} + \left(1-\beta_{qi}\right)x_i^{(2,t)}\right]$ and $x_i^{(2,t+1)} = 0{,}5\left[\left(1-\beta_{qi}\right)x_i^{(1,t)} + \left(1+\beta_{qi}\right)x_i^{(2,t)}\right]$ after two parental solutions $x_i^{(1,t)}$ e $x_i^{(2,t)}$. This operator simulates recombination operator in one point for binary variables: first it generates the random number $0 \le u_i \le 1$. The parameter $\beta_{qi} = \left(2u_i\right)^{1/(\eta_c+1)}$ *when* $\mathrm{u_i} \le 0.5$ and $\beta_{qi} = \left(2(1-u_i)\right)^{-1/(\eta_c+1)}$ *when* $0.5 < \mathrm{u_i} \le 1$ is calculated so that its probability area is the number value u_i. The η_c is the recombination distribution index. The more elaborated version of this SBX was implemented in the present paper.

Polinomial Mutation

Apply the distribution of the polynomial probability to create a solution $y_i^{(1,t+1)} = x_i^{(1,t+1)} + \overline{\delta}_i \Delta_{\max}$. The parameter is estimated as $\overline{\delta_i} = \left(2u_i\right)^{1/(\eta_m+1)}$ *when* $\mathrm{u_i} \le 0.5$ and $\overline{\delta_i} = 1 - \left[2(1-u_i)\right]^{1/(\eta_m+1)}$ *when* $0.5 < \mathrm{u_i} \le 1$

where η_m is the index for the mutation probability distribution and $\Delta_{\max}$ is the maximum allowed perturbation. We implemented the more elaborated version of this parameter estimation

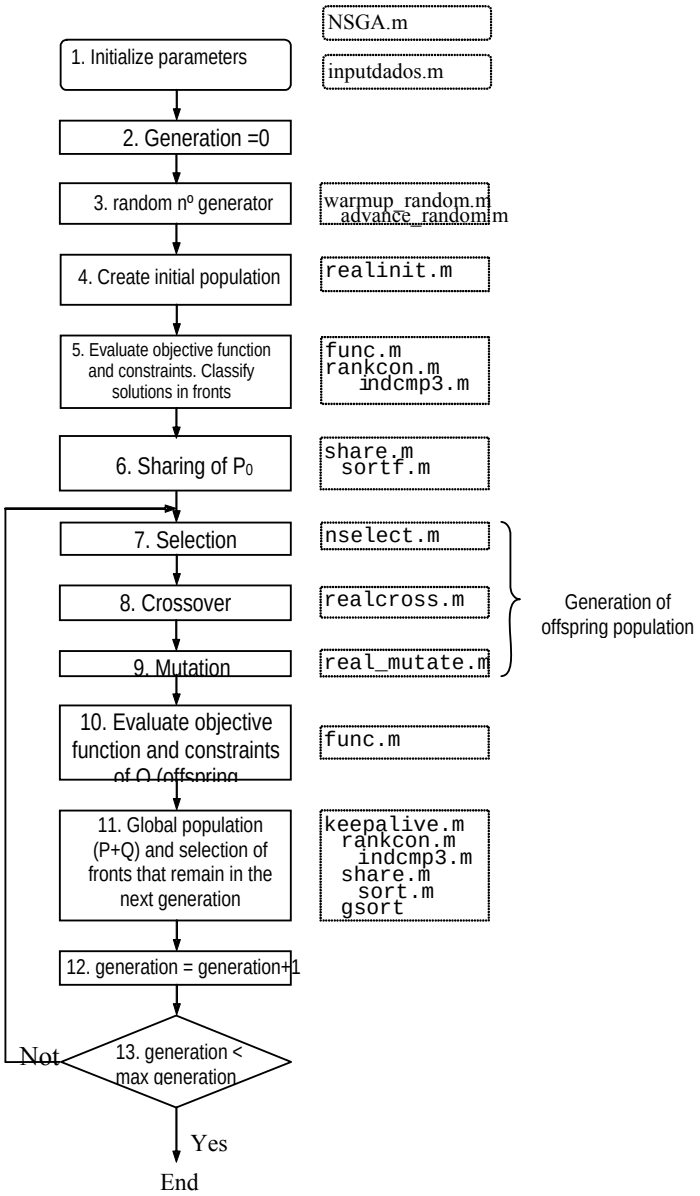

Figure 1: Flowchart for NSGA II

3. Evolutionary Multi-objective Optimization of the Activated Sludge Process

The wastewater treatment system dynamics was modeled in Simulink, see Sotomayor et al. [7-9] for details. The multi objective functions to be minimized are the Kjeldahl nitrogen EQ_{NK} , the nitrate EQ_{NO} and the energy required for aeration AE .

$$\min \begin{cases} EQ_{NK} = \frac{1}{T}\int S_{\mathrm{NK,e}}(t)\cdot Q_e(t)dt \\ EQ_{NO} = \frac{1}{T}\int S_{\mathrm{NO,e}}(t)\cdot Q_e(t)dt \\ AE = \frac{1}{T}\int \sum_{i=2}^{3}\left(0{,}4032(K_{\mathrm{LA}})_i^2 + 7{,}8408(K_{\mathrm{LA}})_i\right)dt \end{cases} \tag{1}$$

with the restraints

$$\begin{aligned}
SS_{\max} - SS &\geq 0 \\

\frac{dS_{\mathrm{NO}}}{dt} &= \frac{F}{V}\left(S_{\mathrm{NO}_{entra}} - S_{\mathrm{NO}}\right) - \frac{1 - Y_{\mathrm{H}}}{2{,}86Y_{\mathrm{H}}} r_2 + \frac{1}{Y_{\mathrm{A}}} r_3 \\
\frac{dS_{\mathrm{O}}}{dt} &= \frac{F}{V}\left(S_{\mathrm{O}_{entra}} - S_{\mathrm{O}}\right) - \frac{1 - Y_{\mathrm{H}}}{Y_{\mathrm{H}}} r_1 - \frac{4{,}57 - Y_{\mathrm{A}}}{Y_{\mathrm{A}}} r_3 + K_{\mathrm{LA}}\left(S_{\mathrm{O}_{sat}} - S_{\mathrm{O}}\right) \\
\frac{dS_{\mathrm{ALK}}}{dt} &= \frac{F}{V}\left(S_{\mathrm{ALK}_{entra}} - S_{\mathrm{ALK}}\right) - \frac{i_{\mathrm{XB}}}{14}(r_1 + r_2 + r_3) + \frac{1 - Y_{\mathrm{H}}}{40{,}4Y_{\mathrm{H}}} r_2 - \frac{1}{7Y_{\mathrm{A}}} r_3 + \frac{1}{14} r_6
\end{aligned} \tag{2}$$

For the details of this activated sludge ASM1 model with the explanation of the reaction rates $r_1,...,r_8$, see Tomita et al. [10]. The parameters applied for this problem were: the size of the population 100, number of iterations 50, recombination probability 0.9, mutation probability 0.1, recombination distribution index 1, mutation distribution index 1, $NO^{sp}_{\min} = 0\ g.m^{-3}$, $NO^{sp}_{\max} = 3\ g.m^{-3}$, $OD^{sp}_{2,\min} = 0\ g.m^{-3}$, $OD^{sp}_{2,\max} = 6\ g.m^{-3}$, $OD^{sp}_{3,\min} = 0\ g.m^{-3}$, $OD^{sp}_{3,\max} = 6\ g.m^{-3}$ For the control of this activated sludge wastewater treatment, see Sotomayor et al. [11]. The simple and partial results of the evolutionary multi-objective optimization are shown in Figure 2.

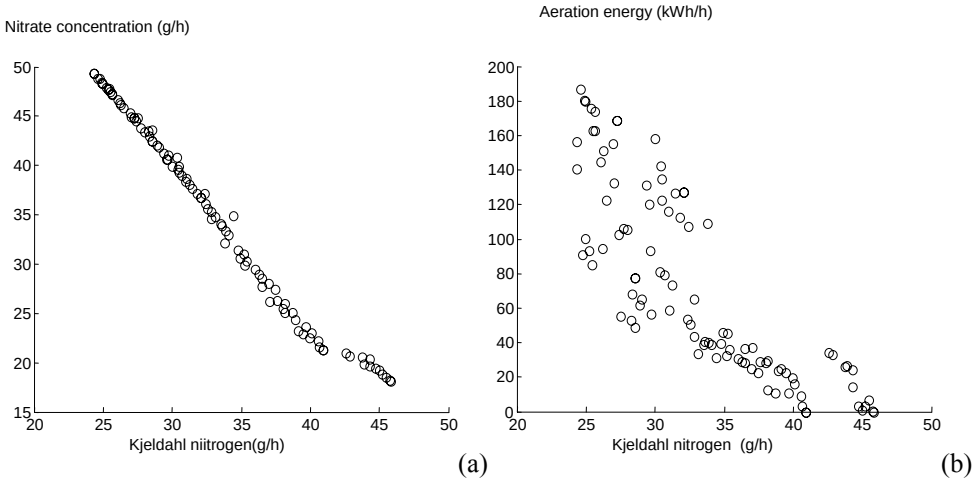

Figure 2. (a) nitrate concentration versus Kjeldhl nitrogen (b) aeration energy Kjeldhl nitrogen

In the ASM1 activated sludge model the process is highly nonlinear due to the kinetics similar to Monod. In Figure 3-b, it is observed that the convergence of the evolutionary optimization is not finished. However, these results are good enough to illustrate the methods of multi-objective optimization. In our complete work [12] the sensitivity analysis of the optimization results was performed due to parameters of the NSGA II algorithm, but this is not the main scope of the present paper.

4. Concluding remarks

The main contribution of the paper is the Matlab implementation of the NSGA II with more efficient and flexible programming for chemical engineering problems. Here, it can be integrated with a dynamic process model. This is illustrated with an ASM1 model implemented in Simulink. The usual implementation of NSGA II considers the maximum iteration as one of the stopping criteria, with no guarantee of optimization convergence. More efficient convergence criteria for chemical process applications have to be developed. Another issue for further development is the presentation of the clear decision-maker criteria for the upper layer of the multi-objective applications. The evolutionary algorithm also deserves more developments. Finally, after this experience,

the authors prefer to work, in the future, with differential evolutionary studies rather than adaptive and co-evolutionary algorithms.

Abstract

This study had the objective to evaluate alternative methods for determining properties of commercial gasoline, based on models that establish correlations between their properties and mid infrared spectra (Mid-IR) for spectra obtained with medium resolution portable equipment or obtained with high resolution equipment. Different methods of identifying outliers and pre-processing spectral data were analyzed. Methods for sample classification of the training set of data, model validation and model prediction, based on either Mahalanobis distance criteria or soft independent modelling of class analogy method (SIMCA), showed similar results. Models based on multiple linear regression (MLR), principal component regression (PCR) and partial least squares (PLS) showed similar deviations for prediction of gasoline properties. Techniques for data pre-processing by derivative and smoothing did not improve robustness of the models. Models based on spectra obtained in high resolution infrared equipment showed acceptable deviations within the limits of reproducibility of the primary method, with less than 10% error. Models based on spectra obtained in medium resolution equipment showed errors higher the limits of reproducibility of the primary method in 30% of the samples.
Keywords: gasoline; infrared spectroscopy; octane number

1. Introduction

In order to ensure the quality of automotive gasoline offered to the final consumer, frequent collecting of samples is needed for analyzing their quality properties according to ASTM methods. Among the parameters used for evaluating the quality of gasoline are mainly anti-knock characteristics, distillation, density, aromatics content and for Brazilian gasoline, the ethanol content. The anti-knock characteristics are expressed by indexes of octane “motor” (MON) and “research" (RON), described by the methods ASTM D-2699-94 and ASTM D-2700-94.

These properties are determined by methods of analysis that require long time of execution, relatively high costs and large amount of samples, generating waste residues. The use of spectroscopy in the range of near infra red (NIR), proposed by Kelly et al. (1990) and Litani et al. (1997), and in the range of mid infrared (Mid-IR), studied by López et al. (1996) and Andrade et al. (1997), stands out among the alternative methods to estimate the properties of gasoline in a faster and more economical way. The use of infrared spectroscopy based on the Fourier transform (FTIR) has been proposed by Brereton (1986), Williams et al. (1989) and Giancaspro (1983), using chemometric algorithms for processing data and for calibration and validation of models.

Brazilian gasoline has some peculiar characteristics because of the content of 20% to 25% v/v of bio-ethanol and different composition of hydrocarbons in each state of the

country. These characteristics lead to the need to develop models and correlations that are able to predict diversity of gasoline properties and provide monitoring of the final product quality using fast and economical analysis.
Infrared spectroscopy-based methods are acceptable for quality control in a production line, where the samples do not have wide range of composition. Even with the use of high resolution IR equipment, models based on infrared have not been recognized as reliable for classification of commercial gasoline samples to be predicted by the model. The objective of this study was to evaluate the usefulness and limitations of alternative methods of analysis based on infrared spectroscopy for estimation of properties of commercial samples of gasoline collected at random from a macro-region of Brazil. Influence of different methods for detecting outliers and calibrating models on the robustness of the models were studied, especially for portable infrared equipment with medium resolution.

2. Experimental

The wide range of variation in composition of commercial gasoline in Brazil makes difficult to obtain generalized models. It is necessary the use of fuel samples from various regions of the country and require a statistical treatment of results for sample classification and model calibration and prediction. Database included 160 samples obtained from commercial gasoline, collected randomly at different gas stations along the Northeast region of Brazil. Half of these samples contained average volume fraction of 20% of ethanol and the other half contained a volume fraction of 25%. Samples were divided randomly into two groups, 107 of them are reserved for calibration or training models and 53 for model validation. Models were applied to predict properties of all samples for evaluating errors of classification. Infrared spectra were generated by two types of equipment, with high resolution measurements and another one with medium resolution measurements. Those data were treated separately generating two sets of models for comparison performance of models. For each set of models, various methods of detection and exclusion of outliers, parameters estimation and classification of validation data were tested comparing calculated errors.
Analyses of octane index were done in a CFR engine from Waukesha Motors. The analyses of composition of the samples were performed on a Varian CP-3800 gas chromatograph with a 100 meter PONA column. Infrared spectra were obtained with a portable equipment for analysis on field from Grabner Instrumensts IROX-2000, Mid-IR range, resolution of 4 cm^{-1}. For comparison purposes, infrared measurements were done from a high resolution spectrophotometer Perkin-Elmer Spectrum GX100, Mid-IR range, resolution of 8.3 cm^{-1}.
For the pre-processing and multivariate analysis of the infrared spectra, software Unscrambler, version 8.0 from CAMO, was used. Classification was done by comparing different methods for detection of outliers for refining the calibration set of data. Verification of clustering was done by principal component analysis (PCA) of the original spectral data, using the Unscrambler software, followed by graphic analysis of residual variances and leverages of the calibration set. Classification of samples for model validation was done by the estimative of the Mahalanobis distances (MD) from data after PCA analysis, using the toolbox of Matlab, and by soft independent modelling of class analogy method (SIMCA), based on Euclidean distance, as described by Wold et al. (1981). Each method of outlier detection generated a different set of calibration data that was used to compare models. After exclusion of possible outliers in the calibration set of data, models were trained based on the original spectra with parameter estimation for three different methods: multiple linear regression (MLR), principal component regression (PCR) and partial least squares (PLS). Alternatively, it was tested the influence of pre-treatment of spectral data by techniques of either smoothing or derivatives on the models performance. In the validation step, models built for each set

of data, from medium and high resolution infrared equipment were compared by analysis the errors of prediction of properties. In order to compare models performance, their predicting errors were compared to the reproducibility limits of each primary method used for determining gasoline properties. Reproducibility were also analyzed by calculation of root-mean-square error of calibration (RMSEC) and root-mean-square error of prediction (RMSEP) to evaluate the quality of the models and the method of classification of outliers, both the for calibration set of data for validation set of data for samples selected as adequate to be predicted by the models.

3. Results and Discussion

Figure 1 shows graphical representation of predicted data by the model vs. measured data for calibrated model of octane index RON by PLS method, when using complete spectra of calibration set of data selected by SIMCA method. In this graph predicted values of octane RON by the model were plotted as a function of measured values by the primary method for accepted and rejected samples in the SIMCA selection method. It is observed that from 109 calibration samples, 19 were rejected by the SIMCA method. Figure 2 shows results for predicted RON by PLS model vs. measured values, however, when samples of the calibration set were selected by the Mahalanobis distances (MD) selection method. In this case, from 109 calibration samples, 21 were rejected in the selection of MD. It is observed from Figures 1 and 2, that results of outlier selection are similar, although the two methods are based on different statistical principles, thus resulting in numbers of rejected samples not much different. Figures also show that some samples rejected by either SIMCA or MD criterion were well represented by the model from which were excluded. On the other hand, some samples recommended for use in the calibration were not well represented by the model from which they were used to calibrate. Based on these results, 19 samples were rejected, leaving 88 samples for the calibration set. Calibration set of data was examined for detection and exclusion of outliers by Mahalanobis distance method (MD), principal component analysis (PCA) and SIMCA, using the matrix of original 962 spectral data.

Figure 3 shows Chi-Square distribution of Mahalanobis distances of the refined calibration set of 88 samples. The distribution can set the critical value of 13.57 for the Mahalanobis distance that contains 95% of the samples. Validation samples with MDs above this value of 13.57 were selected as poorly represented by the models calibrated with this set. Figure 4 shows the comparison of three methods for selection of the calibration set. In this figure it is plotted residuals variance in function of the leverages for the first principal component PC1 from the PCA analysis of 88 samples of calibration set of data and 9 samples of validation set that were rejected by any of the three procedures. Among the three methods tested, 9 samples were rejected for the prediction, but there was no coincidence and only 7 of them were both disqualified by all methods. It is concluded that the Mahalanobis distance is not much different from the method based on either SIMCA or the graphical analysis method.

PLS and PCR models for prediction of RON index were tested with 53 samples for validation set of data, as shown respectively in Figures 5 and 6. These figures show results of prediction of RON on the basis of measured values for validation set for samples selected by the Mahalanobis distances, with 8 samples rejected and 45 samples selected as representative, from which 22 samples with a volume fraction of 20% of ethanol and 23 samples with a volume fraction 25% of ethanol in gasoline.

These subgroups are distinguished especially in the PCR model, both in calibration and in model prediction, as shown in Figure 6, which indicates that good results could be obtained with separate models for each of these groups. The performances of the models PLS and PCR are very similar.

Table 1 shows the overall comparison of different options for modeling of octane index RON, with data generated by portable infrared equipment and also the consequences of

using either the Mahalanobis distance or the SIMCA method for selecting samples of the prediction. It is also shown the influence of transforming the spectra by derivative treatment. For the spectra generated with portable equipment, the quality of models is very similar for any of the methods of sample selection (SIMCA or MD) or method of modeling (MLR, PCR or PLS). Pre-treatment of spectra by derivation or smoothing does not alter the quality of prediction. The values of Root Mean Squared Error of Calibration Set (RMSEC) and Root Mean Squared Error of Prediction Set (RMSEP) were generally above 0.7. These values are relatively high when compared to the limits of reproducibility of the primary method. The limits of reproducibility cited in ASTM D-2700 and D-2699 are 0.9 to 0.7 for RON and MON.

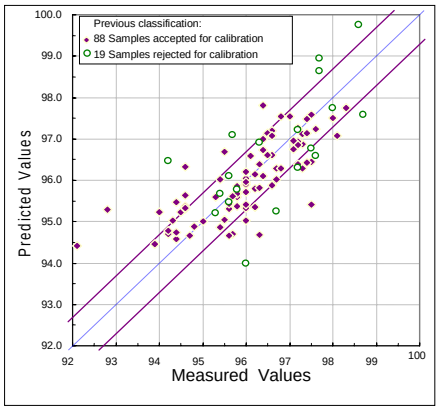

Figure 1 – RON, by PLS model from 962 spectra, 3 PCs, RMSEC = 0.75

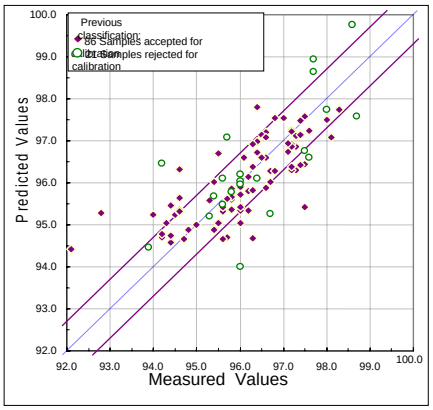

Figure 2 – RON, by PLS model from 962 spectra, 3 PCs, RMSEC = 0.76

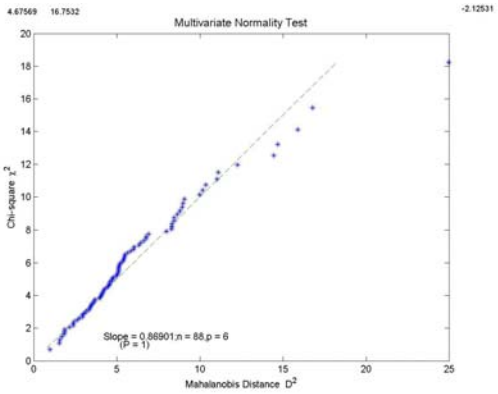

Figure 3 – Chi^2 Distribution for 88 refined samples of the calibration set.

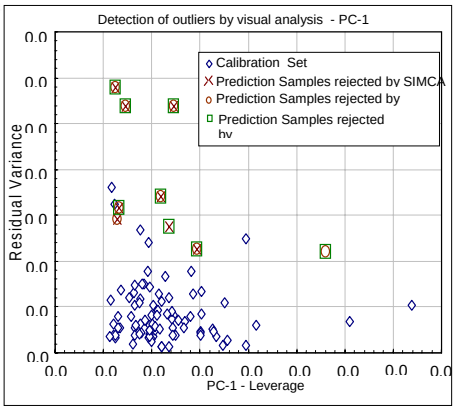

Figure 4 – Residual variances in function of Leverages for PC1.

The errors in the classification of samples are also considerable. Regardless of the method used, 15 to 30% of samples accepted in the calibration as suitable for fitting the model were represented by the model with errors above the limit of reproducibility of the primary method. From 20 to 30% of samples of the validation set and accepted as represented by the model were also predicted with values of RON with errors above the limit of reproducibility of the primary method.

For the models of MON prediction, results are similar to the RON, but the values of RMSEC and RMSEP from models of MON, ranging from 0.6 to 0.7, are lower than values for models of RON. The percentage of wrongly classified samples as represented by the models decreases slightly models of MON, reaching values of around 20%. These values, however, may be considered high for prediction purpose because the

uncertainty on the acceptance of prediction of octane MON data with this portable equipment can be up to 30% of cases.

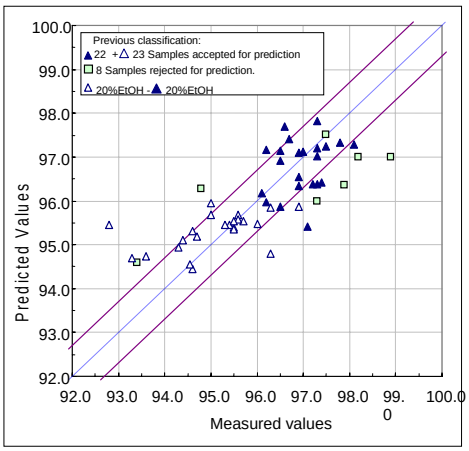

Figure 5 –RON, by PLS model from 962 spectra, 3 PCs, RMSEP = 0.79

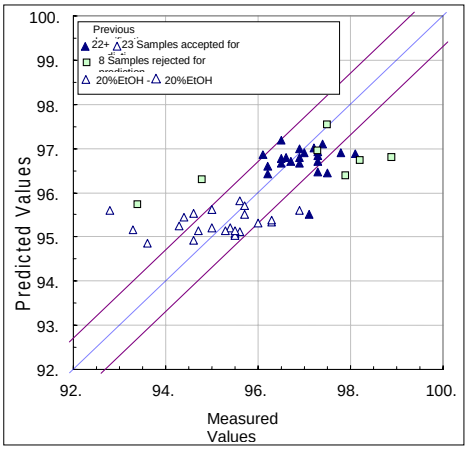

Figure 6 – RON, by PCR model from 962 spectra, 3 PCs, RMSEP = 0.82.

Analyzing spectra generated by the equipment of high resolution corresponding to medium infrared (Mid-IR), the classification of samples led to the identification of only 5 possible outliers among the 107 samples of the initial set of calibration. Figures 7 and 8 show the results of prediction of RON by PLS and PCR, with classification by SIMCA. Table 2 shows the comparison of different options for modeling RON.

Table 2 - Comparison of models and methods of classification of samples for prediction of octane index RON. Infrared spectra via high resolution infrared equipment.

Spectra	**23 pts.**	**Complete**		**3212**	**points**

% errors of acceptance of Prediction SET	6.1	10.2	10.2	6.1	8.2

Comparing the results shown in Figures 5 and 7, which refer to models based on spectra obtained with different equipment but with the same methods of calibration of models and classification of samples, and Tables 1 and 2 for the other methods, it can be checked improved quality of the models when the data of the same spectral range are generated by high resolution equipment.

For the prediction of RON, for example, levels of RMSEC and RMSEP with the use of models based on spectra generated by the equipment with a high resolution of 8.3 cm-1

is reduced to about 0.4, about half of those values obtained from the application of models based on spectra generated with the medium resolution equipment of 4 cm-1. These values are acceptable when compared with the limits of reproducibility established in primary method ASTM D-2699. Ssamples wrongly classified are reduced to less than 10% for high resolution equipment, and 6% in the case of the MLR model.

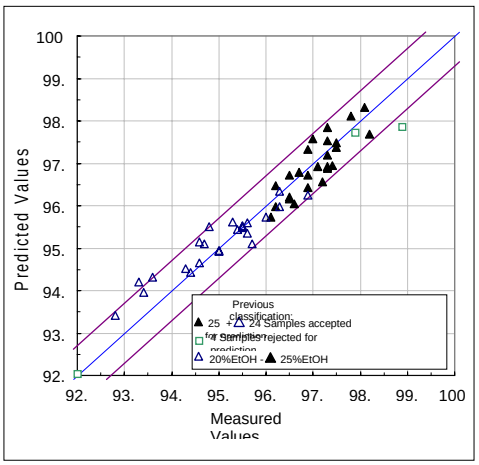

Figure 7 –RON, by PLS model from 3222 spectra, 3 PCs, RMSEP = 0.39.

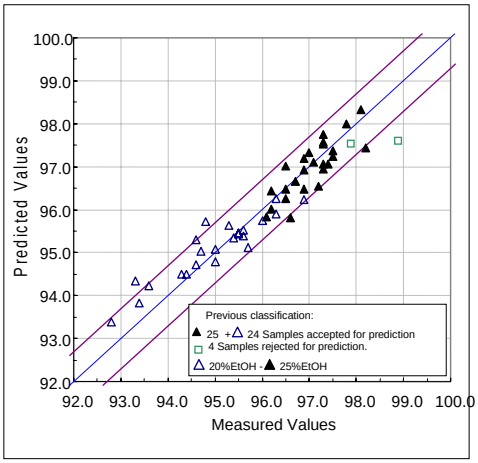

Figure 8 –RON, by PCR model from 3222 spectra, 3 PCs, RMSEP = 0.42.

4. Concluding Remarks

The methods tested for identification of outliers for calibration and for classification of samples of prediction set were similar when the spectral data have the same instrumental origin. Results did not show considerable differences in robustness of linear models for different methods of calibration or for the pre-treatment of spectra by either derivation or numerical smoothing. This suggests that, among the alternatives considered, the best method is the more convenient and more compatible with the computational resources available. Models based on spectra generated by the equipment with 4 cm^{-1} medium resolution were useful only for low accurate prediction of RON and MON. In this case, high values of RMSEP and probability of error exceeds the limits reproducibility of the primary method for more than 30% of samples (prediction set).
Models of octane indexes generated by the equipment with 8.3 cm^{-1} high resolution showed good results and is useful in the analysis of commercial gasoline. These models showed RMSEP of around half the levels of reproducibility of the primary method. At least 90% of samples were correctly classified by the models. However it should be noted that even with the use of high resolution IR equipment, the usefulness of this method is limited to situations in which the unknown samples belong to the same population used in calibration of models, although classification of unknown samples based on their spectra by one of the methods tested in this work is still needed.

Abstract

The ASTM standard methods for experimental determination of gasoline properties, such as octane numbers and Reid vapour pressure (PVR) are, in general, expensive, time consuming and cumbersome. Therefore, the study and development of faster and cheaper methods is of great industrial and scientific interest, particularly when one thinks of large numbers of gasoline samples to be tested. However, gasoline is a mixture of hydrocarbons and presents very complex chemical properties that require the use of several analytical techniques, and so the development of any new method will need to be validated through a series of statistical techniques. This contribution is aimed at the validation of a Thermal Wave Interferometer (IOT), conceived and developed by Vargas et al. at the Norte Fluminense State University – UENF, for the determination of octane numbers (MON and RON), distillation curve and PVR of gasoline and gasohol. The IOT determines these properties through a mathematical correlation of the thermal diffusivity of the components present in the gasoline, or gasohol, sample. This IOT validation study involved the use of a multivariate regression technique, namely SIMCA (Soft Independent Modelling of Class Analogy) for the classification of sample data and identification of outliers and the development of new correlation models for the prediction of gasoline octane numbers. In this study 97 samples of various types of commercial gasoline and gasohol, the latter containing up to 30% v/v of ethanol, were prepared and had their corresponding octane numbers (MON and RON) determined through the CFR motor method and their thermal diffusivities determined through the IOT. These experimental data were then correlated and a PLS (partial least squares) model, based on 89 thermal diffusivity variables, was developed for the prediction of the AKI, a parameter which is the mean value of the octane numbers (MON and RON) of a sample, i.e. AKI = (MON+RON)/2. Better results were obtained when the model was built for distillation curve points (Initial boiling point, 10% evaporated) and PVR data, and the thermal diffusivity data (30-870s) were centred at the mean value and smoothed, giving an RMSEC =1.832 and an RMSEV=2.270. These results indicate that the IOT is a promising, fast and cheap method for the prediction of AKI, provided the

user takes into account the inherent errors of the experimental method. Thus, the IOT may be very useful as a tool for undertaking screening analysis, i.e., selection of gasoline, or gasohol, samples that must be submitted to the more expensive and time consuming CFR motor method.

Keywords: gasoline, gasohol, octane numbers, interferometry

1. Introduction

The quality of gasoline with respect to its resistance to detonation is evaluated through its octane numbers (MON and RON) or Anti Knock Index (AKI), i.e. (MON+RON)/2. Evaluation of octane numbers is justified by the need to guarantee that the fuel meets engine demands at the time of compression and beginning of expansion (when pressure and temperature rise) without auto-ignition. The values of MON and RON are obtained through a special engine, the CFR motor (Cooperative Fuel Research), which is the only test legally recognized by the Brazilian Oil Regulatory Agency (ANP) for that purpose.

Other important tests for determining fuel quality are distillation and Reid Vapour Pressure (PVR). The former gives a measure, in terms of volatility, of HC distribution in a gasoline sample. In Brazil, ANP establishes specific temperatures for evaporation of T10%, T50%, T90% of the fuel, as well as its Initial Boiling Point (IBP) and Final Boiling Point (FBP) and the amount of residue left after distillation. The latter evaluates the tendency of gasoline to evaporate, and, therefore, the higher the PVR the easier it is for a fuel to evaporate.

Although well established and reliable, several of the standard methods used for fuel quality evaluation are tedious, cumbersome and involve the use expensive equipment and highly qualified personnel. Therefore, there is a need for developing techniques and correlations between other physical-chemical properties and gasoline quality parameters[A – B]. This research work is dedicated to the study and evaluation of use of a Thermal Wave Interferometer (IOT)[C – F], which takes photometric measures of diffusivity and relates them to gasoline quality parameters. According to Lima et al[E – F], the thermal diffusivity, defined as the ratio of the thermal conductivity to the sample heat capacity per unit volume, measures essentially the samples thermalisation time. The photothermal techniques are essentially based upon sensing the fluctuation in temperature of a given sample due to non-radiative de-excitation processes following the absorption of modulated light[G]. The importance of thermal diffusivity as a physical parameter to be monitored is due to the fact it is unique for each material. This can be appreciated from their tabulated values published in literature[H] for a wide range of materials.

Application of some multivariate calibration techniques to the modelling of gasoline properties have been reported in the literature[I – K]. Aiming at evaluating the potential of thermal diffusivity for predicting the antiknock properties of gasoline a commercial software has been used (UNSCRAMBLER®, v. 8.0) for chemometric studies. This allowed the development of linear multivariate PLS regression models through the SIMCA (Soft Independent Modelling of Class Analogy) method. The results obtained for pure gasoline (Gasoline A) and gasoline containing 20% to 30%(v/v) of ethanol (Gasoline C) have been used for the multivariate calibration that was later applied in the modelling of gasoline properties, in particular octane numbers.

2. Methodology

Correlations between experimental diffusivity data obtained through the IOT and gasoline properties obtained through the standard methods for PVR, MON, RON, Distillation (IBP, T10%, T50%, T90% and FBP) have been studied. The distillation tests have been undertaken using ISL® and HERZOG® automatic distillation units, in accordance with ASTM D86. For PVR, a Grabner Instruments Minivap-VPS, in accordance with ASTM D5191 has been used. Finally, for octane numbers (MON and RON), a CFR engine has been used, in accordance with ASTM D2699 and D2700.
The reproducibility limits of the standard methods are shown in Table 1, in accordance with their corresponding ASTM methods. These values have been considered in the analysis of the results obtained from the correlation models developed in this research study.

Table 1. Reproducibility Limits of the standard methods gasoline characterisation

Property	**Standard Method**	**Reproducibility Limits**
Specific gravity (g/cm^3)	ASTM D4052	0.0005
IBP (ºC)	ASTM D86	7
T 10% (ºC)	ASTM D86	7
T 50% (ºC)	ASTM D86	8.5
T 90% (ºC)	ASTM D86	9.5
FBP (ºC)	ASTM D86	10.5
MON	ASTM D2700	0.9
RON	ASTM D2699	0.7
Paraffins (%)	chromatography	3.90
Aromatics (%)	chromatography	2.35
Naphthenes (%)	chromatography	1.17
Olefins (%)	chromatography	1.94

These same values have been used for evaluation of the performance of the correlation models to both the calibration data set (RMSEC), Equation 1, and the prediction data set (RMSEP), Equation 2. The latter was also used to evaluate the classifying method used for detection of outliers.

$$RMSEC = \sqrt{\frac{\sum_{i=1}^{n} (\overline{y}_{i,cal} - y_{i,cal})^2}{n}} \quad (1)$$

$$RMSEP = \sqrt{\frac{\sum_{i=1}^{n} (\overline{y}_{i,prediction} - y_{i,prediction})^2}{n}} \quad (2)$$

Where,

- $\boldsymbol{n}$ is the number of samples accepted by the classifying method;
- $\overline{y}_{i,cal}$ is the predicted property;
- $y_{i,cal}$ is the experimental value obtained from a standard method.

The effectiveness of the methods for the prediction of outliers have been compared through the deviations of the refined calibration data set, the classified prediction data

set and the number of correctly identified outliers in the latter by each classifying method.

3. Results and Discussion

The model developed for prediction of AKI involved 89 thermal diffusivity variables obtained through the IOT and the use of the optimal principal components (PC) as determined by the minimum of residual variance of the dependent variable. Projections in orthogonal directions of the thermal diffusivity variables were obtained so that the correlation between the set of projections for these samples and the dependent variable resulted in linear coefficients for each thermal diffusivity variable, allowing the calculation of the partial components in orthogonal axes, which in turn made it possible to predict the value of the dependent variables.

The AKI prediction through IOT's internal model has shown a mean squared error of 3.267 for samples of the training data set and 3.295 for the validation set, while the acceptable reproducibility for this parameter is 0.8. This great discrepancy in the prediction of AKI may be observed in Figure 1, in which the mean squared error exceeds the reproducibility limits, indicating that there is room for much improvement in the model used by the IOT.

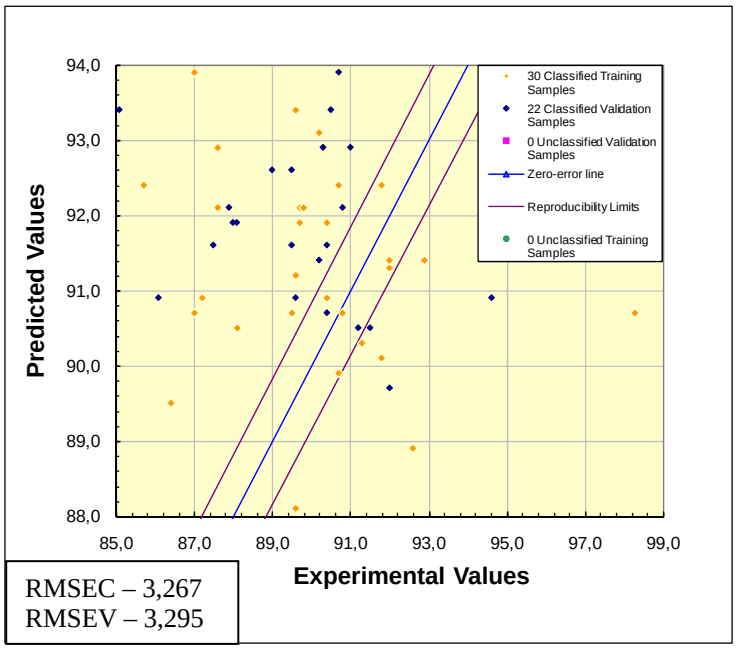

Figure 1 – AKI prediction through IOT's internal model

Figure 2 shows the results obtained from thermal diffusivity and PVR data for 30 samples. The resulting correlation shows to be unsatisfactory, since the error limits have been shifted so that the samples from the validation set would lie within the allowed area.

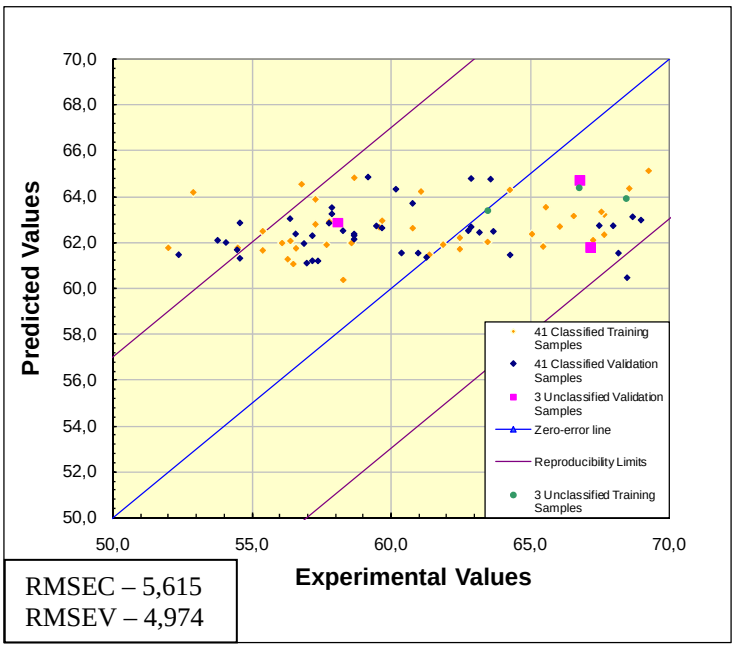

Figure 2 – PLS model for PVR data for Gasoline A and C samples

Better results, however, have been obtained when some distillation points were used. Figure 3 shows data of T10% for 44 samples, and it can be observed that these are evenly distributed along the diagonal and prediction errors are within the ASTM reproducibility limits. Therefore, the correlation thus obtained is in accordance with those obtained using thermal diffusivity.

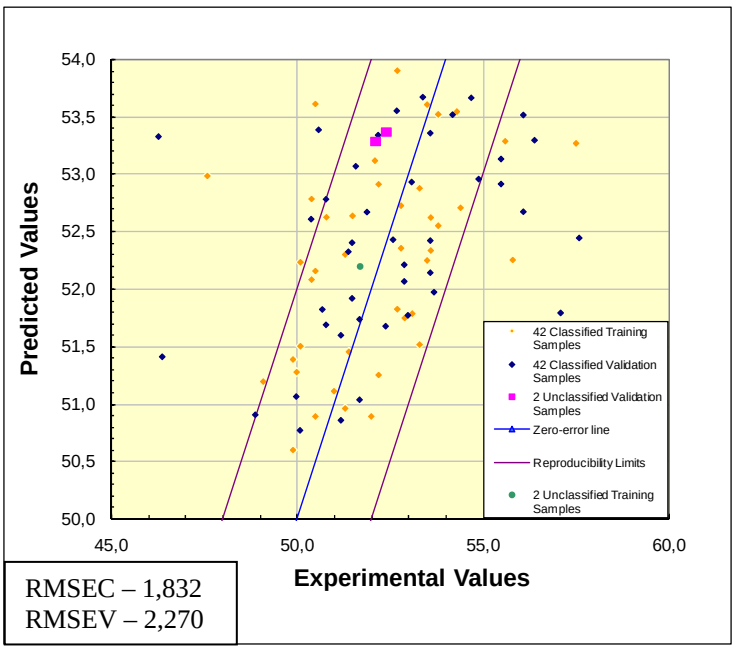

Figure 3 –PLS model for T10% data for Gasoline A and C samples

4. Concluding Remarks

In this research study PLS linear multivariate regression has been used for the development of models correlating thermal diffusivity data and gasoline properties obtained through their corresponding standard methods. Among the properties analysed, the best correlation was obtained for T10%. With respect to octane numbers, IOT has shown to be a valuable asset for screening samples that should be submitted to the standard CFR engine test.

A Reactive Scheduling Approach Based on Domain-Knowledge

Juan M. Novas, Gabriela P. Henning
INTEC (UNL-CONICET), Güemes 3450, Santa Fe, CP 3000, Argentina

Abstract

Real world industrial environments frequently face unexpected events that generally disrupt in-progress production schedules. This contribution presents advances in the development of a support framework to address the repair-based reactive scheduling of industrial batch plants. When facing an unforeseen event, the framework is capable of capturing the current operational plan and its status. Based on this information, a rescheduling problem specification is developed. Tasks to be rescheduled are identified and, for them, the set of the most suitable rescheduling action types (e.g. shift, reassign, etc.) is specified. For a given specification, many solutions to the problem could exist. Then, the second step of this approach relies on the generation of a constraint programming (CP) model to address the rescheduling problem just specified. To create such model each rescheduling action type is automatically transformed into different constraints. In addition, a search strategy based on domain knowledge can also be developed. Finally, the solution of the CP model and its associated search strategy will render the repaired schedule in which the repair action types that were suggested will be instantiated. A case study of a multiproduct multistage batch plant is presented, where an event of unit failure is considered.

Keywords: Reactive Scheduling, Decision Support Systems, Batch Plants.

1. Introduction

Usually, predictive scheduling techniques generate production plans which assume stationary operating conditions along the whole scheduling horizon. However, real industrial environments are dynamic in nature; unforeseen events frequently disrupt the in-progress schedule. Reactive scheduling, or rescheduling, is then performed in order to update the current agenda. This task can be periodically executed or when an unexpected event, such as a unit breakdown, order cancellation or arrival, occurs, leading to periodic versus event-driven rescheduling, respectively. To be adopted, reactive scheduling systems must provide immediate responses to disruptions. Besides, minimum changes to the original schedule are desired to maintain a smooth plant operation. Hence, repair-based or partial rescheduling is preferred to a full-scale one.

Several works about reactive scheduling of batch plants have been reported. Janak et al. (2006) presented a review of approaches tackling this kind of problem and other papers in the field have recently been published (Ferrer-Nadal et al., 2007). Even though the review of Vieira et al. (2003) focused on discrete manufacturing plants, most of the issues described in it can be found in process industries too.

This contribution tackles the reactive scheduling problem by developing a support environment based on both, an explicit representation of the domain knowledge and a CP approach. The next section presents an overview which addresses these two components. Finally, Section 3 discusses an illustrative example.

2. Reactive Support Environment

When addressing a rescheduling situation most of the objectives and basic constraints that define the original problem still apply; however, the partially executed schedule and the perturbation or triggering event has also to be taken into account. This contribution presents a support framework able to represent this knowledge and use it in the development of a solution. It has been envisioned to operate under an event-driven policy. The framework explicitly captures the status of an in-progress schedule and characterizes the disrupting event in order to specify the rescheduling problem to be faced and, afterwards, solve it. The environment integrates different modules, as it is shown in Fig.1, all based on an explicit domain representation.

As the first step of the proposed approach, tasks to be rescheduled are identified, and for each of them, the most suitable rescheduling action type is specified. An action type not only prescribes what to do (e.g. shift, reassign, etc.) on a processing task, but also a range of possibilities, i.e. feasible equipment for a reassignment, shifting interval, etc. For a given specification, corresponding to the set of action types associated to the tasks to be rescheduled, many solutions could exist. Then, the second step of this approach relies on the generation of a constraint programming (CP) model to address the rescheduling problem just specified. To create such model each rescheduling action type is automatically transformed into different constraints. A search strategy based on domain knowledge can be employed, too. Finally, the solution of the CP model and its associated search strategy will render the repaired schedule, in which the proposed repair action types will be instantiated.

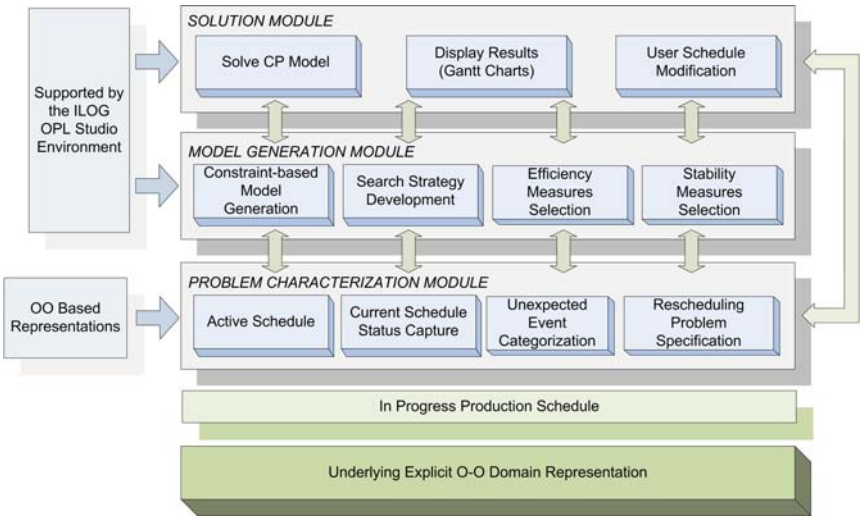

Fig.1. Components of the Reactive Scheduling Support Framework

2.1. Domain Knowledge Representation and Problem Characterization

Scheduling is a knowledge intensive activity in terms of domain knowledge. The representation of this type of knowledge is a critical issue in any scheduling support system. Fig. 2 presents a simplified version of the conceptual model of multiproduct batch plants scheduling knowledge included in the proposed framework. This information is organized into different conceptual levels. Generic concepts represent engineering or plant information that is used by entities which model a given scheduling scenario. Because of the fact that scheduling is an evolving activity, different versions

of a schedule need to be captured which are related among themselves. A schedule version is a snapshot of an active schedule, which is valid at a given moment, and is represented by means of scheduling domain entity versions (i.e., versions of the instances of *Task, ResourceSchedule, Schedule,* etc.). The handling of versions is not discussed here due to space limitations.

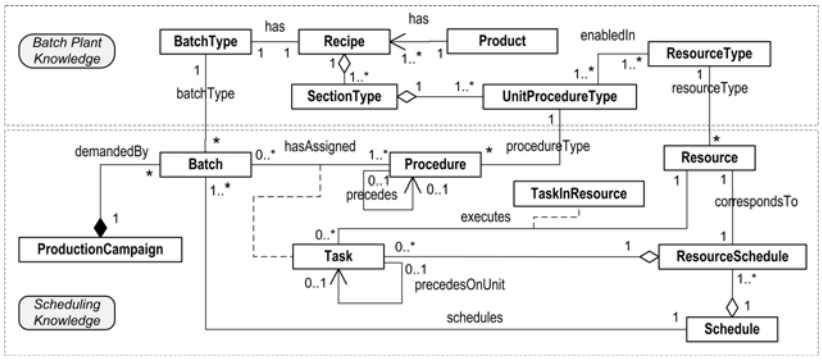

Fig.2. Partial view of batch scheduling domain concepts

Since the domain knowledge is explicitly captured, the problem characterization module fulfills the following functional requirements.

- *Capture the current operational plan and its status at the rescheduling point*. Instances of entities represented at the scheduling knowledge level, their relationships, as well as the values of their attributes, allow modeling each problem to be tackled. When addressing a rescheduling situation, the status of each task involved in the disrupted schedule must be known. At a rescheduling point *t*, a decision-making activity about tasks to be included in the reactive process has to be made. Hence, all the tasks involved in the disrupted agenda, T , are classified into the following sets, depending on their status at time point *t*: (i) already executed tasks, T_t^{AE}, (ii) non-executed tasks, T_t^{NE}, and (iii) in-progress tasks, T_t^{IP}. In addition, if the disrupting event is a batch cancellation, its associated tasks are included in the set T_t^{CE}. In turn, new tasks to be considered due to a rush batch arrival, belong to the set T_t^{NW}. These sets are related in the following way: $T = \{T_t^{AE} \cup T_t^{IP} \cup T_t^{NE}\}$; $T_t^{CE} \subseteq T_t^{NE}$; $T_t^{NW} \not\subset T$. Then, the status of a batch can be inferred from the condition of its associated tasks. Moreover, equipment status is also domain information which is taken into account.
- *Identification of the disruptive event type and its specific characteristics.* The characterization and modeling of events is another critical aspect of the problem too. The framework is able to handle equipment breakdowns, new batch arrivals and batch cancellations as disrupting events. Other types of events will be considered in the future. Based on task classification and event information, activities to be drawn in the rescheduling process are identified. Thus, RT_t is the set of tasks that needs to be considered due to the unexpected event taking place at time *t*. The remaining tasks are those not directly involved in the reactive process, referred as NT_t.

The problem characterization module uses information from the object instances pertaining to the sets previously described and from the entity representing the *UnexpectedEvent* in order to determine: (i) the updated equipment ready times, (ii) the earliest start times of those tasks that pertain to in-progress batches. This information is also employed to properly specify the reactive scheduling problem, as discussed below.

2.1.1. Rescheduling Problem Specification

For each task belonging to RT_t, its associated rescheduling action type (RAT) has to be decided. By means of the proposed methodology, each task does not have a specific and pre-defined rescheduling operation related to it; instead, it has a type of rescheduling action. Each action type prescribes a category of rescheduling operation and a range of possibilities to apply it. In this framework, the following RATs have been considered up to now: *a) Shift*, which simply "pushes" the task start time forward (right-shift) or backwards (left-shift) on the current unit. To apply such action on a task, or set of tasks, allowed left shift (*lsv*) and right shift values (*rsv*) are defined to specify a time window for the new start time. *b) Reassign*, which allows a task to be reallocated to a unit belonging to a set of feasible ones. *c) Freeze*, which is not a scheduling action itself, but is required for tasks that must keep their timings as well as their equipment assignments. In order to define the RAT to be associated with each task, they are previously classified into: (i) directly affected ones, comprising set RT_t^{DA}, (ii) indirectly affected tasks, represented by set RT_t^{IA}, and (iii) non-affected tasks, included in set RT_t^{NA}. The way tasks are categorized depends on the event type and to the extend tasks are disrupted by it. Directly and indirectly affected tasks are linked to specific rescheduling action types, which depend on the event type. On the contrary, action types associated with non-affected tasks are defined employing domain knowledge of each specific problem. To illustrate these ideas, sets RT_t^{DA}, RT_t^{IA} and RT_t^{NA} are defined for a unit failure event and their associated RATs are discussed. Similar definitions can be made for a batch cancellation (not shown due to lack of space) or other disruptions.

Task Classification for a Unit Failure Event

RT_t^{DA}. Tasks in T_t^{NE}, which are assigned to the broken-down unit, and start later than *t* but earlier than the unit recovery time. Besides, if a task is interrupted by the unit failure and cannot be recovered, its batch is canceled and all its associated tasks are inserted as a new batch (*NewBatchArrival* event) to be included in the rescheduling process.

RT_t^{IA}. These indirectly affected tasks are linked with, at least, one of the directly affected activities. They are the ones located downstream in those batches having at least a directly disrupted task. Activities located upstream can be considered as indirectly affected too, as will be shown in the example presented in the next section.

RT_t^{NA}. Includes tasks which are not affected, neither directly nor indirectly, by the unit breakdown.

RATs for Tasks Associated with a Unit Breakdown

Tasks in RT_t^{DA} are associated with a reassign action type that forces them to find another processing unit. Similarly, members of RT_t^{IA} are associated with a reassign action type that allows them to retain their current unit allocations (with a possible change in timings) or to choose a different one. Finally, different criteria were established to define the RATs to be associated with tasks included in set RT_t^{NA}. Two criteria were proposed in this work: the scheduling horizon-based (*SHB*) and a batch information-based (*BIB*) criteria.

SHB criterion: It takes into account the moment the disruptive event takes place in relation to the length of the whole scheduling horizon. Depending on the scheduling scenario and the costs of changing the current task allocations, it can be decided to: (i) freeze tasks belonging to set RT_t^{NA}, whose current start times are very close to the rescheduling point, (ii) enable shift movements over those tasks from set RT_t^{NA} having a start time not as close to the rescheduling point, but not located at the end of the

horizon, (iii) enable reassign action types over those tasks placed at the end of the scheduling horizon. A parameter V is employed to identify these three intervals.
BIB criterion: Information about the status of the current schedule is employed to define the RATs over those tasks in set RT_t^{NA}. For instance, batches having an important progress at the rescheduling point are not allowed to have their non-executed tasks reassigned, (ii) tasks associated with batches having a small positive or negative values of their slack times, are allowed to be reallocated to avoid violating their due dates.
In this way, a rescheduling problem specification gives rise to a set of rescheduling alternatives for every task, and many solutions to the problem could exist. Then, the second step of this approach relies on the generation of a constraint programming (CP) model to address the rescheduling problem just specified. To create such model each RAT is automatically transformed into different constraints.

2.2. Model Generation
In order to create a repaired schedule, the model generation module is in charge of setting up a constraint programming (CP) model, complying with the syntax of the OPL language from ILOG OPL Studio (ILOG, 2002). This model (not shown due to lack of space) comprises: (i) the basic constraints set (assignment, precedence, timing constraints, etc.), which are part of any scheduling problem. They are generated for all tasks in RT_t and (ii) event-dependent constraint set. These last ones depend on the disrupting situation been faced, and on the adopted RATs for tasks included in sets RT_t^{DA}, RT_t^{IA} and RT_t^{NA}. The objective function can be chosen among several efficiency or stability measures. Despite just one of them is optimized, the values reached by the rest are taken into account to comprehensively evaluate the scenario.

3. Example

This proposal was tested with various case studies. One of them, introduced by Pinto and Grossmann (1997), is presented in this section. The plant involves 4 processing stages and 10 units. During the scheduling horizon, 20 orders have to be processed. Fig. 3.a shows an in-progress schedule, with tasks labeled by batch name. Let us assume that unit *u4* shuts down at t = 31.00 h and it will be unavailable till a *recovery time* = 134 h.
The problem was solved employing three different approaches in order to compare results: by resorting to a full-scale rescheduling (*FSR*) and to two partial ones. In the first case all tasks involved in the rescheduling process were allowed to be reassigned. The second approach was a partial reschedule, identified as *PR1*, which employed the *SHB* criterion to handle tasks in RT_t^{NA}. Tasks in sets RT_t^{DA} and RT_t^{IA} were associated with a reassign rescheduling action type. For tasks in set RT_t^{NA}, V = 24 h was adopted (justification not discussed due to lack of space), meaning that tasks having their planned start time within the rescheduling point, and 24 h after it, were associated with freeze action type. Tasks in RT_t^{NA}, starting at least 24 h after the rescheduling point, were associated with a shift action type. The new schedule, obtained under these conditions, which is not shown due to lack of space, was not a good quality one due to the topological constraints that had to be considered. Because of them, batches assigned to units *u1* and *u2* in the first stage, which were in set RT_t^{NA}, could not be assigned to unit *u5* in the second stage and had to wait for the recovery of *u4*. On the contrary, the other partial reschedule approach (*PR2*) employed topological knowledge. The criterion used was also *SHB*, but now upstream tasks were considered in RT_t^{IA}, too. So, in order to give more flexibility to tasks assigned to units *u1* and *u2*, they were associated with

reassign action types. The solution that was obtained is shown in Fig. 3. Schedules were assessed by means of a Makespan performance measure, plus equipment and temporal stability functions that allow quantifying a smooth plant operation, among others. The solution obtained with the *PR2* approach (Mk = 259.9) is of better quality than those obtained with the *PR1* (Mk = 301.9) and *FSR* (Mk = 262.8) strategies.

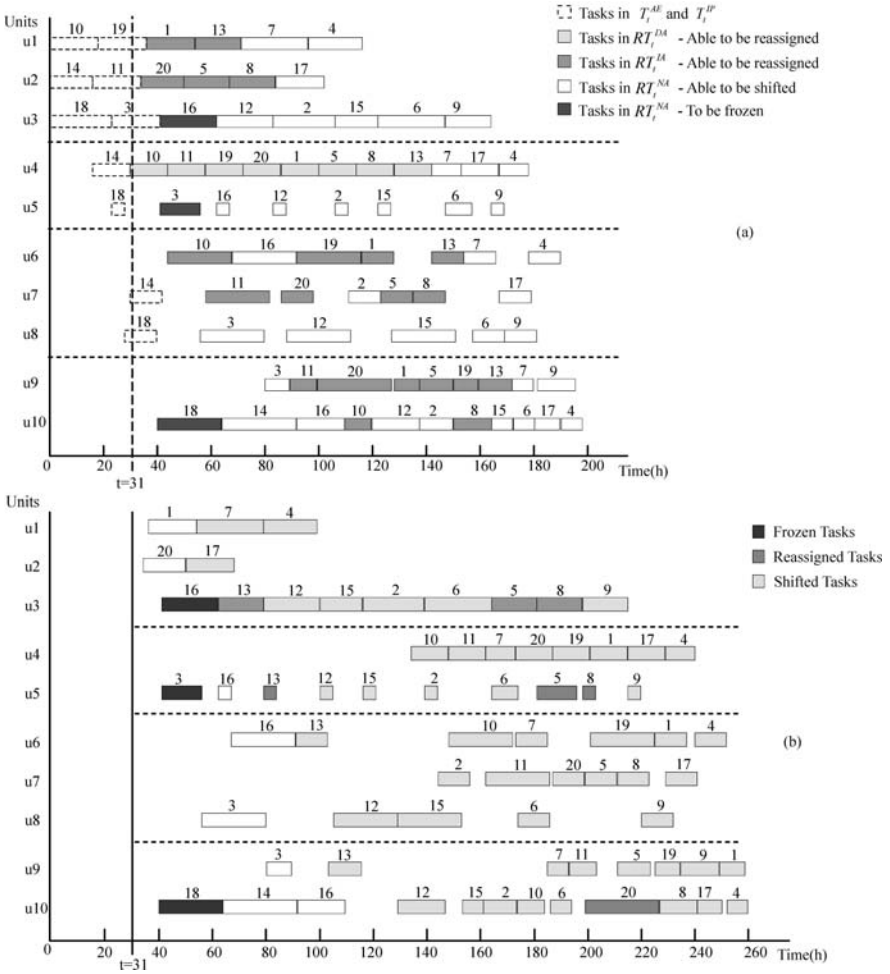

Fig.3. a) In-progress schedule (UIS policy). Classification of tasks according to *PR2* is depicted with grey shades. b) New schedule obtained after applying the *PR2* approach.

Abstract

Studies of petroleum asphaltenes have gained considerable attention in the past decades due to the increasing production of heavy crude oils. The reduction of light crude oil reservoirs and the increasing of light oil demand, forced the petroleum industry to develop upgrading processes for raw materials and residues. Due to the limited global oil reserves, more and more heavy crudes are being processed. These crudes contain large amounts of asphaltenes and resins. Petroleum must be processed in order to have the major quantity of higher aggregated compounds. All types of petroleum are colloidal systems. In a dispersion medium consisting mainly of hydrocarbons, which can be classified into alkanes, naphthenes and aromatics, there are two groups of dispersed colloidal particles in solution: asphaltenes and petroleum resins. Reduction of asphaltenes and metal content can be achieved by disturbing the solvatation equilibrium via addition of suitable solvents, e.g., propane. The Residuum Oil Supercritical Extraction (ROSE™) process is the premier deasphalting technology available in industry today. This state-of-the-art process extracts high-quality deasphalted oil (DAO) and asphaltenes from atmospheric or vacuum residues and other heavier feedstocks. The ROSE process operates near to the critical point of the solvent and applies thermodynamic fundamentals and high-pressure phase equilibrium principles in order to provide an energy-efficient process. Depending on the solvent selection, the DAO can be an excellent feedstock for catalytic cracking, hydrocracking, or lube oil blending. The energy consumption in supercritical extraction is considerably lower than in conventional extraction, which requires a higher ratio of solvent to crude. The use of supercritical fluid has some advantages such as higher yield and improved quality of the valuable DAO and asphaltenes product, and recovery of the supercritical solvent, reducing significantly operating costs compared to other solvent deasphalting processes. This work presents a new method for petroleum deasphalting. The proposal involves the extraction of the residue fractions from molecular distillations using supercritical propane or pentane as solvent. The thermodynamic calculation and representation of the ternary system is shown. The calculation is very complex since the asphaltenes have to be represented as a set of molecules whose properties have to be predicted using special

methodology and the UNIFAC method. Our research group at State University of Campinas (UNICAMP) has developed a real supercritical extraction pilot plant and a virtual one which are optimized and validated. This work is carried out in association with Petrobras (Brazilian Oil Company).

Keywords: deasphalting process, ternary system, pilot plant

1. Introduction

In developing the technology of supercritical extraction, solvent selection is a basic problem. The efficiency of the process depends mainly on the solvent selection. The development of the deasphaltation technology using supercritical fluid (SCF) appears as a solution to improve the separation of DAO from asphaltenes. The use of supercritical fluid has some advantages like: the difference of densities between the extraction phase and the rafinate phase is larger than that obtained by the conventional liquid-liquid extraction, becoming the separation between the phases easier; the mass transfer is faster using the supercritical fluid; the quantity and the quality of the DAO can be easily controlled adjusting the temperature and the pressure of the extraction system and the efficiency to recover the oil is a function of the density of the supercritical fluid (Rodrigues, 2006 and Mendes *et al.*, 2005).

The knowledge of a proper thermodynamic modeling for mixtures of hydrocarbons in high pressures is extremely important for diverse applications in the petroleum engineering, such as reservoir simulation at high pressures and evaluation of extraction techniques of oil in deep waters.

In this work, it was studied the behavior of ternary diagrams for two systems and a supercritical deasphalting pilot plant was developed in order to reach the operational conditions desired.

2. Thermodynamic Modelling of Supercritical Phase Behavior

As it is well known, pressure and temperature conditions, composition of the mixture and molecular classes which the components belong to affect the phase equilibrium. However, different unities of a supercritical process work in a wide range of pressure, temperature and composition, so the modelling tools should be capable to predict and correlate situations where exist equilibrium such as solid-SCF, liquid-SCF and liquid-liquid-SCF.

Fortunately, in many applications, high-pressure phase behavior can be reasonably represented with a single equation of state (EOS) if the components in the mixture do not differ substantially in size, structure or shape. The most commonly used cubic EOS are the Soave-Redlich-Kwong (SRK) and Peng-Robinson (PR) equations.

In this work, the model used is the Predictive Soave-Redlich-Kwong equation of state (PSRK), which is an extension of the SRK equation of state. This model uses the Holderbaum-Gemehling mixing rules; these rules can predict the binary interactions at any pressure. Using UNIFAC, the PSRK method is predictive for any interaction that can be predicted by UNIFAC at low pressure. The main advantage of using PSRK equation of state is that it is more accurate in prediction of the binary interaction parameters and it gives more satisfactory results for mixtures of non-polar and polar components, as the case of the asphaltenes-oil mixture.

The Holderbaum-Gemehling mixing rules use a relationship between the excess Helmholtz energy and equation-of-state. The goal of these mixing rules is to be able to use binary interaction parameters for activity coefficient models at any pressure. They

do not use a relationship between equation-of-state properties and excess Gibbs energy, as in the Huron-Vidal mixing rules.

3. Development of supercritical deasphalting pilot plant

The supercritical deasphalting pilot plant has been developed at the LOPCA/LDPS Laboratories at State University of Campinas (UNICAMP). The system is equipped with an extractor, a separator, a propane reservoir, valves, pumps, a refrigerating system, temperature controllers and instrumentation for measuring pressure. The extractor has an internal removable column with a 3000ml capacity, 700bar can be reached in this vessel. The extraction unit is equipped with a heating system, temperature controllers and pressure measurement devices. The solvent is charged through the bottom of the extractor, using a booster that is also used to reach the desired work pressure. The solvent feeding line is set with a retention valve, in order to prevent reflux from the oil previously charged in the extractor. The unit has independent pumps for each solvent that will be used in the experiments. The boosters were designed for the equipment in order to attend the process. The separator consists in a 360 stainless steel column and 200bar can be reached. This unit is equipped with independent heating devices for top and bottom, with the purpose of creating a temperature gradient and consequently, enhancing the separation yield. Finally, the propane reservoir consists in a pressure column and a closed cylinder in which circulates a cooling bath, to maintain the propane in the liquid state. This reservoir is used to store the propane that will be used in the experiment, and also to receive the propane recycled from the previous run. The pressure column is made from a pressure resistant glass (up to 20bar can be reached) in order to allow a visual evaluation on the level of the propane.
Modifications were carried out in a conventional equipment design. The lines and valves were modified due to the fact that the equipment presents pressure drop. Besides, the pumps were carefully designed because they easily can present cavitation. After the modifications, the pilot plant has been shown to be able to attend the operating conditions of the process. These modifications/details have largely contributed to the equipment performance.

4. Results and Discussion

4.1 Ternary phase behavior

Simulations were carried out in *Aspen Plus* simulator in order to generate the ternary diagrams. The ternary phase behaviours were analyzed to the asphaltene-oil-pentane mixture and asphaltene-oil-propane mixture at three different conditions. As it is known, crude oil asphaltenes represent a solubility class, not a specific molecular species or family. For this, there is not a specific molecular structure for asphaltenes, since different chemical structures exist for asphaltenes, depending on the origin of the crude oil; different molar mass among several types of asphaltenes are also reported.
The characterization of the asphaltene component in the process simulator was done based on the molecular structure. For the system asphaltene-oil-pentane, it was used the molecular structure presented in Figure 1. For generating the ternary diagrams of the mixture asphaltenes-oil-propane, it was considered the asphaltene molecule of a heavy Canadian residue. The molecular structure of the heavy Canadian asphaltene is shown in Figure 2. The molecules were characterized with UNIFAC group contribution method. The thermodynamic equilibrium model used in the simulation was PSRK with Holderbaum-Gemehling mixing rules. The binary interaction parameters k_{ij} were well predicted using UNIFAC for all pairs of components.

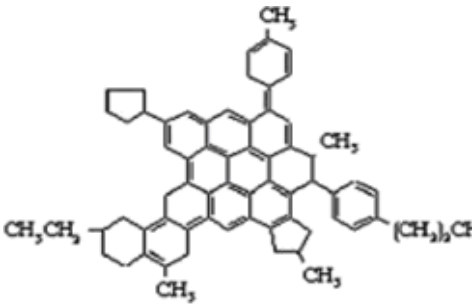

Figure 1. Molecular structure of asphaltene

(Adapted of Loh *et al*., 2007).

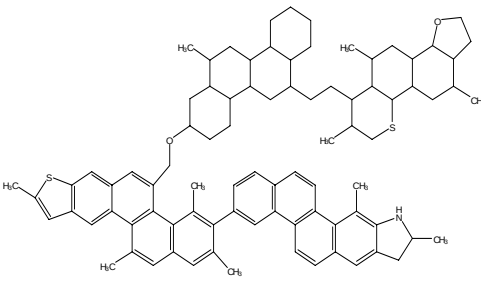

Figure 2. Molecular structure of an asphaltene from a heavy Canadian vacuum residue (Siskin *et al.*, 2006).

The ternary diagrams generated with *Aspen Plus* for the systems asphaltenes-oil-pentane and asphaltenes-oil-propane are shown in Figures 3 and 4, respectively. The principles governing the phase behavior shown in these diagrams are similar to those described qualitatively by Wilson et al. (1936).

For the system asphalt-oil-pentane, at 10 bar (subcritical conditions), pentane is almost entirely miscible with the oil, the oil is entirely miscible with the asphalt too, but the pentane is only partially miscible with the asphalt, therefore the asphalt falls out of the solution. This represents the first step of the lube oil refining process. Figure 3 (B) shows that for a pressure slightly below the critical pressure of pentane (33 bar) the two-phase region of the diagram expands considerably, so liquid pentane is in a much more expanded state than at 10 bar. According to Figure 3 (C), it can observed that the degree of separation appears to have improved at this condition for asphalt-oil feed mixtures. As the solubility power of pentane decreases it is possible to separate resins and lighter components of the oil phase. This represents the last step of separation in the oil deasphalting process.

For the system asphalt-oil-propane, Figure 4 (A) shows (15 bar) subcritical conditions. The oil is totally miscible with asphalt and the propane is partially miscible with asphalt, as it is shown by the region of immiscibility through the curve in the propane-asphalt axis, however propane presents complete miscibility with the paraffinic phase (oil), therefore the asphaltenes are dropped out of the solution. This represents the first stage of the refining process of lube oil. Figure 4 (B) shows that in a pressure slightly below to the critical pressure of the solvent (41 bar), there is an expansion in the two-phase region of the diagram, thus the liquid propane is in a more expanded state than at 15 bar. If the pressure is increased to above the critical pressure (Figure 4 (C)), the system will present a immiscibility between oil and propane, being possible to separate the resins and the lightest fractions of the residue from the propane-oil mixture, due to the reduction of the density and to the solvent power of propane in these conditions, allowing a separation of the extract stream free of asphaltenes in DAO and propane, which after some refining operations can be recycled to the process. This condition corresponds to the last stage of the ROSE process.

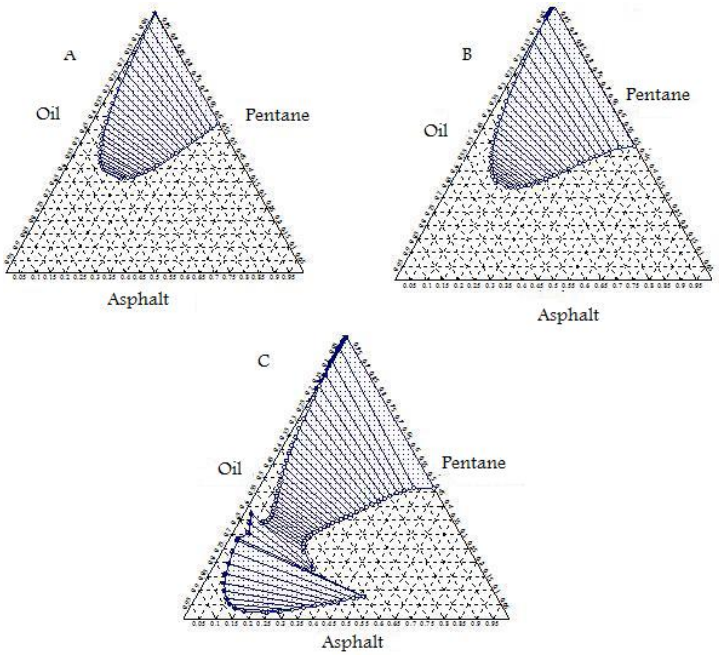

Figure 3.Ternary diagram of the asphalt-oil-pentane mixture at (A)10 bar, (B)33 bar and (C)40 bar.

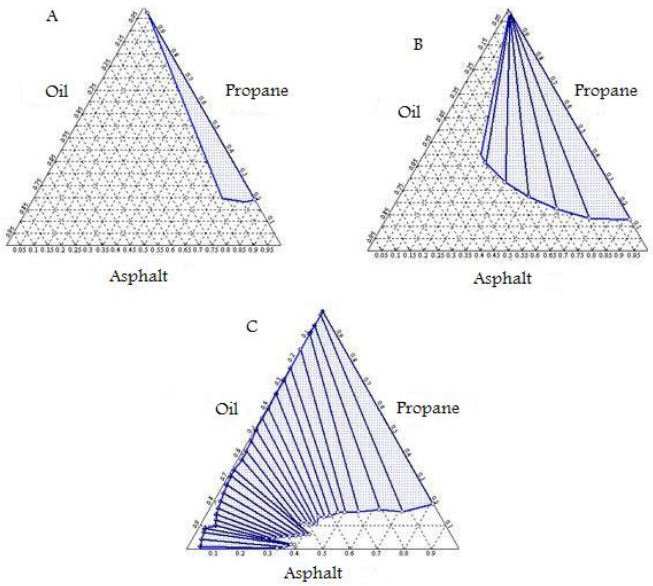

Figure 4. Ternary diagram of the asphalt-oil-propane mixture at (A)15 bar, (B)41 bar and (C)60 bar.

The simulations carried out in the Simulator ASPEN Plus have as aim to know the behavior of the system asphaltene-solvent-oil which is influenced by important parameters, such as: pressure, temperature, component compositions, among others. The knowledge of the system behavior and of the influence of each parameter becomes easier to understand the extraction process. Firstly, the simulation of ternary diagrams provided us an idea of the solubility degree among the components and how this solubility behaved in different operating conditions. To take into account this information, the assembly and operation of virtual plant become easier to be understood, helping to estimate the appropriate parameters in the experiments in the pilot plant developed for our research group.

5. Concluding Remarks

The evaluation of the phase equilibrium through the ternary diagrams is important in order to verify the operational conditions that could be use in the deasphalting extraction column, for different values of temperature and pressure and also for different kinds of solvent used, and to evaluate through these graphs which are the best separation conditions regarding to the liquid-liquid extraction, near to the critical extraction and to the supercritical extraction of asphaltenes from a vacuum residue, in order to obtain lubricant oil. Global understanding of the equilibrium and phase behavior of the system was necessary to develop the supercritical deasphalting pilot plant. This equipment has a complex operation and running, so the development and adaptation of the plant design is worth to carry out experiments in supercritical conditions in a safe and flexible way.

Data Reconciliation Practice at a Petroleum Refinery Company in Brazil

José Plácido,[a] Alexandre Almeida Campos,[a] Daniel Ferraz Monteiro,[a]

[a]*Soteica do Brasil Ltda, Rua Dr. Cid de Castro Prado 108, São Paulo 04064-040, Brazil*

Abstract

In spite of being prone to both random and gross errors, measurements are vital for process monitoring, modelling, optimization and control, as well as for plant accounting. However, poor data quality may in general lead to both bad corrective actions and significant deviations between estimated and actual process state, product and feedstock storage and daily Key Performance Indicators (KPI). Data reconciliation, a widely recognized technique that can aid to improve data quality in industrial processes, has being applied since August 2005 at several PETROBRAS petroleum refineries in Brazil. With data reconciliation one is able to find out process leaks, unexpected flow deviations, product losses, errors in storage measuring devices and flowmeter biases, so these findings may be combined with suitable maintenance programs in order to get the desired data quality. In this work we report some results from our daily experience as users of Sigmafine, a data reconciliation package from OSI Software Company. Major common sources of gross errors are illustrated using actual cases taken from one of PETROBRAS refineries, and improvements in data quality and in process performance are stressed. Particularly, potential financial gain are commented, and daily actions performed to circumvent gross error sources provide not only better plant accounting, but also reduce nominal losses and suggest actions to deal to or even eliminate these otherwise unknown trouble sources.
Keywords: data reconciliation, gross errors, plant accounting, petroleum refineries.

1. Introduction

The basic idea in data reconciliation is to adjust each redundant measurement in order to obtain reconciled values which satisfy restrictions like material balances around process units. The smaller the meter tolerance, the smaller will be its correction. A meter *mj* is said redundant when its value can be obtained (e.g. by means of material and energy balances) by the set of all other *mk* measurements, $k \neq j$.

The problem here is to minimize an objective function, e.g. the sum of the squared adjusts pondered by their reciprocal variances, subject to linear restrictions (material balances), and the solution can be found in the literature (Crowe et al, 1983; Mah et al., 1976). Reconciled values constitute a reference set which can be used in data quality analysis and in gross error detection schemes (Serth et al, 1986; Iordache et al., 1985).

One can say that many process improvements certainly result when this kind of analysis is performed in petroleum refineries. We hope the results presented here, taken from our experience working on Sigmafine Project at PETROBRAS, can contribute to disseminate this practice to other process industries also.

In the next section some comments are made about Soteica's Sigmafine Project. In section 3 some common sources of gross errors are described. Section 4 presents some cases with potential financial gains, and then the conclusions follow to close the work.

2. The Sigmafine data reconciliation project at PETROBRAS

The process studied consists of several units, varying from atmospheric distillation and product treatment up to LPG (Liquefied Petroleum Gas) and solvent units. Additional considerations are also taken for the storage park and its interactions with process units, receipts and shipment measuring systems. Water and energy do not enter the dry-basis mass balances considered here.

Reconciliation runs generally consist of 24h periods where all data are appropriately averaged. Because of the dynamic nature of storage tank/sphere alignments, in Sigmafine process models these product/feedstock *transactions* are dynamically created daily at the data reading step. A transaction from a given process unit may have its target tank/sphere changed several times in a reconciliation period, and so it's important having adequate tracking of these changes in order to avoid misleading results.

Data fed into Sigmafine environment have different origins, e.g.:

(a) BDEMQ, a corporate oracle data base containing information concerning storage device measurements, product/feedstock transactions and quality lab analysis;

(b) PI, Plant Information system from OSI Software with information on process measuring devices such as temperature meters, pressure gauges and flow meters;

(c) Truck weights in shipment operations;

(d) Manual changes supplied by the user in order to keep model-to-process data adherence.

In order to reduce the manual user interventions and to automate, whenever possible, tasks such as data treatment and filtering, a new tool called SALA was developed. The SALA interface gets its information from BDEMQ and PI systems, performs tank/sphere volume balances in order to solve for simultaneous transactions and then obtains transferred masses for all transactions and the final stocks for all tanks/spheres. These are the primary data to be used in the subsequent Simafine runs.

An important advantage of the reconciled data over the measured one here concerns to consistency: one always get the same information no matter the data source used. In other words, information conflicts are eliminated by data reconciliation and all users have the same information in all data basis. Another advantage is that values for all non-measured streams are also obtained.

In the next section comments are done about major gross error sources one can expect to find in refineries.

3. Gross error sources in petroleum refineries

We have grouped the error sources into three categories: (1) errors in storage devices; (2) errors in product transactions; (3) errors in flow meters. These are explained in the next sections.

3.1. Errors in storage devices

The "measuring" of amounts of hydrocarbon mass in tanks is not a trivial task. To illustrate this, consider the following formulas:

$$Mass = V_{20} \, x \, d_{20} = (V_T \, x \, F_{T\text{-}20}) \, x \, d_{20}$$

$$V_T = V_G - V_{F\text{-}W} - V_{BSW\text{-}W} = (V_G - V_{F\text{-}W}) \, x \, (1\text{-}P_{BSW} /100)$$

where $V_{F\text{-}W}$ is a function of ($H_{F\text{-}W}$, strapping table) and V_G is a function of (H_T , strapping table, floating roof weight); V_{20} = hydrocarbon volume at 20oC (m^3); d_{20} = hydrocarbon density at 20oC (t/m^3); V_T = hydrocarbon volume at the product temperature, T (m^3); $F_{T\text{-}20}$ = tabulated conversion factor defined as $F_{T\text{-}20} = V_{20} / V_T$ (is a

function of both T and d_{20}); V_G = total fluid volume (m^3); V_{F-W} = volume of free water (m^3); V_{BSW-W} = volume of BSW water (m^3); P_{BSW} = percentage of BSW water (%); H_{F-W} = height of free water (mm); H_T = total height measurement (mm).
Hence, in order to calculate the hydrocarbon mass in tanks one needs measurements of total height H_T, height of free water H_{F-W}, temperature T, percentage of BSW P_{BSW} and density at 20oC d_{20} (and sphere *pressure*). As an additional requirement one needs to know the strapping table and (for floating roof tanks) the roof weight. Strapping tables convert height readings into tank volumes. In case of floating roof tanks, these tables discount the volume displaced by the roof according to the actual height measurement.
Hence, concerning mass determination in storage devices, one can observe that:

- Tank level readings: there exists a problem common to radar-metering systems in tanks that occurs when the product height in the tank gets values bellow the minimal operating height. Below this level the conic waves emitted by the radar can reflect at the tank side walls, generating readings that haven't correlation with the real product height in the tank. As an example, a gross error occurred in streams related to the URFCC material balance corresponding to 4.5% of its feed. This error was caused by a fault in the height measured by the radar of a RAT (Atmospheric Residue) tank.
- Temperature readings: thermocouple mal-functioning may cause false V_{20} volume gains/losses.
- Water level readings: this information is rarely available, since the automatic detection of the water-oil interface does not provide accurate results. In some tanks the zero at the height reading scale implies a great amount of dead volume below it, and then smaller free water contents cannot be appropriately accounted for.
- Product losses through valves: this is a common source of errors in spheres of intermediate propylene, and may difficult getting the correct values for *transactions*.
- Lack of homogenization: see Figure 4. This is a common error in LPG storage spheres as described in section 4.3. The thermocouple is positioned closer to the sphere shell and its readings reflect much more the environmental atmospheric variations then the real average product temperature.
- Strapping table problems: for floating roof tanks an error in the volume evaluation may result if the tank height falls bellow the position where the roof gets supported on their legs, when the position is set to the maintenance one.
- Accumulation of rain water on roof of floating roof tanks: the water weight on the roof presses the product inside the tank causing it to rise through the metering tube. The final effect is a false higher level reading in the tank, which causes several plant accounting problems depending on several factors. Several actions can be devised in order to deal with this problem, depending weather the rain occurred before, during or after the product transaction, and on the drainage efficiency also.

3.2. Errors in product transactions

Here the errors are associated mainly with cultural and human reasoning. Product transactions not always follow exactly the real alignment timing verified in the process plant. This was one of the reasons why we decided to develop the SALA interface. In order to save space, we are not going on giving more details on this topic.

3.3. Errors in flow meters

Even good flow meters can eventually fall into problems and then give bad value readings. These readings may fail because of several reasons. Some of them are explained in the topics that follow.

- Errors of zero and false measurements: these errors are more frequent on plant shutdowns. Possibly one of the pressure gauge legs keeps pressurized after the line is

blocked by the plant operator, and so a false flow reading results. In some cases this may turn difficult to find out, in searching a data base containing information from several months, the periods where the plant was really stopped. The worst case occurs when the process unit operates in a step-wise way, since the non-zero readings of the flow meter may be always present.

- Negative measurements: these measurements may appear when alignment valves are closed. The problem is that, for a period of 24 hours, the negative part contributes for the integration of flow meter readings and then a value smaller than the expected results for the whole period.
- Instrument biases: bias may have different causes, e.g., water accumulation in one of the pressure gauge legs, instrument miscalibration, mal-functioning of signal transmitters and so on. Figure 1 illustrates the latter case for a naphtha flow meter. The maintenance team tried to fix the problem several times without being successful, until someone remembered to check the signal transmitter. As can be seen in the figure, after fixing the error the measurement values started to agree with the reconciled ones, as expected

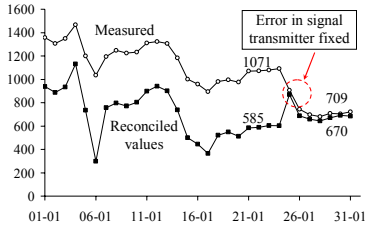

Figure 1: Bias in naphtha flow meter due to signal transmitter malfunctioning (in volume units per day).

- Design errors: in this case the flow meter is not suitable for the service and should be replaced with a new-designed one. Under-dimensioned flow meters generate excessive head losses and should not be used in order to avoid excessive erosion.

4. Some (potential) financial gain cases

4.1. LCO deviation into ODEC storage tanks

LCO (light FCC cycle gas oil), beyond having its own market value and uses, has various operational uses, e.g., as a flushing oil to clean ODEC (decanted oil) in-line filters and obstructed valves, as a make-up fluid to the bottom of equipments during process starting-ups, as a compositional oil for finished products and so on, the former being the principal one (in general the LCO used ends up entering into ODEC tanks). However, this oil consumption is not ordinarily measured. With reconciled estimations nowadays directly visible in PI system, interested people can easily verify whether LCO consumption is excessive or not, and take actions in order to minimize it if necessary.

It was realized also that sometimes there are leaks from the LCO production line directly into ODEC tanks, or, otherwise, possibly, operators may simply use the oil without taking care of the amount being expended. As an example, it can be noted in Figure 2 that initially about 50% of the LCO production was being deviated to the cited LCO sinks. This excessive consumption was then communicated to the process operation team, which, after in site verification, reported there was a leak in the ODEC tank line valve. The leak reduction "point" is marked in the figure, corresponding to about six hours of practically zero leak/consumption operation. After this period the LCO deviation increases again, probably due to operational needs, and stays at a level about 20-30% of the LCO production value. This consumption level is still historically high, but is better than the initial consumption of 50%.

Considering that LCO market price is higher than that of ODEC, it becomes clear that it's highly advisable to minimize the cited LCO deviations into ODEC tanks. It is worth

while remember that part of these LCO deviations represents operational requirements and, as so, cannot be reduced. But certainly there is enough room for improvements here!

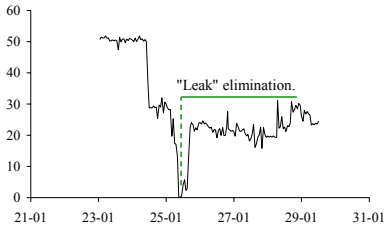

Figure 2: LCO percentage production deviation into ODEC tanks.

4.2. Solvent losses at the Aromatics Removal Unit (UDS)

This process was initially represented as a black-box unit with a feed and two production lines (rubber solvent and BTX – benzene, toluene, xylene). A little later a gross error (bias) has been found in the rubber solvent stream flow meter and, after that, reconciliation results have shown a mass leak in this process unit.

The process operation team has confirmed entrainment losses from this unit to the top drum of the URFCC fractioning tower because of an operational problem in one of the rectifying towers, which operates practically without reflux. The process model in Sigmafine was then modified in order to consider this entrainment between units.

One must note that there are no physical losses but just a product being deviated; this product ends up into gasoline tanks instead of rubber solvent tanks.

Because of the differences between rubber solvent and gasoline market prices, this deviation represents a financial loss. Total reconciled losses from June 2006 to May 2007 amount to 14% of the feed to UDS. Corresponding non-reconciled losses are 71% higher than the reconciled losses. In engineering project studies aiming at minimizing these losses, reconciled values give more realistic estimations for economic viability analysis and thus give more realistic estimations for investment return rates.

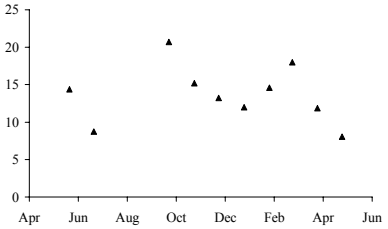

Figure 3: Percentage entrainment losses from the Aromatic Removal Unit, total amounts by month from Jun-2006 to May-2007.

4.3. Lack of homogenization in spheres of LPG

Figure 4 illustrates some typical operations concerning LPG spheres. First of all, sphere C receives LPG from external suppliers (curve 1). Thereafter a LPG transfer takes place from sphere C to sphere B (curve 2). Sphere B receives also the LPG production and so the transfer from sphere C is a simultaneous operation.

In this case, the LPG production is calculated by a V_{20} volume balance around sphere B, since the transferred volume from C to B can be obtained considering the sphere C stock variation. Any error in this transferred volume evaluation causes an error in the LPG production calculation also.

In this example, one can observe a sudden increase in the sphere C temperature at the beginning of the transference (curve 3), which reveals a lack of homogenization in the product inside the sphere. Ideally, this product homogenization should have happened before the transference operation. When calculations were repeated by using the correct temperature, considering also a small stock variation occurred before the transference,

one obtained a gain of 3.1% in the LPG production and a reduction of 1.7% in the LPG received in sphere C from the suppliers.
Taking into account that this kind of problem is not uncommon, one concludes that the annual accumulated differences may amount to a considerable value. One must consider that, with these corrections, improvements in the information quality are also obtained.
This problem has occurred because the temperature read at the only thermocouple installed in the bottom of the sphere does not reflect the actual average of the product temperature. By this reason, before any LPG selling operation the product in the sphere is recycled, a procedure that minimizes the difference between the stock reduction in the sphere and the amount of product registered at the Measuring Site (EMED). However, it's not always operationally possible recycling the products in the LPG spheres. In the case of intermediate propylene spheres, the differences caused by the lack of homogenization are much smaller since there are three installed thermocouples (bottom, middle and top) and a suitable averaged temperature is employed.

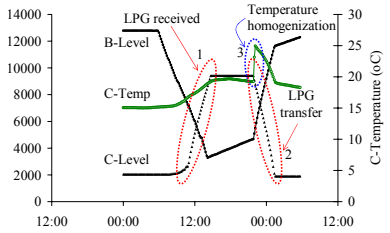

Figure 4: Lack of homogenization in LPG storage spheres.

5. Conclusion

Data reconciliation is an invaluable tool for data quality improvement in the process industry. It can help maintenance engineers to focuses attention on just the most critical instruments and this can save both time and money. Process leaks, product deviations, wrong alignment transactions, faults in stock-metering devices, product losses in general and many other sources of errors can be detected with the aid of this technique.
This work presented illustrative cases where money can be saved provided investments are done and other cases where minor daily differences may result in considerable annual accumulated savings.
In all cases, it can be said that it's worth while using this technique in daily applications to improve plant accounting and getting more reliable results for generating significant process key performance indicators and for use in plant monitoring systems.

6. Acknowledgement

We would like to acknowledge to the many people who helped us during the development of the Sigmafine Project, so many that it wouldn't be possible to name them here.

Exploiting Modern Computing Architectures for Efficient Large-Scale Nonlinear Programming

Yu Zhu[a], Daniel Word[a], John Siirola[b], Carl D. Laird[a]

[a]*Dept. of Chemical Engineering, Texas A&M University, MS 3122, Collete Station, TX*
[b]*Sandia National Laboratories, P.O. Box 5800, Albuquerque, NM, 87185*

Abstract

While large-scale nonlinear programming (NLP) has seen widespread use within the process industries, the desire to solve larger and more complex problems drives continued improvements in NLP solvers. Because of physical hardware limitations, manufacturers have shifted their focus towards multi-core and other modern parallel computing architectures, and we must focus efforts on the development of parallel computing solutions for large-scale nonlinear programming. In this paper we briefly describe some existing and emerging architectures for parallel computing and demonstrate the potential of some of these architectures for parallel solution of nonlinear programming problems. In particular, we show the scalability of an integrated design and control problem using two techniques within a multi-core architecture.

Keywords: parallel computing, numerical computing, optimization, nonlinear programming

1. Introduction

Large-scale nonlinear programming (NLP) has proven to be an effective framework for optimization within the process industries. However, the scale of the NLP problems of interest to both industry and academia continues to grow increasingly large, often outstripping the capacity of modern workstations. While significant theoretical advancements have been made in general (serial) NLP algorithms, few parallel algorithms exist and off-the-shelf tools often are not able to provide solutions efficiently for problems larger than the capacity of a single workstation. Furthermore, computer chip manufacturers are no longer focusing on increasing clock speeds and instruction throughput, but rather on multi-core architectures and hyper-threading. This means that the "free" performance improvements that we have enjoyed as a result of advances in computing hardware will no longer be possible unless we develop algorithms that are capable of utilizing modern concurrent architectures efficiently. Furthermore, modern computing architectures are becoming more complex and the parallel computing community is seeing a shift from the use of general purpose CPUs towards specialized processors and heterogeneous architectures. In order to continue to see performance improvements, effective utilization of these parallel architectures will be necessary. This reflects a significant paradigm shift in the design and implementation of numerical optimization algorithms that can exploit emerging architectures.

All parallel architectures are not created equal. Distributed-memory Beowulf clusters are a scalable solution that can provide for many available processors, however, the communication limitations among machines may present a significant bottleneck. On the other hand, multi-core computing systems promise fast inter-process communication through shared-memory, however, memory bandwidth issues can significantly limit

parallel performance. Several fundamentally new architectures are being introduced into the scientific computing realm: Graphics Processing Units (GPUs) and the Cell Broadband Engine Architecture (Cell) provide potential for large-scale scientific computing, but their architectures are complex and present significant challenges not encountered in general computing. The Cray XMT massively threaded supercomputer represents a fundamentally new architecture that mitigates many of the memory latency problems seen in common platforms but requires a level of fine-grained parallelism heretofore unseen in parallel algorithm development.

In this paper, we contrast the different architectures available for modern scientific computing and outline their potential for efficient parallel nonlinear optimization. As a detailed case study, we consider the parallel solution of the integrated design and control of heat-integrated distillation columns under uncertainty using both serial and parallel algorithms on multi-core machines.

2. Parallel Computing Architectures for Scientific Computing

There are a number of emerging architectures for parallel scientific computing. In this section, a few of the proven and promising architectures are described in further detail.

2.1. Distributed-Memory Cluster Architecture

Beowulf clusters are an example of a distributed-memory parallel processor architecture. The cluster is built by networking affordable desktop computers through standard Ethernet or specialized networking technologies. The system consists of a primary computer functioning as a master node, controlling access to the compute nodes. Each compute node has its own local RAM. Since the memory is not shared with other nodes, communication among nodes occurs over the network. This is typically done via a Message-Passing Interface (MPI) although other technologies and paradigms exist. Communication via Ethernet is the biggest cause of latency, so for a program to run efficiently, this communication and the need for synchronization must be kept to a minimum. These architectures are most appropriate for coarse-grained problems that require limited communication (Hairgrove et al, 2001), and our previous work has demonstrated that this architecture is highly appropriate for parallel solution of large-scale structured nonlinear programs (Zavala et al., 2007). Grid computing represents an extreme case of a distributed memory architecture where compute nodes are typically heterogeneous and geographically distributed, with communication over the internet.

2.2. Multi-core Processor Architectures

Multi-core architectures allow for shared-memory and parallel computation within a single node. Each of the processing cores has access to the same local memory and these architectures promise significantly faster communication among processes (or threads) through local RAM. Nevertheless, in most multi-core systems access to local RAM is shared through a common memory bus, and the performance of individual processes may deteriorate as each process competes for access to the local memory it needs. Even with a sufficient number of processors, the memory bandwidth can become a bottleneck and deteriorate the expected benefits from parallel computing. In this current work, we demonstrate that multi-core architectures are also appropriate for parallel solution of large-scale structured optimization problems, however, they do not scale as well as distributed architectures for the class of problems studied.

2.3. GPU Architecture

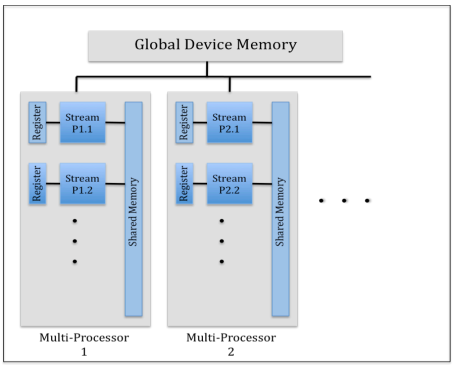

Figure 1: Diagram of GPU Architecture

Graphics Processing Units (GPUs) are another type of multi-core processor that has recently emerged within the scientific computing community. GPUs typically contain several hundred basic processing cores, however, these cores are not general purpose CPU cores. Therefore, while these systems may give access to many hundreds of cores at an affordable price, these cores are limited in their capability. For example, the general GPU architecture shown in Figure 2 is modeled after the NVidia Tesla GPU units for scientific computing. Here, each GPU device contains a number of *multiprocessors*, each with a number of single-instruction-multiple-data (SIMD) *stream processors*. These architectures have complicated memory structures that must be considered. The different types of memory in a GPU can be grouped into categories based on their scope. Registers serve individual processors; shared memory, constant cache, and texture cache serve multiprocessors; global device memory serves all cores (Richardson and Gray, 2008). While this memory hierarchy allows for very low latency at the processor level, access to global device memory has high latency. Thus, the problem must be highly parallel so that the program can break it into enough threads to keep the individual processors busy (Wolfe, 2008). In spite of these and other drawbacks, there is significant potential for these architectures in certain scientific computing tasks and examples of their success are numerous. Current efforts indicate significant potential for efficient parallel solution of linear systems. With regards to parallel nonlinear optimization, this provides a promising avenue for immediate use of these architectures since most NLP algorithms require the solution of a large linear system at each iteration.

2.4. CELL Architecture

The Cell (Cell Broadband Engine Architecture) is similar to the architecture of the GPU systems in that there are a number of non-general purpose processing cores that have shared access to various levels of memory. The Cell processor contains eight Synergistic Processing Elements (SPEs). Each SPE contains a Synergistic Processing Unit (SPU) that operates using an SIMD architecture.

Processors are mated closely to their own independent memory allowing for very low latencies between the processor and memory. However, this is a distributed memory system (Kurik et al, 2008). The Cell system has gained popularity, as it is available rather inexpensively and fully supports the Linux operating system. As with the GPU architectures, there have been significant efforts towards efficient parallel solution of linear systems on the Cell processor (Kurik et al, 2008), and the use of parallel linear solvers provides potential for parallel nonlinear optimization.

2.5. Cray XMT Architecture

The Cray XMT system is designed to give a relatively inexpensive, scalable multithreading, shared-memory supercomputing platform (Cray Inc., 2008). It is built with up to 96 processors per cabinet. Each processor accommodates 128 fine-grained hardware streams and is associated with its own memory system. Since these memory systems are linked together the system can function as a shared-memory computer

(Chavarria-Miranda, 2008). The latency associated with shared-memory systems is masked in this supercomputer through multithreading. Multiple threads give processing efficiency by skipping threads that are waiting for data from memory and running threads that have data available This is ideal for data-intensive applications requiring irregular memory access (Chavarria-Miranda, 2007).

3. Parallel Nonlinear Optimization on Modern Architectures

A wide variety of optimization formulations can result in very large-scale problems. While significant advancements have been made in nonlinear optimization algorithms (Gould et al, 2004), as the size of the problem increases, general off-the-shelf tools may not be able to provide solutions efficiently, and we may need to make use of specialized parallel solution strategies. Fortunately, very large-scale optimization problems are almost always inherently structured since they are necessarily formulated from a repeating set of mathematical expressions (Gondzio and Grothey, 2005), and approaches can be developed that exploit the structure of the problem and allow solutions in parallel.

Common approaches for decomposition of structured problems include problem-level techiques based on Bender's and Lagrangian decomposition. However, given the complicated nature of modern parallel computing architectures and the number of architectures with non-general purpose processing cores, it is important to keep the parallelism as straightforward as possible. For example, it is not possible with SIMD architectures to have different processors solving completely different subproblems since each processor must be performing the same instruction. Internal decomposition approaches for structured problems provide an alternative to problem-level decomposition techniques. Instead of modifying the optimization problem, the internal linear operations of a particular host solver are specialized to exploit problem specific structure. Parallel full-space approaches have been developed for linear and quadratic programming problems (Gondzio and Gothrey 2005, Gondzio and Sarkissian, 2003). In previous work, we developed a parallel algorithm, SCHUR-IPOPT for large-scale general nonlinear optimization problems (Zavala et al, 2007) using a parallel Schur-complement decomposition approach.

The internal decomposition approach shows significant promise for effective parallel algorithms on modern architectures since it relies on the parallelism of linear operations appropriate on SIMD systems. Furthermore, as scientific computing becomes mainstream on these architectures, linear solvers are and will continue to be the focus of development. The internal decomposition approach is an appropriate vehicle for efficient nonlinear optimization of structured large-scale problems through the use of parallel linear solvers. In this work, we demonstrate our Schur-complement internal decomposition approach (as described in Zavala et al., 2007) on multi-core systems, considering the optimal design of heat integrated distillation columns under uncertainty.

4. Case Study and Conclusions: Optimal Design of Heat Integrated Distillation Columns Under Uncertainty

The internal heat integrated distillation column has been regarded as a potential energy saving configuration for separation. The rectifying section and the stripping section in this process are separated into two columns operating at the different pressures. To adjust the pressures, a compressor and a throttling valve are installed between the two sections. Unlike the case of the conventional columns, the condenser and reboiler are not required in this process. While past research has considered conceptual design and

dynamic control, little research in this area considers potential uncertainties in the design phase. In order to minimize the total annual cost under uncertainties, a rigorous mathematical model is derived from the mass and energy balances coupled with the equilibrium relationships. Detail model information can be found in Liu and Qian (2000) ,while the design formulas for installation and operating cost can be found in Huang (2007), Olujic (2006), and Douglas (1988).

The three main design variables selected include: the diameter of distillation columns, the heat transfer area, and the brake horsepower. Two types of uncertainty are considered in this work, unmeasurable and measureable uncertainty. The relative volatility of benzene and toluene, which may vary from 2.517 to 2.117 is selected as an unmeasureable uncertainty. The range is discretized by selecting 7 points assuming a normal distribution. Measureable uncertainties include the concentration of the feed flow (Zf), which varies from 0.55 to 0.45, and the feed flow rate (F), which varies from 90 to 110 (mol/s). Both of them are measurable during operation and may be compensated by two control variables, rectifying section pressure and thermal condition in the feed flow. Here, we discretize the uncertainty in Zf and F by selecting 15 points with normally distributed assumptions. In this large-scale structured problem, there are 1575 scenarios and approximately 300,000 total variables including 453 common variables (the design and control variables common across the scenarios). In addition to the model, controllability constraints are included in the formulation.
To demonstrate the scalability of different techniques, we solve the problem with an increasing number of scenarios (225 scenarios for each of 7 blocks). We tested the scalability using the parallel internal decomposition strategy that we have implemented within SCHUR-IPOPT, which is designed to exploit the specific structure induced by the multi-scenario problem. We also tested the scalability using the general purpose shared-memory linear solver PARDISO (Schenk and Gärtner, 2006, 2006). We do not have a version of the solver interfaced with the nonlinear optimization tool Ipopt. Therefore, to test scalability, we measured the computational time for PARDISO to perform the numerical factorization and backsolve of the same linear system arising from a particular iteration of the SCHUR-IPOPT solver. It is important to note that PARDISO performs a symbolic factorization prior to performing the numerical factorization. However, within an optimization context, the symbolic factorization would only need to be performed once, at the beginning of the optimization, therefore this time was not included in the results. For this reason, coupled with the fact that PARDISO is simply solving the linear system and not performing the other serial operations required by SCHUR-IPOPT, the comparison is conservative (that is the

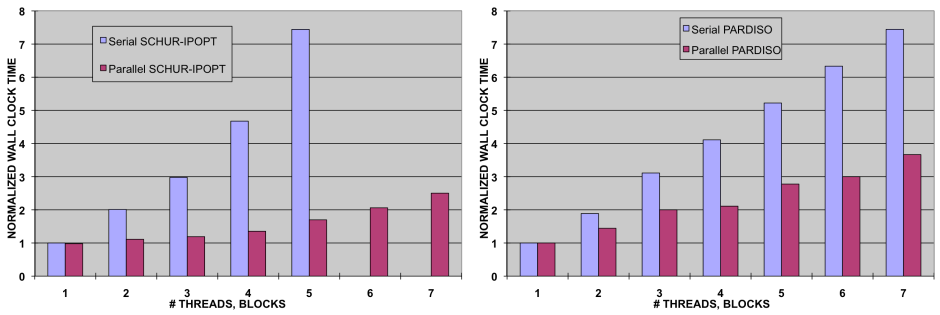

Figure 2: Parallel Scalability Results on a Multi-core System

comparison favors PARDISO somewhat). Figure 2 shows the normalized wall clock time for the two techniques. The x-axis shows the number of blocks, with an additional thread or process added along with each block. We can see that, in both cases, the scalability as we increase the size of the problem is impressive. We see a slight increase in the wall clock time as we increase the size of the problem, which is primarily due to memory bandwidth issues. In previous work, we have shown that the wall clock time is almost completely flat up to 32 processors when a distributed memory architecture is used. Furthermore, while the SCHUR-IPOPT approach is specialized for the particular problem structure, the general-purpose solver PARDISO performs comparatively well. Further tests with PARDISO integrated within the Ipopt optimization package will be necessary to draw stronger conclusions.

Clearly, the multi-core parallel architecture presents advantages in reducing the solution time of large problems. However, the multi-core architecture is limited by memory bandwidth and the number of available cores. Current research in our group is investigating the use of advanced scientific computing architectures like GPUs and the Cell processor for parallel solution of large-scale structured nonlinear programming problems.

Entropy Production Analysis in Extractive Distillation Using Non-Equilibrium Thermodynamics and a Rate Based Model

Diego F. Mendoza, Carlos A. M. Riascos

Department of Chemical and Environmental Engineering, National University of Colombia, Cra. 30 No. 45-03 Edif. 453 Of 300, Bogotá, Colombia.
Grupo de Ingeniería de Sistemas de Procesos.

Abstract

Entropy generation (EG) in an extractive distillation column for ethanol dehydration was determined. The rate based model and non-equilibrium thermodynamics (NET) leads to quantify separately the EG due to interface heat and mass transfer and mixing. Additionally, this model allows estimating the effects of operational conditions such as reflux ratio and feed condition on the EG. The results obtained show that mixing effects at the feeding points (hydrated ethanol and separation agent) and interface mass transfer are the main sources of EG with 55% and 41% of total EG, respectively. The significance of this work is the use of a rate based model and NET theory as a tool for energy use analysis in multicomponent distillation processes. EG analysis is the starting point to define new operational strategies and design characteristics that allow a more efficient energy use.

Keywords: extractive distillation, non-equilibrium thermodynamics, entropy production.

1. Introduction

Since the industrial revolution, the energy consumption has incremented vigorously, at the beginning; there was not preoccupation for an efficient use of the energy, because of unknowing on energy sources limitation and environmental effects of industrial activities. The global energy crisis, in the late 1970s, and the current energy generation costs have forced the reevaluation of the energy use (Linnhoff and Flower, 1978).

Separation by distillation is a major energy demanding operation in chemical process industries. Due to their low energy efficiency several strategies to improve it have been developed, distillation with heat pump and multiple-effect distillation (Seider et al., 2003) are useful techniques for saving energy; however, they can be applied only to mixtures with special characteristics; internally heat-integrated distillation columns has been developed as an alternative, at this configuration the energy consumption can be reduced in about 40% but the controllability of the systems requires special attention (Nakaiwa et al., 2003).

Recently, the energetic efficiency analysis has been focused on the loss of energy quality; it may be estimated by exergy analysis (Demirel, 2007) or using non-equilibrium thermodynamics (NET) (Liang et al., 2006). Exergy is defined as the maximum available work, in a source, bringing it to the equilibrium with its surrounding (Demirel, 2007). The exergy loss is proportional to the EG and it is estimated by the difference between exergy going into and out of the system. This

analysis provides a systematic method to diagnose whether and to what magnitude it is possible to increase the process efficiency. Whereas, the NET approach identifies the mechanism of EG and shows the location and causes of exergy losses (Liang et al. 2006), accordingly, it allows to predict the effect of operational conditions and equipment design on energy efficiency and to define the best conditions for maximizing the energy usage.

2. The Rate Based Model

The rate based model (Taylor and Krishna, 1993), considers liquid and vapor phases separated by an interface through heat and mass transport occur. Transport through both phases occurs due to temperature and concentration gradients located in the liquid and vapor films. Vapor and liquid compositions at the interface are related by equilibrium relationships. The equation set that describes the rate based model is presented in Taylor and Krishna, 1993.

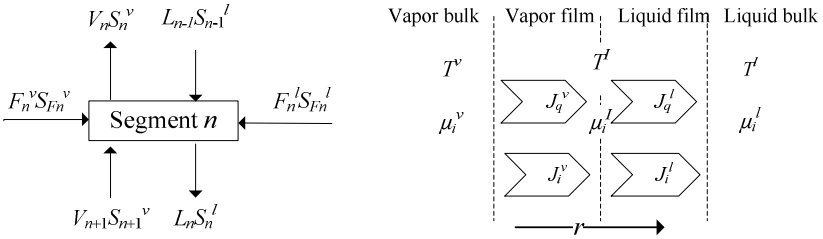

Figure 1. A segment in the distillation column (left), fluxes and forces in the system (right).

3. Entropy Production

In a distillation column three main sources of EG can be identified, namely, heat and mass transfer and mixing. EG due to transfers is calculated using NET theory in the liquid and vapor films, whereas the EG due to mixing is indirectly calculated as the difference between the global EG and the entropy generation in the films.

3.1. Global Entropy Production

The entropy balance (EB) is used to quantify the total EG in a column segment as well as in the boiler and condenser.

The EG in the *n*-th column segment, Figure 1, is:

$$S_n^p = V_nS_n^v + L_nS_n^l - V_{n+1}S_{n+1}^v - L_{n-1}S_{n-1}^l - F_{Fn}^vS_{Fn}^l - F_{Fn}^lS_n^l \tag{1}$$

Where V, L, F are vapor, liquid and feed flows; S is the molar entropy, subscripts n-1 and n+1, identify the upper and lower segments, superscripts v and l identify vapor and liquid phases. EG in the total condenser and boiler are:

$$S_C^p = V_1(S_C^l - S_1^v) - \frac{Q_c}{T_c} \qquad S_B^p = V_BS_B^v + BS_B^l - L_nS_n^v - \frac{Q_B}{T_B} \tag{2), (3}$$

Where Q_C, T_C , Q_B and T_B are heat and temperature at the condenser and boiler.

3.2. Entropy Production in the Films

According to the NET theory the local EG rate per unit of volume, σ, is the sum of the products of fluxes and forces related to heat and mass transfer in the films, Figure 1.

$$\sigma = J_qX_q + \sum_{i=1}^{C} J_iX_i \tag{4}$$

Where J_q and J_i are the diffusive flux of heat and mass, and X_q and X_i are the thermodynamic forces for heat and mass transfer, given by:

$$X_q = -\frac{\partial}{\partial r}\left(\frac{1}{T}\right) \qquad X_i = -\frac{\partial}{\partial r}\left(\frac{\mu_{i,T}}{T}\right) \qquad (5), (6)$$

Where T is the absolute temperature and $\mu_{i,T}$ is the chemical potential of species i, at constant temperature. The Gibbs-Duhem theorem leads to rewrite Equation (4) in terms of mass fluxes in the laboratory frame of reference, N_i, instead of interfacial one:

$$\sigma = J_q X_q + \sum_{i=1}^{C} N_i X_i \qquad (7)$$

The EG in the liquid film is:

$$\int_{V^{lf}} \sigma dV = \int\int J_q^l X_q^l dr dA + \sum_{i=1}^{C} \int\int N_i^l X_i^l dr dA \qquad (8)$$

Where V^{lf} is the volume of the liquid film, r is the film thickness and A is the liquid-vapor interface area. The entropy in vapor film is estimated analogously. Now, the RHS in later equation (and in the one for vapor film) must be integrated through the film thickness. For terms associated to the mass transfer we have:

$$\int_r N_i^v X_i^v dr = -N_i^v \left(\frac{\mu_{i,T}^I - \mu_{i,T}^v}{T^{vf}}\right) \qquad \int_r N_i^l X_i^l dr = -N_i^l \left(\frac{\mu_{i,T}^l - \mu_{i,T}^I}{T^{lf}}\right) \qquad (9), (10)$$

For vapor and liquid phase, chemical potentials differences are:

$$\frac{\mu_{i,T}^I - \mu_{i,T}^v}{T^{vf}} = R \ln\left(\frac{\hat{\phi}_i^I y_i^I}{\hat{\phi}_i^v y_i^v}\right) \qquad \frac{\mu_{i,T}^l - \mu_{i,T}^I}{T^{lf}} = R \ln\left(\frac{\gamma_i^l x_i^l}{\gamma_i^I x_i^I}\right) \qquad (11), (12)$$

The fugacity and activity coefficients, $\hat{\phi}_i$ and γ_i, are calculated at the average vapor and liquid film temperatures, respectively. For terms associated to heat transfer we have:

$$\int_r J_q^v X_q^v dr = \overline{J}_q^v \left(\frac{1}{T^I} - \frac{1}{T^v}\right) \qquad \int_r J_q^l X_q^l dr = \overline{J}_q^l \left(\frac{1}{T^l} - \frac{1}{T^I}\right) \qquad (13), (14)$$

Where $\overline{J}_q^v$ and $\overline{J}_q^l$ are the average heat fluxes in the vapor and liquid films:

$$\overline{J}_q^v = \frac{\int_r J_q^v dr}{\delta^v} = h^v (T^v - T^I) \qquad \overline{J}_q^l = \frac{\int_r J_q^l dr}{\delta^l} = h^l (T^I - T^l) \qquad (15), (16)$$

Here h^v, h^l are the film heat transfer coefficients at the vapor and liquid sides. Finally, EG rate due to interface heat and mass transfer for a segment (n) of the column, $S_n^{p,f}$, is given by the sum of EG in vapor, $S_n^{p,vf}$, and liquid, $S_n^{p,lf}$, films:

$$S_n^{p,vf} = \int_{V^{vf}} \sigma dV_n = \overline{J}_q^v \left(\frac{1}{T^I} - \frac{1}{T^v}\right) - R \sum_{i=1}^{c} N_{i,n}^v a_n \ln\left(\frac{\hat{\phi}_i^I y_i^I}{\hat{\phi}_i^v y_i^v}\right)_n \qquad (17)$$

$$S_n^{p,lf} = \int_{V^{lf}} \sigma dV_n = \overline{J}_q^l \left(\frac{1}{T^l} - \frac{1}{T^I}\right) - R \sum_{i=1}^{c} N_{i,n}^l a_n \ln\left(\frac{\gamma_i^l x_i^l}{\gamma_i^I x_i^I}\right)_n \qquad (18)$$

4. Simulation

The case to be analyzed is a pilot size, extractive distillation column (Table 1) which

process 50 l/h of an ethanol-water (EtOH-W) mixture, the entrainer used is ethylene glycol (EGly). Column simulations were carried out using the Ratefrac model from Aspen Plus® processes simulator.

Table 1. Specifications for simulation

Condenser		Total (segment 1)
Boiler		Partial (segment 30)
Packing	Type	Pall, random, metal
	Size	15.875 mm
Total packed height		10 m
Column diameter		76.2 mm
Number of segments		30
Reflux ratio (molar)		1
Distillate rate		0.651 kmol h^{-1}
Pressure		1 bar
Feed 1 (Entrainer)	Location	Segment 3
	State, T & P	Liquid; 333.15 K;1 bar
	Flow rates (kmol h^{-1})	EGly=0.8331; W=0.0509; EtOH=0.0
Feed 2 (W-EtOH)	Location	Segment 16
	State, T & P	Liquid, 343.15 K, 1 bar
	Flow rates (kmol h^{-1})	EGly=0.0; W=0.1149; EtOH=0.7691
Thermodynamic model	Liquid phase	NRTL
	Vapor phase	Ideal
Transport properties	Mass transfer coefficients	Onda correlation
	Heat transfer coefficients	Chilton-Colburn analogy

5. Results and Discussion

5.1. Current Operation

According to EB equation, Figure 2A, the 48% of total EG is located in the boiler, 51% comes from the packed column and only 1% is generated in the condenser. The high value of the EG in the boiler is due to heat transferred there causes the biggest changes in temperature and composition in the lower column section, Figures 2C and 2D, while in the condenser temperature and composition changes are little, because in it takes place the condensation of high purity EtOH.

In the packed column the main irreversibility source is the mixing at the feeding points, with 86% of the total EG in the packed column. Interfacial heat and mass transfer, calculated by NET, Figure 2A, generate only 14% of EG in the column. This behavior departs from works of de Koeijer and Rivero (2003), Tsirling et al. (2006) and Bandyopadhyay (2007) who claim that EG due to mass transfer is the main irreversibility in a distillation column, but agrees with the work of Tarap and Ishida (1996). The work of de Koeijer and Rivero analyzed the EG in ethanol rectification while we analyze EG in ethanol dehydration. In a rectification, the distance between operating and equilibrium lines is bigger than in extractive distillation, therefore driving forces for heat and mass transfer are higher for ethanol rectification than in our process. The relative contribution of heat (12%) and mass (2%) transfer to EG agrees with aforementioned works, where mass transfer effect is the most important irreversibility.

5.2. Feed Ratio

The Figure 3A shows that EG is reduced when feed ratio (FR) decrease, and this is due mainly to reduction on mixing effects, and the heat load in the boiler, Figure 3B. However there is minimum FR, near to 1, which makes feasible the operation i.e., to get high purity ethanol (>99%) in the distillate.

5.3. Entrainer Feeding Temperature

The influence of the entrainer temperature, Figure 4A, shows that EG is sensitive to this variable, because of the irreversibility in mixing decrease when the difference between

entrainer feed and internal flows are reduced, Figure 4B. One important thing to remark is entrainer feeding temperature, at the analyzed values, does not have influence on the distillate composition which is advantageous for the process.

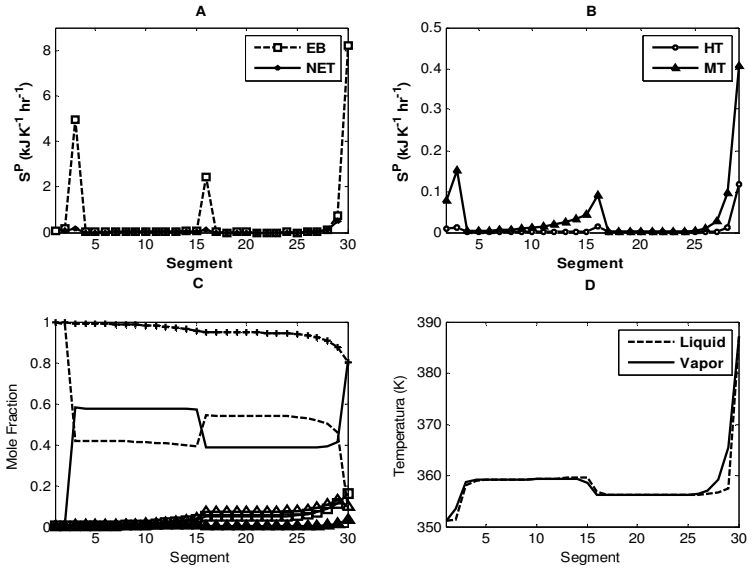

Figure 2. EG for the current operation: A. Entropy production profile calculated form EB equation and NET. B. EG due to heat (HT) and mass transfer (MT). C. Composition profile: --- EtOH(L), + EtOH(V), Δ W(L), □ W(V), − EGly(L), ▲ EGly(V). D. Temperature profiles.

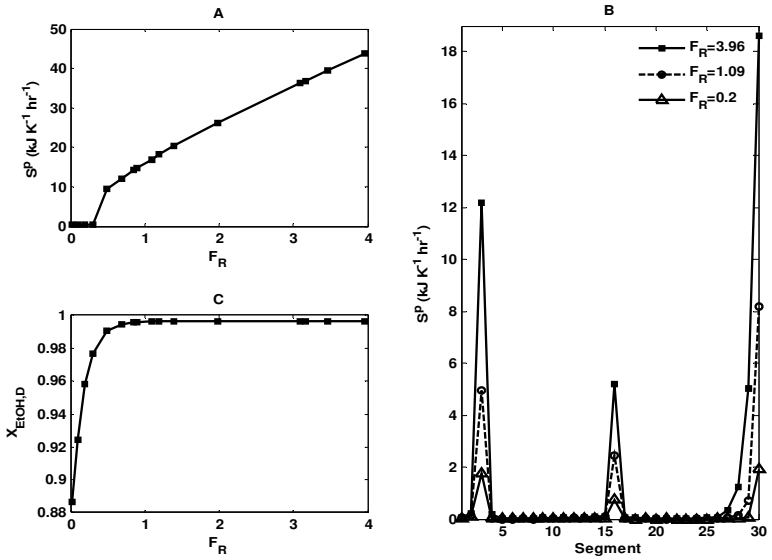

Figure 3. EG related to feed ratio. A. Total EG. B. profile of EG for different feed ratios (FR). C. Mole fraction of ethanol in distillate.

Other variables were evaluated (feeding temperature for W-EtOH mixture and reflux ratio) but the most important effects on the EG are those related with FR and entrainer feeding temperature.

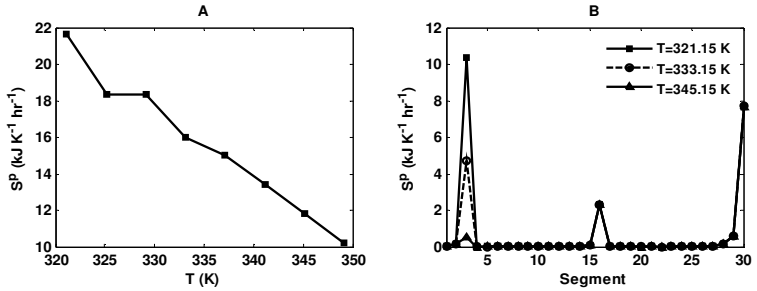

Figure 4. EG related to feed streams temperatures. A. Total EG in function of entrainer temperature. B. Profile of EG rate vs. entrainer temperature.

6. Conclusions

For Ethanol dehydration, EG take place in reboiler (48%) and column (51%) principally. Mixing effects in feeding segments have the major influence on the column`s EG (86%) followed by mass transfer (12%); heat transfer effects on EG has the least influence (2%). In segments different to feeding points, mass transfer is the major contributor to EG.

Among process variables analyzed feed ratio and entrainer temperature showed the major influence on EG. Low feed ratios and high entrainer temperatures diminish the EG due to mixing and heat load in the boiler.

EG analysis using EB and NET are valuable and complementary tools for a detailed mapping of the different entropy production sources. This analysis is useful to establishing the main process variables to be considered in the energy optimization of the distillation column.

Generative Modeling of Holonic Manufacturing Execution Systems for Batch Plants

Milagros Rolón[a], Mercedes Canavesio[b], Ernesto Martinez[a]
[a]*INGAR (CONICET/UTN), Avellaneda 3657, S3002GJC Santa Fe, Argentina*
[b]*UTN, Lavaise 610, S3004EWB Santa Fe, Argentina*

Abstract

Most batch plants are constantly subjected to unplanned disruptive events such as arrivals of rush orders, raw material delays or equipment breakdowns along with a multitude of interactions in the supply chain demanding automatic on-line rescheduling and execution control. For responsiveness and agility at the shop-floor, a holonic batch control architecture based on autonomic units is proposed. A generative modeling of the proposed holonic manufacturing execution system (MES) is presented in order to evaluate its emerging behavior and macroscopic dynamics in a multiproduct batch plant. A simulation model of the proposed holonic MES for a case study was implemented in *Netlogo*. Different scenarios are considered to assess disturbance rejection capability by the holonic MES. Results obtained are very promising.

Keywords: Generative Modeling, Agent-Based Simulation, Batch Control, Manufacturing Execution System.

1. Introduction

Centralized and hierarchical control approaches are good for optimizing static schedule models but lacks agility and responsiveness mainly due their rigid and centralized nature of traditional control structures. To trade-off *a priori* schedule optimization and industrial practice in the face of disturbances most common MESs in use today (Kletti, 2007) heavily resort to a given schedule so as to focus control only on handling details and contingencies in task execution. One such manufacturing control architectures is the holonic MES implemented by a multi-agent system along the PROSA architecture (Valckenaers et al, 2007) where the MES tries to follow a given schedule and make informed choices when it cannot follow the schedule exactly (Verstraete et al, 2008). Along similar ideas, the ADACOR architecture (Leitao et al, 2005) alternates between stationary states, where system control relies on supervisors and coordinator levels, and transient situations, triggered by the occurrence of disturbances where the MES switches its decision-making policy to a *heterarchical* structure. In this work, for agility and responsiveness decentralized schedule generation and execution control are tightly integrated through holons designed as autonomic units that managed orders and resources at the shop floor level. An interaction mechanism has been designed using the Prometheus-Hermes design methodology and a simulation model (North and Macal, 2007) was used to allow an objective evaluation of the emergent dynamic behaviors.

2. Holonic Manufacturing Execution Systems

Despite some sophisticated control methods, traditional production planning and control has serious weak points in the planning and scheduling of production orders. In that respect Manufacturing Execution Systems (MES) have the aim to make the value-

adding activities transparent and to react quickly and cost-effectively to meet new requirements (Kletti, 2007).

The holonic MES designed in this paper is the result of ongoing interactions among decentralizing decision-making agents. These agents are conceived as autonomic manager units (IBM Corp., 2006) and when integrated to a physical or abstract object (managed element) they conform the holons (HMS Consortium, 2009). As shown in Fig. 1, each agent playing its role implements the monitor-analyze-plan-execute (MAPE) loop which comprise both scheduling and control for a given order or resource. For the agent to be self-managing regarding its managed object, it must have an automated method to collect the details it needs from the manufacturing system (monitor function); to analyze those details to determine if something needs to be changed (analyze function); to create a plan, or sequence of actions that specifies the required changes (plan function); and to perform those actions (execute function).

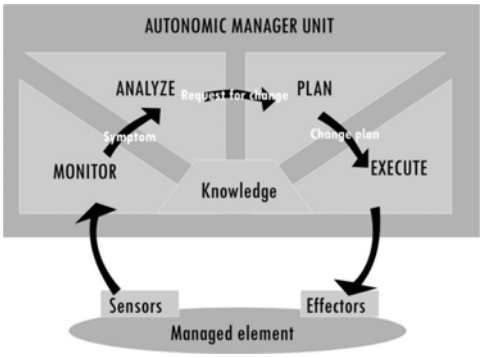

Figure 1. The autonomic agent's MAPE loop

For detailed design and specification of the holonic MES, the Prometheus-Hermes methodology was used (Padgham and Winikoff, 2004; Cheong and Winikoff, 2005, 2006). The design methodology highlights the interaction goal hierarchy, action sequences and a number of failure recovery mechanisms to provide design guidelines for multi-agent systems. An overview of the integrated methodology is shown at Fig. 2 where design artifacts for modeling interactions between agents are highlighted.

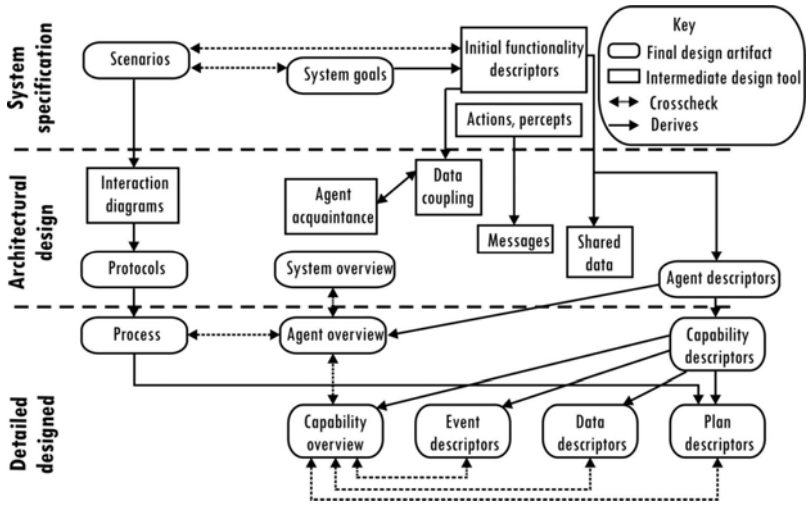

Figure 2. The phases of the Prometheus methodology integrated with Hermes

There are two different roles that can be assigned to an agent in the holonic MES, depending of the object being managed by each of them: *orders* and *resources*. The order agent (OA) is responsible for complete the order as required which determines the operations for the processing of that order. The order agent chooses the processing route to be communicated as the current order process plan (selecting one best-performing solution) and follows it moving the order between the resources. The resource agent (RA) manages the schedule for a resource and registers its usage and failure state at the Gantt chart. It is the responsible for the execution of tasks for different orders. The interaction goal hierarchy for the holonic MES is shown in Fig. 3 in which the undirected lines denote sub-goal relationships and the directed lines depict temporal dependency. The roles involved in the achievement of each goal are shown with the letter R, and it is also identified the initiator of each interaction goal with the letter I.

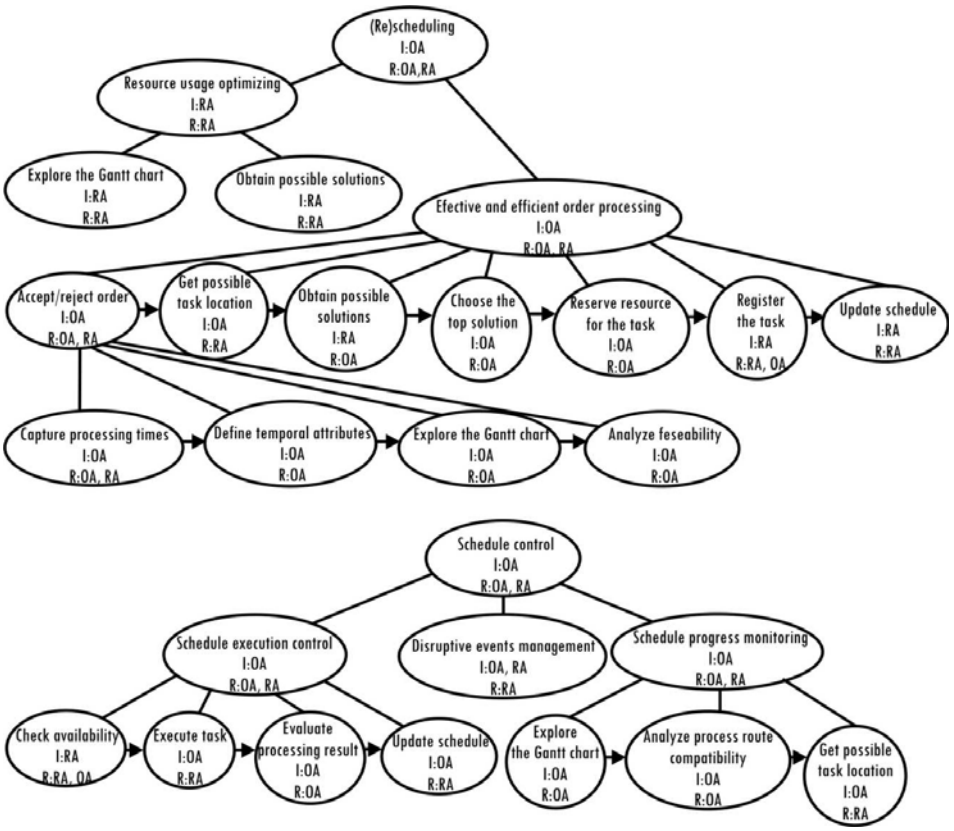

Figure 3. Goal Hierarchy in the holonic MES

When a new order arrives, the corresponding order agent looks up the Gantt in order to discover if the new order is feasible. If so, the order is accepted, and if not, it is rejected with a feasible due date. If it is accepted, the order agent asks candidate resource agents, stage by stage, different options for the probable arriving time at their queue and makes them a request about the probable finalization time at their resource. These options given by resource agents allow making a list of solutions. Given the different solutions provided by resource agents, the order agent selects the top one, with the aim of booking the time slot corresponding to the different tasks in the order. In the current

intention selection, feasible orders can be placed according to different resource agent decision rules such as SPT: shortest processing time, EDD: earliest due date and FIFO: first in first out. As a response to confirmation of resource usage by an order agent, the resource agent registers the task and updates the Gantt chart accordingly.

3. Generative Modeling

3.1. Holonic MES simulation

A computational model was implemented in Netlogo® (Wilensky, 1999), a software environment specifically designed for generative modeling of artificial agent societies. In this system, a feasible schedule for batch process emerges from the combination of individual holon' schedules. Internal coordination mechanisms between the entities in the architecture form the basis for the resultant schedules. In this simulation world, order agents (clients) negotiate with resource agents (servers) the provision of required resources to process an order and the dynamic scheduling emerging as a result of such interactions are perceived in a dynamic Gantt chart (Fig. 4).

Figure 4. A view of the resultant dynamic Gantt chart

3.2. Case Study

To exemplify the proposed approach let's consider the application of the holonic MES in a multiproduct batch plant comprising of 4 stages and 10 units to obtain 5 different products (Fig. 5). Each order has different attributes such product type and due date whereas arrival times, processing times and machine failure rates are stochastic. A batch (order) can follow many different routes through the batch plant while using different pieces of equipment. So there is a great deal of flexibility in order scheduling and it is not obvious how smoothly each order will flow through the batch plant due to a number of disruptive events. It is assumed that order agents have the objective of decreasing late deliveries, so they have decision-making logic needed to choose from the list of solutions the earliest global finalization time alternative. Resource agents resort to the FIFO dispatching rule for request processing at their resources.

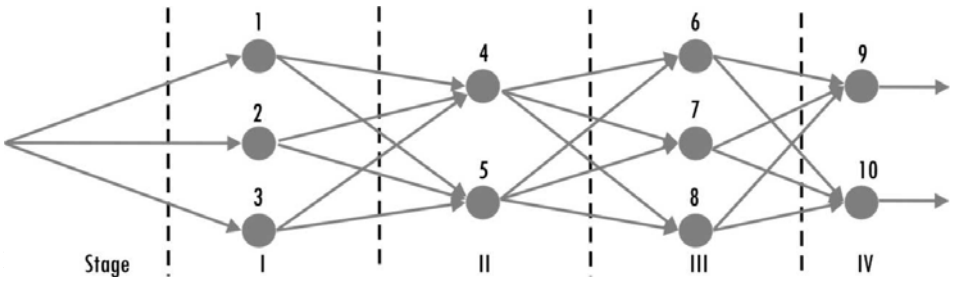

Figure 5. Multi-product plant network structure

3.3. Simulation results

Fig. 6 exhibits the dynamics of the plant for the normal operating scenario. As can be seen the total processing times of both order types shown tend to stabilize roughly after a time equal to 1000 mins. Fig. 7 shows the impact of total processing time for the order types 2 and 3 when orders of type 3 experiments and instantaneous increase in the processing time at stage II.

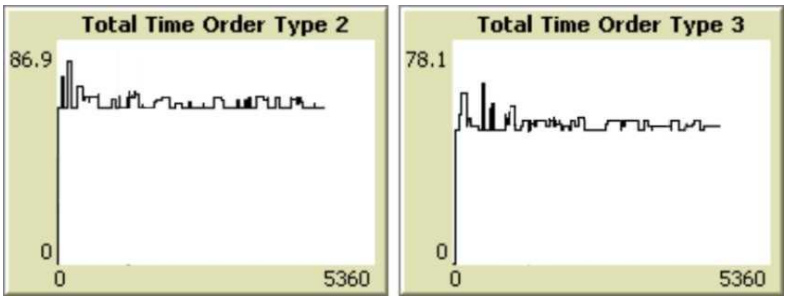

Figure 6. Total processing time for order types 2 and 3 for the normal scenario

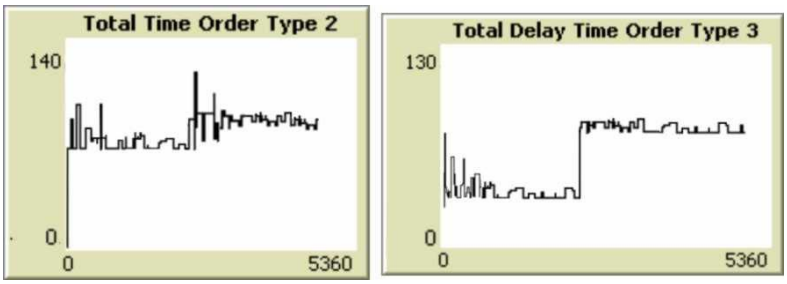

Figure 7. Total processing time for order types 2 and 3 for the scenario when order type 3 becomes more demanding of processing time at stage II since time 2000 min.

Fig. 8 describes the dynamic response of the holonic MES when the resource 1 experiments a sudden increase in its breakdown rate. Order type 3 is somewhat affected whereas type 2 orders are severely disrupted in their processing times even when this order type is not processed at this resource. At Fig. 9, the processing times for the same type of orders are shown, for the scenario where order type 2 suddenly become rush orders. Type 3 orders type are affected by this priority change but then their processing time stabilizes again, yet at a higher average whereas the type 2 orders do not suffer any sudden disruptions and their processing time stabilizes at a lower average.

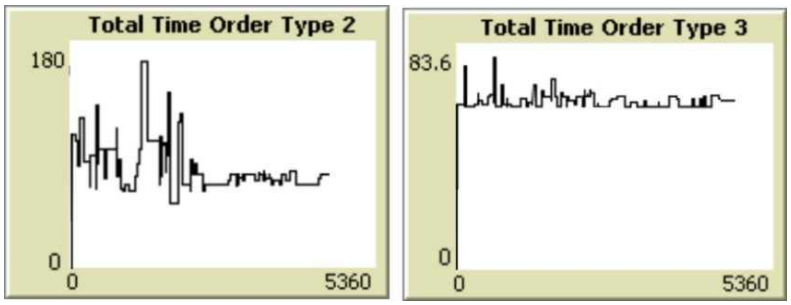

Figure 8. Total processing time for order types 2 and 3 for the scenario where an increase of resource 1 breakdown rates between minute 1000 and 2000 is simulated

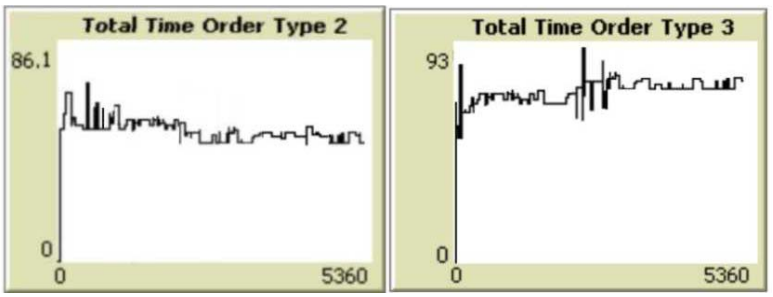

Figure 9. Total processing time for order types 2 and 3 for the scenario where type 2 orders change its priority from normal o rush orders at the 2000 min.

4. Final comments

This paper proposes a novel design of a holonic manufacturing execution system based on well-defined interactions between autonomic agents which manage two different types of objects: orders and resources. The design methodology highlights agent interactions to provide a detailed overview of a holonic MES dynamics. To asses the proposed design a generative simulation model has been implemented. Results obtained for different simulated scenarios indicate that the proposed MES is robust and stable despite the total autonomy given to order and resource agents when negotiating resource usage without resorting to a priory defined schedule.

Abstract

The need for sustainable operation has propelled the batch process industries to consider waste minimization starting from the early stages of process development. However, the time-dependent characteristics of batch operation present challenges in minimizing, recovering and recycling of waste. We present an intelligent system that addresses these by integrating different process systems engineering methodologies – process graph (P-graph), hierarchical design strategy, water reuse method, and multi-objective stochastic optimization. We illustrate the system on a well-known literature case study.

Keywords: sustainable development; multi-objective decision making; process synthesis; simulation-optimization; simulated annealing.

1. Introduction

The drive towards sustainability has prompted the batch process industries to switch from end-of-pipe treatment to waste minimization in tackling the pollution problem. However, unlike in continuous plants, the waste profile in batch processes differs in many aspects. As the same equipment can be used for multiple operation steps, wastes differing in quantity and composition are generated intermittently with the execution of each operation step. This complicates the opportunities for waste minimization, material recycling and energy recovery within the process. Further, most of the existing methodologies for waste analysis are restricted to solving individual waste sources, such as reaction by-products (Chen and Feng, 2005), cleaning agents (Foo *et al*., 2005) and energy (Majozi, 2006) without considering the trade-off between them. This may result in incomplete waste solution at best and an incorrect one at worst. Therefore, a systematic framework to identify the various elements that affect each operation and have a potential role in the waste generation should be developed. In this paper, we introduce such a framework that amalgamates three domains: knowledge-base analysis, process simulation, and mathematical optimization for comprehensive and cost-effective analysis.

2. An Intelligent Simulation-Optimization Framework

Batch-ENVOP*Expert* has been implemented in an object-oriented framework using Gensym's G2 expert system shell. It consists of qualitative and quantitative knowledge domains. A qualitative analysis is first conducted to identify the sources of wastes and to propose heuristic solutions for eliminating or minimizing them. Simulation of process

variables responsible for the waste traits is next performed to measure the efficacy of each solution in terms of economic and environmental impacts. This is followed by multi-objective optimization to resolve the conflicting effects between the objectives.

2.1. Waste Source Heuristic Diagnosis

The first step in the quest for waste minimization in batch processes is to identify each material component present in each unit of the process. We have used Grafcet in combination with unit-based simulation to establish the material flow within the batch plant − this can be represented using P-graph model. Once the P-graph model for the process is developed, materials present in each stream and unit are fully established and then waste sources can be diagnosed. To do this, the P-graph model is decomposed into sub-graphs comprising of operation steps that contribute to the presence of each material component in the waste stream (or unit). This is done by tracing each component in the waste stream upstream through the P-graph model to detect the operations that lead to the escape of materials into waste streams. Once the waste origins are identified, the next stage of the analysis is to propose heuristic design alternatives for each of them. The reader is referred to Halim and Srinivasan (2008) for a list of design heuristics.

2.2. Functional Variables Identification

While the heuristic analysis provides an overview of the various design modifications, the actual benefit of each can only be substantiated through modification at the process variables level. For this, we classify each operation step in term of the phenomena it causes (general function) and the variables affecting the phenomena (specific function). The general function of each operation step is represented by the P-graph model, which captures the physical phenomena in the operation. The specific function of each operation is defined through a subset of variables affecting the phenomena. Once the list of functional variables representing an operation is available, the next step is quantitative assessment using a process simulator to evaluate the economic and environmental impacts arising from the modifications.

2.3. Water Reuse Method

One of the heuristic alternatives that can be proposed is reuse of cleaning waste. For this, we apply water reuse methodology of Mann and Liu (1999) to minimize the cleaning agent requirement in a batch process. Figure 1 shows the basic flow scheme of a water-using operation. A contaminant j with a mass load of $\Delta m_{i,j,tot}$ is to be washed away during an operation i using water as the cleaning agent. The maximum concentrations of contaminant j at the inlet and outlet of this operation are $C^{\max}_{i,j,in}$ and $C^{\max}_{i,j,out}$, respectively. The inlet stream consists of fresh water source f_i (i = 1, 2, …, $n_{operations}$) with zero contaminant and water from the upstream operation k, $X_{i,k}$ with the contaminant loading of $C_{k,j,out}$. The term upstream is used to describe any operation k (k = 1, 2, …, $n_{operations}$ with $k \neq i$) whose finishing time precedes the starting time of the operation i. The outlet stream from operation i consists of flowstream W_i to wastewater treatment and $X_{l,i}$ to downstream operation l (l = 1, 2, …, $n_{operations}$ with $l \neq i$).

The inlet concentration of contaminant j to operation i, $C_{i,j,in}$, is defined as a constraint with the following bound:

$$C_{i,j,in} = \frac{\sum_{k \neq i} X_{i,k} C_{k,j,out}}{\sum_{k \neq i} X_{i,k} + f_i} \quad (1)$$

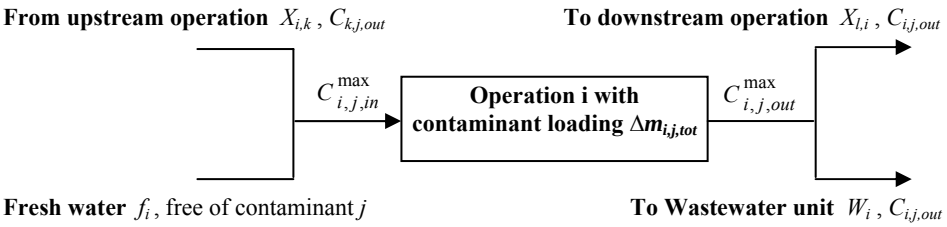

Figure 1. Schematic of water-generating operation

Likewise, the outlet concentration of contaminant j from operation i, $C_{i,j,out}$, can be described as follows:

$$C_{i,j,out} = C_{i,j,in} + \frac{\Delta m_{i,j,tot}}{\sum_{k \neq i} X_{i,k} + f_i} \tag{2}$$

Setting $C_{i,j,out}$ to be equal the maximum allowable oulet concentration gives the following equation:

$$C_{i,j,out} = \frac{\sum_{k \neq i} X_{i,k} C_{k,j,out} + \Delta m_{i,j,tot}}{\sum_{k \neq i} X_{i,k} + f_i} = C^{\max}_{i,j,out} \tag{3}$$

The following two equations can be obtained through rearranging (1) and (3):

$$\sum_{k \neq i} \left(C^{\max}_{i,j,in} - C_{k,j,out} \right) X_{i,k} + C^{\max}_{i,j,in} f_i \geq 0 \tag{4}$$

$$\sum_{k \neq i} \left(C^{\max}_{i,j,out} - C_{k,j,out} \right) X_{i,k} + C^{\max}_{i,j,out} f_i = \Delta m_{i,j,tot} \tag{5}$$

An overall mass balance around each unit operation can be written as:

$$f_i + \sum_{k \neq i} X_{i,k} - W_i - \sum_{l \neq i} X_{l,i} = 0 \tag{6}$$

The above equations form a set of constraints over which the total fresh water flow can be minimized. For a process involving multiple contaminants, an iterative optimization procedure is to be solved for each of the contaminants to obtain minimum fresh water flow that satisfies all the process constraints.

2.4. Multi-Objective Optimization Simulated Annealing-Jumping Genes

The combined outputs from the process simulation and water reuse method yield the complete set of sustainability measures for the design. They also serve as the objective function for a stochastic optimization. For this, we use the simulated annealing − jumping genes algorithm introduced by Sankararao and Gupta (2007) together with the multi-objective simulated annealing of Suppapitnarm et al. (2000) as follows:

(1) Start by specifying the solution vector x, whose elements are the decision variables of the process. To initialize, the variable values from the base-case design x' are used as the solution vector to the result of $[x', f_{env}(x'), f_{econ}(x')]$. Here, f_{env} and f_{econ} are the environmental and economic impact, respectively.

(2) Specify an initial annealing temperature T. Initially T is set to a large number $T_{initial}$ and then gradually reduced. Specify also the initial size of step change $ST_{initial}$.

(3) For N number of decision variables, a constant parameter f_b is first determined with $f_b < N$. A random number is next generated to identify the location of a decision variable p as one end of the jumping genes that lies between 0 and $N - f_b$. The other end of the jumping genes is set as $p + f_b$.

(4) Perform random perturbation to generate a new solution vector x'' in the neighborhood of x', $x'' = x' + \mathrm{R}.ST_{initial}$ (7)
where R is a random number between -1 and 1.

(5) Subsequent to the perturbation of the decision variables, jumping genes operation is next performed: $x_i''' = x_i'' + r\ (x_{i,\ max} - x_{i,\ min})$ (8)
where $i = p$ to $p + f_b$ is the length of jumping genes, r is the random number between 0 and 1 and $x_{i,\ min}$ and $x_{i,\ max}$ are the minimum and maximum values for the respective variables. Using the candidate solution vector, simulate the process to obtain new objective values $f_{env}(x''')$ and $f_{econ}(x''')$.
(6) Compare the objective values of x''' with all solutions in the Pareto set. If x''' dominates any element of the Pareto set, replace that element with x'''. If x''' is Pareto-optimal with all the elements in the set, then include it in the set.
(7) If x''' is dominated, then accept it as the current solution vector with a probability $P = \min\{1, \exp[-(f_{env}(x''') - f_{env}(x'))/T).\exp(-(f_{econ}(x''') - f_{econ}(x'))/T)]\}$ (9)
At the same time, a random number P_{rand} is generated between 0 and 1.
(8) x''' is accepted as the new solution only when $P > P_{rand}$; otherwise the earlier solution vector x' is retained.
(9) Periodically the annealing temperature T is reduced using a reduction factor R_T. The step change size is reduced also.
(10) Periodically, x' is replaced with a selected solution from the Pareto set.
(11) Repeat steps (3) to (10) for a predefined number of iterations N_{iter}.

3. Case Study: Batch Production Plant

We have tested the framework on a literature case study (von Watzdorf *et al*., 1994). Figure 2 shows the flowsheet of the process which involves reaction between chemical A and B in a cooled-jacketed vessel resulting in formation of product C and byproduct D. After the reaction is performed, the reaction mixtures are transferred to an intermediate storage tank and the reactor vessel washed with cleaning liquid. After three reaction cycles, the mixture in the storage is batch distilled to produce two main cuts of high purity A and C. The final residue from distillation is D, which is sent to a separate storage. The process requires substantial amounts of fuel due to heating operations − steam is needed in the reboiler and heater HE101. Our objective here is to minimize the environmental impact from three waste sources: process waste (T111), cleaning waste (T106) comprising mainly component A, C, and D and fuel emission due to heating process without adverse economic impact from the changes. The process currently generates an environmental impact of 1691 calculated using the WAR algorithm software (Martin and Young, 2008). The impact of the fuel emission is calculated as the sum of the total heating energy (MJ) multiplied by an equivalent environmental impact factor of 0.0043. The limiting contaminant concentration data for the three washing process is shown in Table 1. The economic objective as represented by the operating cost – including costs of waste treatment (process and cleaning waste), cleaning agent and heating and cooling energy – is $6084/hour. This is calculated using the cost data of Table 2.

Table 3 shows some of the proposed qualitative solutions for this process. Based on the solutions proposed, cooler set point, reboiler set points at different stages of operation, and purity specifications of A and C are set as the decision variables as they directly impact the waste generation. Figure 3 shows the Pareto optimal set that is obtained by manipulating the functional variables. Compared to the base-case design, the maximum reduction in the environmental impact and operating cost is found to be 1.9% and 2.8%, respectively. Figure 4 shows the proposed recycle network of cleaning agent. The savings in the amount of cleaning agent comes from recycling of cleaning effluent from the first wash operation to the second and from the second washing to the third.

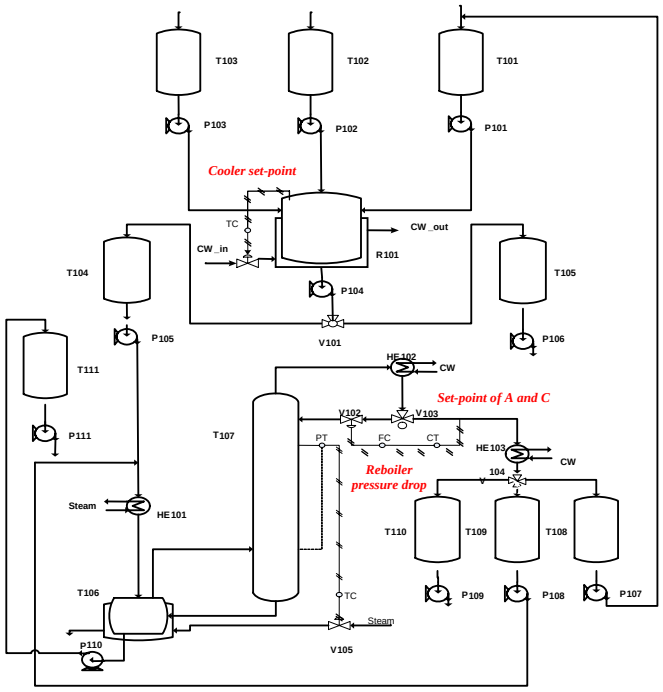

Figure 2. Batch process flowsheet

Table 1. Limiting concentration for washing process

Operation i	Contaminant j	$C^{max}_{i,j,in}$	$C^{max}_{i,j,out}$
1st wash	A	5500	7500
	C	20000	27786
	D	11000	15667
2nd wash	A	6000	8000
	C	21000	28714
	D	12000	16571
3rd wash	A	7000	9500
	C	26000	35643
	D	15200	20914

Table 2. Economic data

Unit	Cost
Washing agent ($/kmol)	2
Hot Utilities ($/MJ)	0.07
Cold Utilities ($/MJ)	1.0
Process waste ($/kmol)	5
Washing waste ($/kmol)	5

4. Conclusions

We propose an intelligent simulation-optimization framework for identifying sustainable alternatives for batch processes. We account for waste generated by the reaction-separation operation, cleaning waste and fuel emission. The knowledge-based approach is able to diagnose the waste sources and identify heuristic design alternatives. Specific variable-level manipulation is evaluated using process simulator to minimize the amounts of process wastes as well as energy. Water reuse model is applied to reduce the amount of cleaning agent through optimal design of recycle network structure. Optimal variable manipulation is next identified using a jumping gene based simulated annealing technique to evaluate both the environmental and economic objectives. The system has been successfully tested with convincing results.

Table 3. Waste minimization alternatives

Operation Step	Solution
Reaction (R101)	Optimize the reaction condition to eliminate byproduct D and fully convert material A
Washing (T105)	Recycle the liquid waste to the next cleaning process
Distillation (T106)	Use further separation after the vaporization process to avoid C from becoming waste

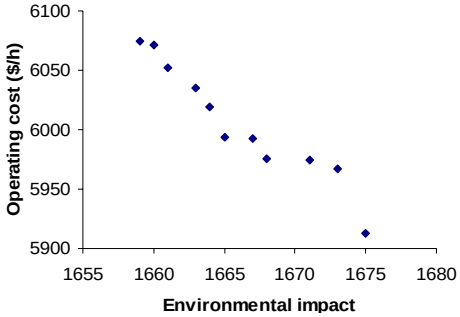

Figure 3. Pareto optimization

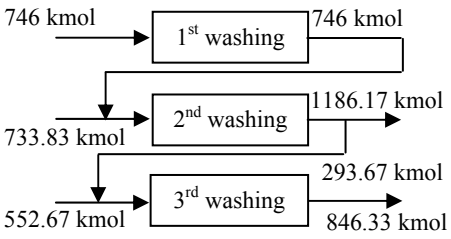

Figure 4. Proposed recycle network

Plant Design Project Automation Using an Automatic Pipe Routing Routine

Ewerton E. S. Calixto,[a] Paula G. Bordeira,[a] Hugo T. Calazans,[a] Cesar A. C. Tavares,[a] Marco T. D. Rodriguez[a]

[a]*Chemtech Serviços de Engenharia e Software LTDA, Rua da Quitanda, 50, andar 21, Rio de Janeiro – RJ, CEP 20011-030, Brazil*

Abstract

The front-end engineering and design (FEED) phase of an industrial plant project aims to determine the feasibility of the enterprise, and to produce accurate cost estimates. Successful FEED studies guarantee that provisional decisions on investments can be made more quickly by the owner or investor. Thus, the stakeholders are aligned with the project purposes, minimizing the risks involved for the acquisition of materials. The routing of pipes is a crucial phase in the plant design field, representing approximately 20% of total project costs for the industry as a whole. This work discusses the state-of-the-art concerns for plant design projects, and presents an effective software product for automating the pipe routing process. The results presented herein indicate that the developed solution is able to reduce man-hours and costs involved in the FEED phase of a project by providing, in quantitative terms, a satisfactory pipe routing.

Keywords: Automatic Pipe Routing, Front-End Engineering and Design, Automation, Plant Design, Materials Take Off.

1. Introduction

Specific literature on project management indicates that approximately 70% of all projects executed during the last five years were not finished on time or within budget (Saputelli et al., 2008). Therefore, the optimization of time, cost, materials and human resources are important aspects to be taken into consideration during the project's life-cycle.

A front-end engineering and design (FEED) study is a Process Engineering approach applied during the early planning stages of an industrial plant project. The strategy of this type of study consists of two main activities: (1) determining the feasibility of the enterprise, and (2) producing more accurate cost estimates. During the FEED stage of a project, about 80% of the total development costs are determined (Peters and Timmerhaus, 1991). By separating the two activities mentioned above and performing them earlier in the project, it is possible to take better advantage of scope definitions, reducing project risks and costs.

One important concept for understanding the FEED study activities is that of materials take-off (MTO). MTO is the list of all piping material to be used for the execution of a certain project. Successful FEED studies guarantee that provisional decisions on investments for the construction of an industrial plant can be made more quickly by the owner or investor. Thus, the stakeholders are aligned with the project objectives, minimizing the risks involved for the acquisition of materials. In this context, it is important that MTOs provide reliable estimates (Burdorf et al., 2004).

Due to the complexity and the time-intensive nature of the evaluation, the modeling of pipework items represents a significant portion of the overall costs of industrial plant projects. The main goal of the study presented here was to develop an integrated system which could reduce design time and maintain the accuracy of the quantitative analysis during the FEED pipe routing activities of plant design projects.
The designing principle adopted for the design and development stages of the proposed system aimed at the possibility of creating a software environment that could communicate with third-party, commercial computer-aided design (CAD) software products, such as PDMS[1] (Plant Design Management System).
This paper proposes a rule-driven pipe routing tool for decreasing the time needed for the execution of FEED projects. The results presented herein indicate that the developed system is able to reduce man-hours and costs involved in the FEED phase of a project by providing, in quantitative terms, a satisfactory pipe routing.

2. Pipework for Industrial Plant Projects

The importance of pipework in the industrial plant field is enormous. All industries have pipe networks which are responsible for conveying different types of fluids all over the industrial plant layout. Each part of the pipe network has a specific role, and based on this role, is essential for the industry to run well (Telles, 2001).
In the process industry context, the pipe networks have a great influence in the overall project, connecting equipment, such as pressure vessels, reactors, tanks, pumps and heat exchangers. The industrial plant layout study analyzes the most economical spatial configuration for the industrial plant, meeting constraints regarding construction, safety, operation and maintenance factors (Mecklenburgh, 1985).
According to Telles (2001), the pipework value for the chemical processing industry represents between 20% and 25% of the total industrial plant construction costs. Additionally, pipework assembly reaches, on average, between 45% and 50% of the equipment layout expenses, while the pipework design is worth approximately 20% of the project industry as a whole. Therefore, the pipework design and other correlated activities are often considered the most challenging efforts during a plant design project (Kentish, 1982). Piping design must take into consideration not only economics and design simplicity, but also flexibility, support requirements, and several other mechanical aspects (Guirardello and Swaney, 2005).
The pipework engineering activities depend on several rules and principles which should be met during the design, construction and maintenance phases of the project. Piping projects involve an intricate network of components including pipes, flanges, supports, gaskets, bolts, valves, strainers and expansion joints. These elements are available in a variety of materials, types and sizes, and are manufactured under national, international or proprietary standards. Other aspects such as safety needs should also be considered during the pipework design cycle. Pipe networks containing hazardous fluids, for instance, must be protected from damage by external mechanical impacts, leaks from adjacent pipes and external sources of heat. In addition to these considerations, the designing principles must also provide the unit plant employees with safe access conditions for performing operation, inspection and maintenance tasks, as well as guarantee that the pipe supports and bridges are designed with sufficient traffic impact resistance and mechanical strength to support the loads exerted on them (Holmes, 1973).

[1] AVEVA PDMS is a three-dimensional computer-aided design (3-D CAD) software package for engineering, design and construction projects distributed by AVEVA Solutions Ltd.

The front-end loading (FEL) methodology is an engineering project approach used in order to ensure that exhaustive alternative capital analyses will be performed during the life cycle of industrial plant projects. FEL helps oil and gas operators integrating business and technical goals to reduce project costs, improve operational efficiency and maximize profitability (Saputelli et al., 2008). The FEL Definition phase of a project corresponds to the FEED engineering stage. This stage involves basic engineering, operations plan, risk plan, contracting and sanctioning activities. The FEL's fundamental thesis is that the anticipation of the plant construction phase can effectively advance the return on investment (ROI) of a given industrial project.

3. Automatic Pipe Routing in Computer-Aided Design

In order to decrease the amount of effort required for performing process and plant design activities, a great variety of computer-aided design (CAD) software products has been proposed. One of these products is AVEVA PDMS, which provides PDMS Router, a built-in tool for the automatic routing of pipes. The environment offered by PDMS routes the pipes orthogonally, using graph's theory principles (Guibbons, 1985) and a shortest-path algorithm (Wang and Crowcroft, 1992) to minimize the amount of piping material needed for the routing.

The purpose of the PDMS Router is to minimize material costs while avoiding clashes with other plant elements. The plant designer is able to choose the pipes intended for the routing process, and to create constraints based on spatial planes and points. The routing algorithm used by PDMS Router has three different operational modes, which are called Level 1, Level 2 and Level 3. At first, PDMS Router searches for a route using the Level 1 mode. If no clash-free route is found after the first operational mode, a search is made using Level 2. Similarly, if no free route is found after Level 2, then Level 3 is used.

As shown in Figure 1, the Level 1 operational mode searches for an orthogonal route between the head point (PH) and tail point (PT) of a pipe, using the minimum number of bends and elbows.

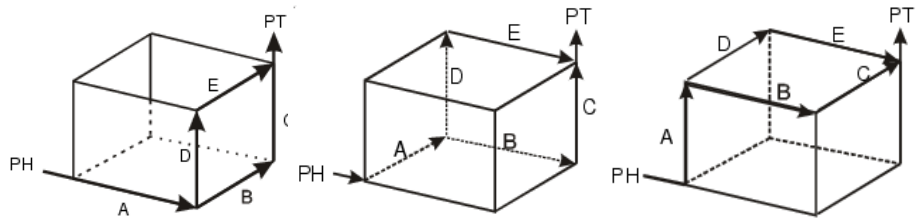

Figure 1. Level 1 mode (AVEVA Solutions Ltd., 2007).

If all Level 1 routes are blocked, PDMS Router will attempt Level 2 routes. In Level 2 mode, PDMS Router will attempt to withdraw the route into the box by a distance that could enable the pipe to bypass the obstruction. Then, PDMS Router tries the same routing patterns as those used in Level 1 mode. An example of a Level 2 route is shown in Figure 2 (a).

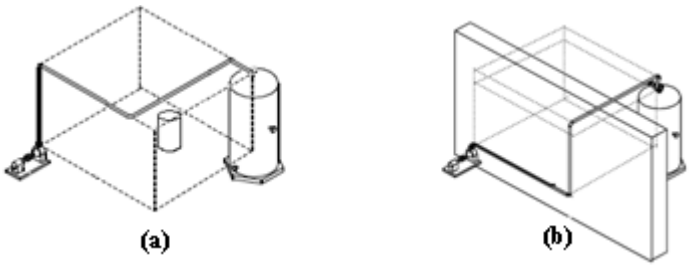

Figure 2. Level 2 (a) and Level 3 (b) (AVEVA Solutions Ltd., 2007).

If PDMS Router cannot find a clash-free route using first and second level routes, it will attempt to find a Level 3 route, as shown in Figure 2 (b). In Level 3 mode, PDMS Router extends the box outwards until it bypasses the obstruction and then attempts to route the pipe using Level 1 routing principles.

It is important to keep in mind that PDMS Router does not provide any other automation beyond the de facto routing of pipes. This means that the designer has to perform all the manual tasks needed for PDMS Router to work, such as creating the pipe hierarchy elements and determining their material specification, as well as creating and connecting the head and tail points of all their branches. The routing features of PDMS Router can only be used after all the previously mentioned tasks are completed.

4. Automatic Pipe Routing Routine

In order to reduce the human involvement in the tasks necessary for the PDMS Router to work, a software architecture environment was implemented in the PML[2] programmable language. The proposed environment should be able to perform the steps shown in Figure 3 and described further down.

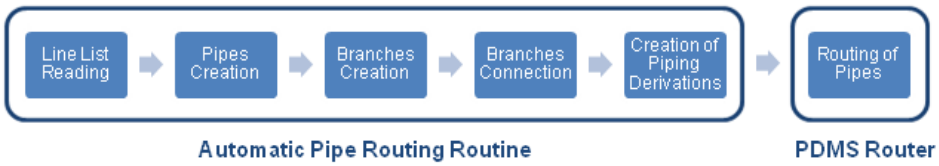

Figure 3. Automated workflow process for the automatic routing of piping elements.

The proposed workflow process consists of a chain of six activities. The first five ones are logically grouped in the implemented Automatic Pipe Routing Routine. Each one of the mentioned activities is responsible for automating a different step necessary for the effective PDMS Router processing.

Initially, the routine reads the information presented in the line list. Using this information, the routine creates the hierarchy elements of the pipes meeting the material specification constraints presented in the list. After this step, the branches are created and then connected to their connection points. By reading the line list, the routine evaluates the number of piping derivations necessary to be created for each pipe. These derivations are created and then, as the last step for the automated workflow process, the pipes are routed with PDMS Router.

[2] PML (Programmable Macro Language) is an object-oriented programming language for interacting with AVEVA PDMS.

The main advantage of using this routine in a FEED project is the possibility of performing an accurate evaluation of piping materials with minimum effort. The resulting estimates may be given in terms of relevant MTO data, such as the total evaluated piping weight and length.

4.1. A practical case study

Some evaluations were performed in a specific refinery plant unit (Figure 4) called the atmospheric distillation unit (ADU) during the FEED phase of an energy company project. The evaluations basically consisted of a comparison between the total pipe length obtained by the manual piping design and that obtained by the automatic pipe routing routine proposed herein.

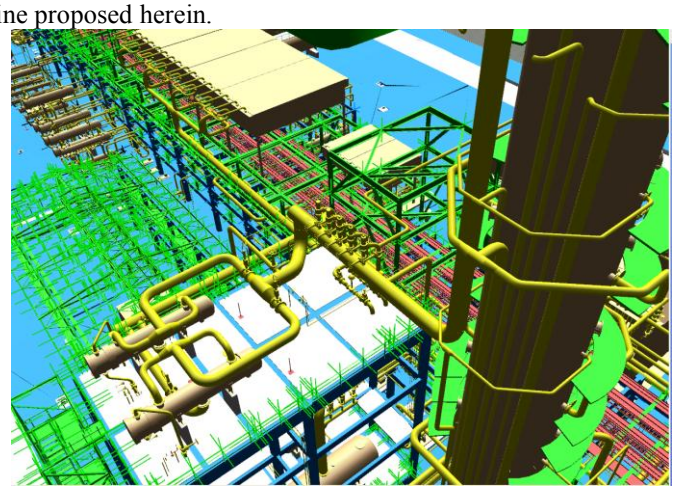

Figure 4. Set of pipes routed in the atmospheric distillation unit of the refining project used as a case study for this work.

A set of fifteen pipes described in the industrial plant engineering flowsheet diagram was chosen. The purpose was to route automatically the selected pipes and compare the results with the routing provided by the company piping design team.

As shown in Table 1, the comparison results indicate an average error of 6.5% between the total piping length obtained by the manual design and by the automatic pipe routing process. According to the literature (Telles, 2001), such an error represents a comfortable and reliable margin for a successful MTO.

Table 1. Pipe Length Comparison Results.

Total Length (With Routine) (m)	334.6
Total Length (Without Routine) (m)	312.86
Error (%)	6.496

This result gives a good margin in MTO reports and the piping materials can be purchased with more reliability.

5. Future Work

For future work, it is important to minimize the layout and measuring differences between the manual and the automatic routing of a single pipe. The impact magnitude of such differences seems to be attenuated, or at least stabilized, when a large set of pipes is being routed in a complex and dense plant unit. The current version of the

proposed integrated environment only evaluates total pipe routing lengths. However, future implementations should provide weight estimates as well, since weight is a very important parameter for MTO reports.
Another working possibility would be to improve the automatic pipe routing routine layout with respect to qualitative terms. For example, in this context, design factors associated with pipe flexibility and stress analysis could be taken into account for the layout design. Such layout considerations could be used as an appropriate strategy for increasing the accuracy of the automatic pipe routing MTO estimates.

6. Conclusions

The use of the automatic pipe routing routine presented herein can reduce the time required for the production of reliable MTO estimates at the end of FEED studies for chemical engineering projects. The results indicate that the implemented solution is able to automate manual and time-consuming stages previously required for the three-dimensional piping design process. The possible benefits provided by the routine should impact all the project stakeholders, ranging from designers to investors. Some improvements should still be considered, however, regarding increasing the accuracy given by the routine's MTO estimates.

A continuous targeting approach for integrated solvent and process design based on molecular thermodynamic models

André Bardow, Klaas Steur, Joachim Gross

Process & Energy Department, Delft University of Technology, Leeghwaterstraat 44, 2628 CA Delft, The Netherlands

Abstract

Solvent properties and process behavior are highly interdependent. The integrated design of solvents and processes in a single optimization problem is, however, still prohibitive mainly due to the discrete nature of solvent selection. In this work, a framework for integrated solvent and process design is introduced using a continuous-molecular-targeting approach (CoMT-CAMD). Based on a detailed molecular-thermodynamic model, a hypothetical solvent is introduced in the process optimization problem. The properties of the hypothetical solvent are relaxed and continuously optimized along the process variables thus achieving the integrated design. In a second step, the hypothetical solvent is mapped onto real components. The framework is implemented using the PCP-SAFT equation-of-state and exemplified for the design of solvents for CO_2 capture.

Keywords: computer-aided molecular design (CAMD), conceptual process design, solvent design, CO_2 capture.

1. Introduction

Solvent design is one hallmark example of product design 0. Solvent-based separations are employed in almost all chemical, biochemical and pharmaceutical processes. The selection of a suitable solvent is thereby the determining step for the feasibility and the efficiency of a separation. Selectivity for specific compounds is the primary requirement for a solvent but properties such as capacity, viscosity or toxicity also have to be considered. A final choice thus requires a trade-off between these properties 0.

In practice, solvent selection is often based on experience and simple heuristics leading to suboptimal solutions. Computer-aided molecular design methods (CAMD) provide a systematic means to identify suitable solvents 0. CAMD can be interpreted as the inverse of property prediction: Given a set of target properties, a molecule is sought that satisfies the property specifications.

However, the definition of a representative set of solvent target properties is by itself an intricate problem due to the strong interaction between solvent properties and the process at hand. The ultimate goal is therefore the integrated design of the solvent molecule and the corresponding process 0.

Due to the discrete selection between molecules, the solution of this integrated design problem in a single mathematical optimization is prohibitive today. In 0, a reverse engineering approach has therefore been followed: First, constraints on property values are obtained from process optimization. Then, components are generated that meet these constraints. While this approach allows for the derivation of process-specific targets, a direct link between process performance and molecular characteristics is not achieved.

Recently, advanced thermodynamic models have been developed in the SAFT-family of equations-of-state 0. While most CAMD-approaches employ thermodynamic models applicable at low pressures only, the integration of an equation-of-state (EoS) allows for a sound description of high-pressure systems 0. More importantly, these models are based on a coarse-grained but still very detailed molecular picture. In particular, a sound integration of multipole interactions has been achieved in the PCP-SAFT EoS 000.
In this work, the advanced properties of molecular thermodynamic models such as PCP-SAFT are exploited to integrate solvent and process design. By relaxing the solvent pure component parameters as free variables during process optimization, a hypothetical target molecule is obtained in a continuous optimization problem. This continuous-molecular-targeting approach to computer-aided molecular design (CoMT-CAMD) thus circumvents the discrete selection in the integrated design problem. Only in a second step, the hypothetical target molecule is mapped onto real solvent molecules.
The proposed CoMT-CAMD approach is presented in the following section. A case study for carbon dioxide capture is discussed in Section 3 before conclusions are given.

2. Continuous-molecular-targeting approach

2.1. Proposed framework for integrated solvent and process design
Thermodynamic tools are usually developed to predict phase behavior in process applications. Given the structure of a molecule, thermodynamic properties are predicted to describe the expected process behavior (cf. upper part of Figure 1).

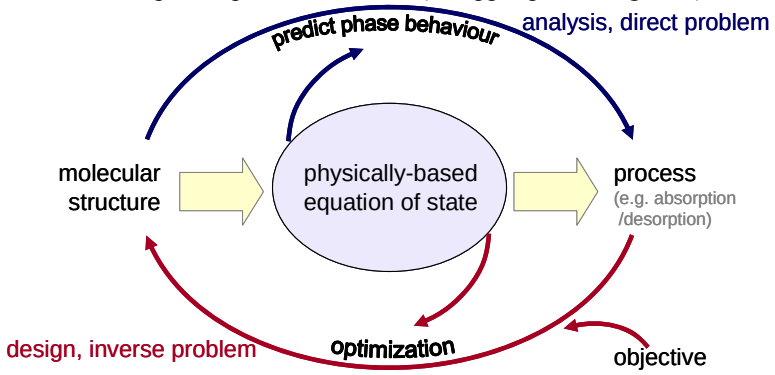

Figure 1: Integrated solvent and process design using a physically-based equation-of-state.

In the proposed design framework, the inverse problem is regarded: Given a certain objective, both the process and the molecular structure are optimized to meet the constraints and reach the optimal process performance (cf. lower part of Figure 1).
In our view, a physically-based equation-of-state is central to truly link molecular characteristics to process performance as indicated in Figure 1. In a physically-based equation-of-state, a molecule is represented by a set of pure component parameters which correspond to clearly defined molecular attributes. In contrast to earlier approaches, these parameters do not lump many effects into one coefficient. Thereby, a close correspondence between a parameter set and specific molecules is achieved. This correspondence is the key factor in the suggested approach.
The integrated solvent and process design problem is approached in two steps:

- Step one: Continuous-molecular targeting
  Both process variables and solvent parameters are simultaneously optimized in a continuous fashion by relaxing the solvent pure component parameters from their

discrete values. This optimization yields settings for optimal process performance and a hypothetical target molecule.

- Step two: Structure mapping
  The hypothetical target molecule characterized by a set of equation-of-state parameters is mapped onto real substances. Only here, discrete decisions have to be taken.

While the approach still consists of two parts, molecular attributes are now directly assessed in process design. The two steps are briefly described in the following.

2.2. Step one: Continuous-molecular targeting

Fully integrated solvent and process design is *de facto* prevented due to the discrete nature of molecule selection. By employing a physically-based equation of state, each candidate solvent is described by a discrete set of pure component parameters. In the continuous-molecular-targeting step, this discrete set is relaxed and a continuous search in the full parameter space is performed. The resulting optimization problem is then

$$\begin{aligned} &\max_{x,y} f(x) \\ &s.t. \quad h(x, g(x,y)) = 0 \\ &\qquad g(x,y) = 0 \\ &\qquad \mathrm{c}(x,y) \le 0 \end{aligned}, \tag{1.1}$$

where x denotes the process variables and y the pure component solvent parameters. The latter typically do not appear directly in the design objective $f(x)$. The process model is given by the equality constraints $h(x,g)$ where the thermodynamic quantities $g(x,y)$ enter. Process and solvent inequality constraints are summarized in $c(x,y)$.

For the integrated design problem (1.1), a standard NLP solver may be employed. Thereby, optimal process settings and pure component parameters for a hypothetical solvent are obtained. The resulting objective gives an upper bound for the process performance achievable by any molecule describable within the chosen thermodynamic framework. This information by itself is valuable in assessing the process design.

To perform the CoMT-step, three elements are required: the thermodynamic model, a process model (incl. constraints) and an objective function. These are discussed next.

2.2.1. Thermodynamic model: PCP-SAFT equation-of-state

As central physically-based equation-of-state, PCP-SAFT is employed 0000. PCP-SAFT has been shown to allow for good predictions of phase behavior in complex mixtures. In PCP-SAFT, the individual molecular contributions to the residual Helmholtz energy are resolved (see 0000). In the present context, it is important that each molecule is represented by a set of seven pure component parameters in PCP-SAFT. These seven parameters correspond to clearly defined molecular attributes:

- two geometric parameters describe size and elongation;
- three energy-related parameters describe dispersion, association energy and volume;
- two polar parameters specifying the point dipole and quadrupolar moments.

The idea of a physically-based model shows from the fact that, e.g., the polar interactions can be obtained from independent sources such as quantum mechanics 00. As an equation-of-state, PCP-SAFT provides a consistent description of all residual thermodynamic properties of a molecule. Given the seven parameters, the behavior in any process application is thus defined. Separate – and probably inconsistent – physical property models describing e.g. heat capacities and saturation pressure are not required. In the present work, PCP-SAFT provides residual enthalpies and equilibrium constants. For the ideal-gas heat capacities, a simple correlation for organic solvents is introduced.

2.2.2. Process model

The proposed method is very flexible with respect to the process model employed. Typically, process equations consist of Material balances, Equilibrium balances, Summation equations and Energy (Heat) balances (MESH). In addition, constraints on process variables (e.g., pressure limitation for safety) may be added.

The process model obtains thermodynamic input from PCP-SAFT.

2.2.3. Objective function

While classical solvent design methods had to focus on solvent properties, process-wide objective functions can be incorporated in the presented CoMT-CAMD-framework. The trade-offs between different solvent properties are thus directly addressed through their implications on process behavior.

Process-wide objective could reflect aspects of cost-, energy- or second-law-efficiency. Different objectives can be employed to study the implications on solvent and process.

2.3. Step two: Structure mapping

The continuous-molecular-targeting step yields optimal PCP-SAFT-parameters y^* of a hypothetical solvent. To implement the findings in practice, these parameters are mapped onto real substances. Thereby, discrete decisions are taken.

Group-contribution methods could provide a suitable tool to implement this mapping. For advanced SAFT-models, these methods are currently being developed 00.

Here, the structure mapping is performed by a database search. In the PCP-SAFT database, potential solvents are represented by their parameter vector y. To assess their expected performance, a Taylor approximation is performed around the CoMT-optimum y^* to predict the expected loss in the objective function $f(x)$ for all database entries

$$\Delta TA(y) = J(y^*)(y - y^*) + \frac{1}{2}(y - y^*)^T H(y^*)(y - y^*), \tag{1.2}$$

where J and H denote the Jacobian and the Hessian of the problem (1.1) available from the optimization in step one. The Taylor approximation criterion allows for a sound assessment of the database entries as it accounts for the different sensitivities with respect to different parameters. Based on the predicted performance, a ranked list of real molecules is obtained. For a final assessment, a process optimization for this limited number of solvent candidates should be performed.

3. Case study: Physical absorption for CO_2 capture

3.1. Problem description

The proposed method is exemplified for the design of physical solvents for CO_2. The study is motivated from the pre-combustion route for carbon dioxide capture and storage. To focus on the characteristics of the proposed framework, the discussion is limited to a single-stage absorption unit. It is straightforward to extend the method to the full process. A solvent is searched that provides the highest separation efficiency with respect to CO_2. Thus, the objective function is given by

$$f(x) = x_{CO2} / y_{CO2}, \tag{1.3}$$

where x and y denote liquid and vapor mole fraction leaving the absorber, respectively. The MESH equations describing the absorber are implemented. The inlet streams and temperatures are fixed. The pressure is constant (p=50 bar). The PCP-SAFT parameters are constrained to the range of values available in the database of existing molecules.

3.2. Results

3.2.1. Step one: Continuous-molecular targeting

In the following, methanol serves as a reference solvent. As initial study, a single property of methanol is varied in seven individual optimizations (Figure 2).

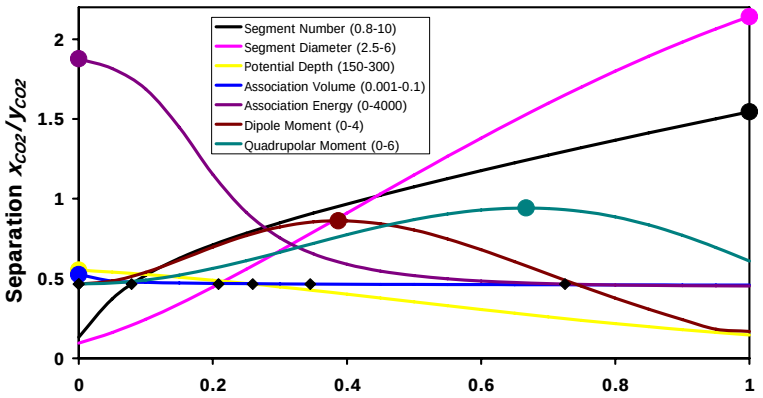

Figure 2: Separation of CO_2 as function of normalized PCP-SAFT parameter values. Circles indicate the optima, and diamonds mark the base case corresponding to methanol.

The method is clearly capable of improving the selectivity. The base case parameters for methanol are PC-SAFT values and do not account for its dipole. The true normalized dipole moment of methanol of is μ=0.425. This value corresponds very well to the maximum found. Indeed, methanol is used commercially in the Rectisol process.

The simultaneous CoMT-optimization of all seven solvent properties generates a hypothetical solvent with a separation factor of 6.31. This value is ten times higher than that of methanol. Indeed, the hypothetical solvent found is a rather extreme molecule. All but one molecular property lie at a bound of the parameter space (Table 1).

Table 1: Normalized PCP-parameters for hypothetical target molecule obtained from CoMT-optimization in comparison to initial guess methanol.

Parameter	m_i	σ_i	ε_i	κ_{iAB}	ε_{iAB}	μ_i	Q_i
Methanol	0.079	0.209	0.259	0.345	0.725	0.	0.
CoMT-optimum	1.	1.	1.	0.	0.512	1.	1.

3.2.2. Step two: Structure mapping

The hypothetical target molecule has now to be related to real substances. The PCP-SAFT database available to us contains parameters for about 120 substances. The structure mapping is performed using the Taylor approximation (1.2) criterion (Table 2).

The solvents suggested from the structure mapping yield significantly improved process performance compared to methanol. It should be noted that the hypothetical target solvent is very far from real existing substances. The average distance in the normalized parameter space is larger than 44%. This undermines the quality of the Taylor approximation as it is based on a local analysis.

Still, the results are intuitively sound as the optimization aims for highest selectivity with respect to CO_2. In an actual process design, the solvent recycling by desorption would also have to be considered. The trade-off between absorption and desorption is expected to lead to less extreme molecular properties.

Table 2: Ranked list of solvents obtained from structure mapping using Taylor approximation criterion. The separation finally obtained is also given. Methanol is included as reference case.

Compound	DMF	DMSO	BNI	PNI	MeOH (PC)	MeOH (PCP)
ΔTA	-5.3	-5.5	-5.8	-6.4	-19.9	-15
Separation	2.53	1.94	2.7	2.59	0.46	1.02

DMF – Dimethylformamide, DMSO – Dimethyl Sulfoxide, BNI – Butyronitrile, PNI – Propionitrile, MeOH – Methanol with PC- and PCP-SAFT parameters, respectively.

4. Conclusions

Integrated solvent and process design is a long-standing challenge. Due to the discrete decisions required, this problem can *de facto* not be solved with a single optimization. In the present work, a continuous-molecular-targeting approach to computer-aided molecular design (CoMT-CAMD) is proposed to address the integrated design by defining a hypothetical solvent. If the hypothetical solvent is characterized by a consistent set of physically-based attributes, a straightforward mapping onto real molecules is possible.
The approach is demonstrated for the design of physical solvents for carbon dioxide capture. Solvents are found that yield significantly higher separation than the commercial solvent methanol. These results demonstrate the potential of the method.
In future work, a more detailed process description will be employed to represent all design trade-offs and to fully exploit the advantages offered by an integrated approach.

Abstract

The solvent recovery section of a soybean oil extraction process has been studied with special emphasis on the effect of design variables on the performance of the process. Two different sets of simulations were carried out to analyze these effects. The first set of simulation results were analyzed with the Plackett-Burman (PB) method to identify the parameters (process variables) that make the greatest impact on the process. The second set of simulations was used to generate a reduced model relating the design variables to the identified parameters. Through the PB methodology, it was possible to obtain a reduction of 40% in the number of process variables to be considered in the performance analysis. Even tough, the response surface pointed out that the process is already within the optimum zone, optimization with the reduced model pointed further improvement in the amount of hexane recovered.
Keywords: Simulation, optimization, solvent recovery, surface response methodology, vegetable oil.

1. Introduction

Fats and oils are a source of energy and play an important role in human nutrition. The production of edible oils/fats involves a great variety of processing steps and unit operations, and state of the art in process modeling has only to a very limited extent penetrated this industry and part of the reason is the complex nature of the lipid systems involved. Lipid technology refers to products and processes (modification, purification, separation, etc.) that involve fatty acids, their derivatives, and related substances. This work develops computer aided methods and tools for the systematic design and analysis of a process that employs lipid technology, the solvent recovery section of the soybean oil extraction process.

It is known that the soybean oil is almost exclusively produced by solvent extraction and the most widely used solvent for extraction of oil from oilseeds is hexane, because it has high solubility for fats and oil, chemical stability and a suitable vapor pressure allowing for easy separation by flash and stripping operations [1]. The hexane recovery section (see Figure 1) includes four parts: An oil recovery, a condensation system, a mineral oil system and a water-solvent separation. After the "washing" of the soybean

flakes, both the miscella (mixture of oil and solvent) and the white flakes (extracted flakes wet with solvent) are heated separately to remove the solvent. The flakes go to a desolventiser–toaster–drier–cooler (DTDC) unit and the miscella enters the first part of the solvent recovery section, the oil recovery system, where the oil is concentrated. Here the solvent is removed from the oil that is subsequently concentrated nearly to 100% (crude oil). All the recovered solvent vapors mixed with steam, including those coming from the DTDC facility, are retrieved by means of three sub-systems that make part of the solvent recovery system: the condensation, the MOS (mineral oil system), and the water–solvent separation. Therefore, vapors are condensed and the residual vapors are captured in the mineral oil system. The condensates from the condensation system enter a water–solvent separation section, where the solvent is recovered and after mixing with a make-up stream, is redirected to the extractor.

The aim of this work is to optimize the performance of the solvent recovery section of the soybean oil extraction process in terms of the important design variables. This is not an easy task since the number of design variables involved in the process (temperature, pressure, and number of stages) is quite large, and optimization of the process performance with a rigorous simulation model in this case, is quite complex. An alternative approach is to use techniques such as the Plackett-Burman and the Full Factorial Designs [2], which are useful tools to identify, observe, and analyze the critical parameters of the process and their effects on the process behavior subject to changes in the design variables; the objective here is to obtain a reduced model. Two techniques are considered here: the first applies a screening procedure to discard design variables that do not affect the overall performance of the process; the second establishes the order to perturb the remaining design variables to observe their effect on the process performance defined in terms of the identified process parameters.

The solution procedure employed in this work consists of three main steps: Process simulation, process model reduction, and process optimization. The process simulation step consists of generation of the properties of the chemicals (lipid compounds: glycerides, fatty esters, and unsaponifiable compounds) present in the process and creating a database for use in process simulation models. The model reduction step applies design of experiments techniques to identify the most significant design variables, the parameters affecting the process performance, and creates a reduced "quadratic" model relating the design variables and the process parameters. The optimization step determines the design variables values corresponding to the optimal process performance.

2. Methods and tools used

2.1. Property prediction of lipid compounds

Oils and fats oils are complex chemical mixtures of compounds such as glycerides, fatty acids, fatty esters, sterols, and tocopherols. In this work, thirteen different types of the most widely used vegetable oils (soybean, sunflower, canola, etc.) and two different kinds of fats (lard and tallow) were reviewed in the literature in order to define their typical chemical composition.

The database created from this literature review includes a total of 28 fatty acids (from C6 to C24), 51 triacylglycerides (from C28 to C58), 44 diacylglycerides (from C14 to C40), 16 monoacylglycerides (from C8 to C22), 58 fatty esters (methyl and ethyl from C6 to C24), and 26 minor compounds (sterols, tocopherols, and tocotrienols). The database also includes predicted properties for the lipid compounds such as melting

point (a new model has been developed); vapor pressure [3]; densities [4]; and critical properties that were calculated by means of the software ICAS™ ProPred [5].

2.2. Process simulation model

The solvent recovery section consists of several unit operations: flash, heath exchange, mixing, splitting, stripping, and absorption. In this work, the process section was simulated using the commercial software PRO II and the database of lipid compounds integrated to PRO II.

The process model describing the solvent recovery section is shown in Figure 1 [1]. According to the flow sheet the streams where both the hexane solvent and vegetable oil can be lost are the following: Crude_Oil, Vap_Out, Solid_Out, S33 (Purge), Mos_Water, and Vap_Mos. The corresponding process design variables are listed bellow:

- Oil recovery section: Temperature and pressure of evaporator 1 (TEVAP1 & PEVAP1), temperature of evaporator 2 (TEVAP 2), and temperature and number of stages (NS) of the stripping column (TSTP1 & NSTP1).
- Condensation section: Pressure of the condenser 1 (PCOND1) and temperature of condenser 2 (TCOND2).
- Water-hexane separation section: temperature and pressure of the decanter (TDECANT & PDECANT).

Process parameters:

- Oil recovery section: Pressure of evaporator 2 (PEVAP 2), duty and pressure drop of evaporator 3 (QEVAP3 & DPEVAP3), and pressure of the stripping column (PSTP1).
- Condensation section: Temperature of the condenser 1 (TCOND1) and pressure of condenser 2 (PCOND2).
- MOS System: Temperature, pressure, and number of stages of the absorption and stripping columns (TABSPC, PTABSPC, NTABSPC, TSTP2, PSTP2, & NSTP2).

2.3. Model Reduction

The Plackett-Burman method is a technique where only the main effects are considered to be significant, achieving thereby a reduction in the number of design variables. The advantage of this technique is that it only requires a number of experimental runs that are a multiple of 4 instead of a power of 2 [2]. The full factorial design is a technique that is sufficient for evaluating many production processes because it considers not only individual effects but also non distinguishable effects on a response.

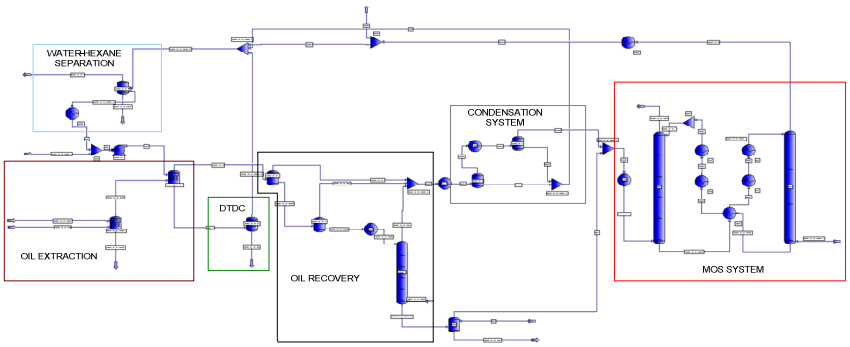

Figure 1 Solvent Recovery PRO II Model [1]

3. Case Study: Optimization of a Soybean Extraction Process

3.1. The Optimization Problem

The goal of this optimization problem is to minimize the loss of hexane solvent and vegetable oil (product) in the solvent recovery process section.

Objective Function

$$OF = Crude\_Oil(Hex) + Vap\_Out(Hex) + Solid\_Out(Hex) + S33(Hex) + Vap\_Mos(Hex) + Mos\_Water(Hex) + Vap\_Mos(Oil) + Mos\_Water(Oil) \quad (1)$$

Constraints

$26.46 \le TCOND2(°C) \le 35.80$ (2)

$25.51 \le TDECANT(°C) \le 28.19$ (3)

$53.34 \le TEVAP1(°C) \le 72.16$ (4)

$88.00 \le TEVAP2(°C) \le 132.00$ (5)

$104.50 \le TSP1(°C) \le 115.50$ (6)

$0.26 \le PCOND1(bar) \le 0.36$ (7)

$0.18 \le PDECANT(bar) \le 0.42$ (8)

$0.39 \le PEVAP1(bar) \le 0.73$ (9)

Number of Stages ≥ 1 (10)

3.2. Results

3.2.1. Process Simulation

Data related to the solvent recovery process was available, so it was possible to make a detailed analysis of the accuracy of the soybean oil extraction process simulation. The average relative deviation (ARD) between the industrial data and the simulated data for the crude oil and the overall loss of hexane was analyzed according to,

$$ARD = \frac{\sum \left| x_i^{\exp} - x_i^{\text{model}} \middle/ x_i^{\exp} \right|}{N} * 100 \quad (11)$$

Where $x_i^{\exp}$ is the plant data for vegetable oil and hexane mass compositions in stream i, and, x_i^{model} are the calculated data for the same variables for N different experimental (plant) runs. The ARD for the oil composition in the crude-oil stream is 0.31%, while the ARD for the loss of hexane in the process is 4.71%.

The analysis of the simulation results generated through the process simulation for various (perturbed) values of the design variables led to the following observations:

- Presence of hexane in the stream Solid_Out can be neglected because, according to the plant data, the DTDC process removes all hexane and water from the white flakes.
- The major loss of vegetable oil in the process is located in the solvent extraction process, where some oil may remain in the waste solid. Since a predictive model to calculate this variable was not available, the stream Solid_out was not considered in the model reduction step.
- The amount of oil in the streams S33 (Purge) and Mos_Water can be neglected as these values were found to be very small.
- Two liquid phases (water and hexane) are present in the vessel named DECANTER. Therefore, stream tagged as Vap_Mos in the flow sheet was neglected in the further solution steps.

Based on the above observations, the objective function (see Equation (1)) is reduced to

$$OF = Crude\_Oil(Hex) + Vap\_Out(Hex) + S33(Hex) \quad (12)$$

Equation (12) actually corresponds to the amount of hexane recovered in the process, which will now be maximized.

$$\text{Objective Function} = \text{Recovery of Hexane} \quad (13)$$

3.2.2. Model Reduction

Plackett-Burman Design: The ±1 levels (perturbed values) used in the 16 simulations for each of the design variables are listed in Table 1. From analysis of the simulation results it was concluded that only five variables significantly affected the amount of hexane recovered in the process.

Full Factorial Design: Based on the results of the PB method a second set of 43 simulations (2^5+2*5+1) was performed using the full factorial technique. From a statistical analysis of the results, a quadratic model for the Hexane Recovery response was obtained. The model, Equation (14), for maximizing hexane recovery is given in terms of 3 design variables (TCOND2, TEVAP2, and TSP1) as only these variables affect the hexane content (see Table 2). The ARD value for the reduced model is 0.008%. Using Equation (14) the response surface for this model was generated (see Figure 2).

Table 1 Plackett-Burman technique levels

		LEVELS	
CODE	**VARIABLE**	**-1**	**1**
V1	TCOND2	26.46	35.80
V2	PCOND1	0.26	0.36
V3	TDECANT	25.51	28.19
V4	PDECANT	0.18	0.42
V5	TEVAP1	53.34	72.16
V6	TEVAP2	88.00	132.00
V7	TSTP1	104.50	115.50
V8	NSTP1	4.00	6.00
V9	PEVAP1	0.39	0.73

Table 2 Plackett-Burman technique results

	HEXANE (Kgmol/hr)		
	Vap_Out	**Crude_oil**	**Purge**
SIGNIFICANT VARIABLES	VAR1	VAR1	VAR1
	VAR2	-	VAR2
	-	-	-
	-	-	-
	VAR5	-	VAR5
	-	VAR6	-
	-	VAR7	-
	-	-	-
	-	-	-

$$\text{Hexane Recovery} = -0.005T_{EVAP2}^2 + 0.013T_{EVAP2} + 0.0054\left(T_{EVAP2}\right)\left(T_{SP1}\right) - 0.0178T_{SP1} - 0.0047\left(T_{SP1}\right)\left(T_{TCOND2}\right) + 99.963 \quad (14)$$

3.2.3. Optimization

The optimization model of the solvent recovery process is represented by Equations (15)-(18). As stated before, the goal is to maximize the objective function

$$\textbf{Max} \quad \text{Objective Function} = \text{Hexane Recovery} \quad (15)$$

s.t.

$$26.46 \le T_{TCOND2}(°C) \le 35.80 \quad (16)$$

$$88.00 \le T_{EVAP2}(°C) \le 132.00 \quad (17)$$

$$104.50 \le T_{STP1}(°C) \le 115.50 \quad (18)$$

The optimal values of the design variables and the percentage of hexane recovered under the optimized condition are: $T_{\mathrm{TCOND2}} = 35.80°C$, $T_{\mathrm{EVAP2}} = 110.14°C$, $T_{\mathrm{STP1}} = 104.50°C$, and $\mathrm{Recovery} = 99.98\%$.

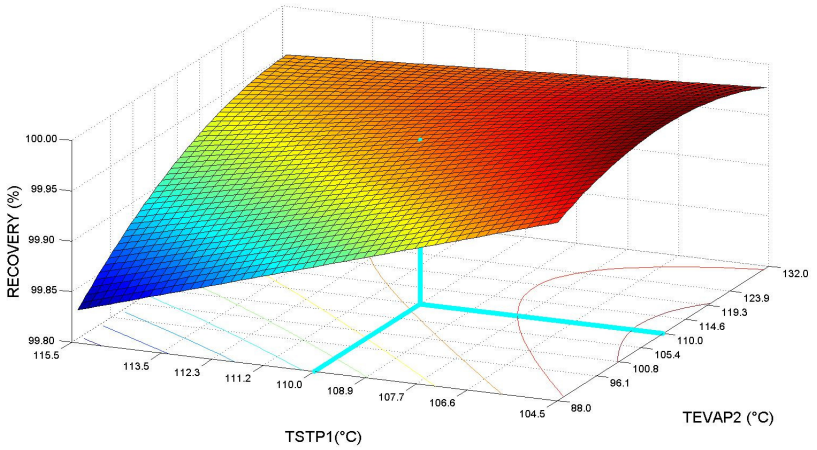

Figure 2 Hexane Recovery Surface Response

4. Conclusions

The predicted properties of the lipid compounds included in the database have been validated by comparing the simulation of the process and the plant data. The first set of operational variables considered in this work would have needed more than 500 simulations if the full factorial technique was used without any pre-analysis. Therefore, the Plackett-Burman method was helpful to significantly reduce the total number of simulations that needed to be performed. With the reduced set of design variables, the full factorial technique was applied and a reduced model correlating the selected design variables and the process parameters was obtained. The development of the reduced model allows the representation of the process in terms if the most important design variables. The response surface generated through the reduced model showed that the process is within the optimum zone, although improvements are possible. Therefore, optimal values of design variables where hexane recovery is maximum, was found. The results confirm that through a combination of property database and process modelling techniques, the operation and design of industrial lipid technologies can be optimized.

The Virtual Product-Process Design Laboratory for Design and Analysis of Formulations

Elisa Conte[a], Ricardo Morales-Rodriguez[a], Rafiqul Gani[a]

[a]*CAPEC, Department of Chemical & Biochemical Engineering, Technical University of Denmark, Soltofts Plads, Building 229, 2800 Lyngby, Denmark*

Abstract

The objective of this paper is to present a virtual laboratory for chemical product-process design (virtual PPD-lab) as a tool for the design and analysis of formulations. With the virtual PPD-lab, users can test their design ideas on model-based computer-aided tools before performing experiments to validate the designed product; also, manifold product and process alternatives matching *a priori* defined targets can be generated. The significance of this virtual laboratory is that the experimental effort in the development of new products and processes can be drastically reduced and attention can be focused on few alternatives; as a consequence, time and resources can be saved. This paper highlights a new feature of the virtual PPD-lab through which the design of formulations can be achieved. The application of this new feature in formulation design is illustrated through different case studies dealing with personal care products.

Keywords: Product Design, Mixture Design, Computer-Aided Formulation Design.

1. Overview of the Virtual Laboratory

In design of chemical products and the processes that can manufacture them, one first tries to find a candidate product that exhibits a certain desirable or targeted behavior and then tries to find a process that can manufacture it with the specified qualities. The candidate may be a single chemical, a mixture, or a formulation of active ingredients and additives. The common practice to develop these products is experiment-based trial and error approach, supplemented sometimes with model-based computer-aided tools to speed-up some of the steps. The virtual PPD-lab is an innovative and more effective approach to product and process design. It contains methods and tools to allow the modeling and simulation of the needed experimental scenarios. For this to work, the 'in-house' models need to be reliable and efficient and the architecture of the software needs to include the work-flows related to different product-process design problems. Also, interfaces for efficient data-flow between different tools need to be defined. The architecture has to be flexible to allow changes in work-flow, addition of new models and of new data for future extension of the application range.

From the virtual PPD-lab it is possible to access ICAS[1], an Integrated Computer Aided System consisting of a number of toolboxes that help to efficiently solve a wide range of problems. Some ICAS toolboxes can be launched as standalone applications for the virtual PPD-lab, such as CAPEC DataBase, the Computer Aided Molecular Design tool (ProCAMD), the Property Prediction tool (PropPred), and the Modeling Tool (MoT). These toolboxes can easily be updated with newer and more reliable models[2]. To guide users in solving specific product and process design problems, templates defining work- and data-flow for different types of design problems have been developed for the virtual

PPD-lab. Two design templates were available in its first version: design of polymeric microcapsules for the controlled release of active ingredients, and, design of pesticide formulations for plant uptake. A third template, which guides the user to design solvent based formulations, has now been added and is presented in this paper as a necessary tool in the design of formulated products.

2. Computer-Aided Formulations Design

Many chemicals-based products of everyday life such as sun lotions, shower creams, paints, insect repellents, and so on, are formulations. These formulations are consumer-oriented products, since they are directly used by the consumers and in order for them to be commercially successful products, they have to meet the consumer needs. These needs can be manifold: an insect repellent, for instance, has to give an effective protection against mosquito bites, to be long lasting, safe, easily applicable, stable, with a pleasant odor. In order to achieve all these different performance criteria, several chemicals have to be blended together, and this leads to formulations. Usually, three main categories of substances are involved: the Active Ingredient (AI), responsible for the activity of the final product (for an insect repellent, the activity is to be effective against mosquito); a solvent mixture; additives (dispersants, emulsifiers, wetting agents, usually less than 2% in volume) responsible for enhancing the end-use product properties. The solvent mixture has a central role in a formulation, since it is usually present in high concentrations and has the important functions of dissolving the AI and providing for some of the end-use product properties; therefore, a tool for designing solvent mixtures, has been developed and has been included in the virtual PPD-lab environment; the new tool is based on the MixD algorithm[3] and has been developed to design liquid mixtures.

In this paper, a methodology for the design of formulations is proposed, and it is shown in Figure 1. The first and most important task is the problem definition (Task 1), which consists of three sub-tasks. In Task 1.1 an understanding of the consumer needs has to be achieved. The consumer needs are the product performance criteria. In Task 1.2, the performance criteria have to be translated in terms of chemical properties (target properties); for instance, an insect repellent has to be long lasting and this performance criteria depends on the evaporation time T_{90}, which is a property that can be modelled and controlled during the design. Then, constraints on the target

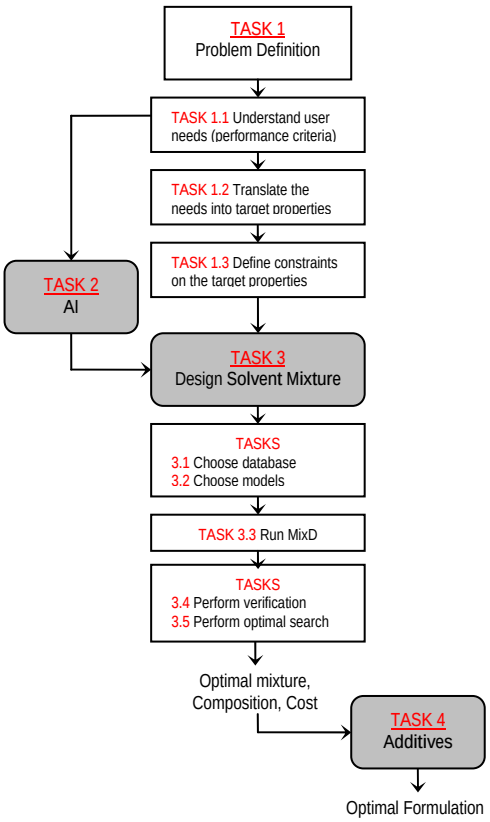

Figure 1. Formulation design methodology.

properties have to be settled in Task 1.3, in the form of lower and upper bounds. After Task 1, the desired activity of the product is known, therefore one or more Active Ingredients need to be chosen (Task 2). The AI affects all the design choices which will be taken in the next task, Task 3, the solvent mixture design. As stated above, the solvent mixture has two important functions: dissolving the AI (also supporting and enhancing its activity), and providing for specific end-use product properties. In order to ensure the AI solubility, at Task 3.1 an appropriate list of solvents needs to be chosen (for instance, if the AI is well known to be oil-soluble, the solvents considered in the database should all be miscible with oils); in addition, it is important to consider the solubility parameter of the mixture as a target property, since when two substances have similar values for the solubility parameters, they are also mutually soluble.
In Task 3.2 the property models with which the target properties have to be modelled are chosen. MixD is now launched (Task 3.3); results consist of all the single liquid phase binary mixtures matching the *a priori* defined constraints, their composition and cost. Task 3.4 involves the verification[3] of the designed mixtures, while Task 3.5 performs the optimal mixture search[3] according to a Performance Index PI.
Once the optimal mixture, its composition and cost have been calculated, the necessity of final additives is analyzed in Task 4. These additives are added in order to enhance the end-use properties of the product; in personal care products, for instance, perfumes or relieving/moisturizing agents can improve the cosmetic properties.

3. Case studies

The methodology developed for the design of formulations is highlighted through two case studies dealing with personal care products: the first formulation is an insect repellent (water-free and water-based products are presented), while the second one is a sunscreen lotion. The design of a paint formulation has previously been presented[3].

3.1. Insect repellent formulations

When consumers think about an insect repellent, they want a product which is effective against mosquito, long lasting, safe, compatible with other material, stable (it does not have to decompose in a relatively short time), and, finally, a product with good cosmetic properties, that is, nice odor and good skin feeling.
The traditionally used DEET-based products have been claimed[4] to be aggressive on surfaces like clothes, glasses, plastics, to show a high potential to irritate eyes, to be sticky and to posses an unpleasant odor. The insect repellent we are interested in aims to be a competitor of DEET-based products; the more recent picaridin has been shown to be far superior to DEET in terms of safety, toxicology, material compatibility and cosmetic properties[4], and it has therefore been chosen as the AI for our formulation.
The main product types available are alcohol-based liquids, emulsions, and sticks. For this case study it has been chosen to design a liquid solution based spray product.
Picaridin provides for the effectiveness of the product; the solvent mixture (including additives) which has to be designed has to guarantee that the final product will match all other consumer needs. The durability of the formulation depends on the evaporation rate of the solvent mixture, which corresponds to the parameter T_{90} (evaporation time: time required for 90% by weight of the mixture to evaporate); the safety can be related to the LC_{50} parameter (aqueous concentration causing 50% mortality in a fathead minnow population after 96 hours); material compatibility can be guaranteed by choosing non aggressive and non corrosive solvents; stability can be controlled by assuring that the solubility parameter of the mixture is close to that of the AI (δ_{AI} = 24.1 $MPa^{½}$), and verifying that the condition for one liquid phase has been satisfied (a step in the MixD

algorithm[3]). The chosen product aims to be a spray: the form of the formulation will be controlled with the mixture kinematic viscosity (v) and density (ρ); products with kinematic viscosity values lower than 75 cS are suitable for a spray formulation[5].
Picaridin shows high solubility in alcohols, and usually insect repellent products are alcohol-based; consequently, for this design, only alcohols (74 alcohols) are retrieved from the database. For modeling all the target properties linear mixing rules are sufficient, except for the evaporation time model[6], which employs the UNIFAC model.
The single phase solvent mixtures matching the target criteria are listed in Table 1 (ordered in terms of increasing cost, the PI). It has been decided not to verify the mixture properties calculated with the linear models, since alcohols are all polar and associating fluids, and mixtures of similar fluids usually do not show large contributions for the excess properties, that is, linear models are reliable.

Table 1. Mixtures suitable for alcohol-based insect repellent formulations. 'AllAl' stands for allyl alcohol. δ [MPa^{½}], v [cS], ρ [kg/l], LC_{50} [mol/l], T_{90} [s], Cost [$/kg].

Mixtures	x_1	δ	v	ρ	LC_{50}	T_{90}	**Cost**
methanol - 1-butanol	0.33	24.89	2.42	0.80	0.05	773	1.74
2,2,3-trimethyl-3-pentanol - AllAl	0.16	26.41	2.89	0.93	0.06	887	1.77
methanol - 2,2-dimethyl-1-butanol	0.55	26.33	2.60	0.84	0.05	805	1.78
methanol - 2-methyl-2-heptanol	0.70	26.96	2.85	0.82	0.06	1096	1.79
2-methyl-2-heptanol - AllAl	0.14	26.54	2.61	0.91	0.05	663	1.81
ethanol - 2,2-dimethyl-1-butanol	0.71	25.27	2.40	0.83	0.05	631	2.30
ethanol - 2,2,3-trimethyl-3-pentanol	0.79	25.34	2.90	0.85	0.05	1084	2.31
ethanol - 2-methyl-2-heptanol	0.82	25.47	2.52	0.82	0.05	755	2.40
methanol - 2-methyl-1-propanol	0.35	25.13	2.98	0.79	0.05	528	2.44
2,2-dimethyl-1-butanol - AllAl	0.23	26.26	2.51	0.91	0.05	598	2.75

If an optimization with respect to the cost is performed (but others or multiple performance index can also be used), the mixture methanol and 1-butanol is found to be the optimal mixture.
Usually, a fragrance is added to these products in order to cover the unpleasant odor of the AI (as in the case of DEET based repellents); picaridin does not have an unpleasant odor, but a pleasant scent could be an additional product quality; α and β-Santalol[7] are almost colorless, slightly viscous alcohols, rarely available separated. They are both soluble in alcohols and oils, so they are suitable for addition to the formulation just designed. A sweet, woody and tenacious scent makes them easily recognizable.
The formulation just designed is water-free, because picaridin has a very low solubility in water; but some commercially available products (Autan®, Bayer) are based on a water-alcohol mixture, therefore, a water-based formulation has also been designed; to ensure picaridin is highly soluble in the alcohol, it has been verified that the solubility parameter of the alcohol in the final mixtures is very close to that of picaridin.
Water is a polar and associating fluid like alcohols, and mixtures of similar fluids should be reliably described by linear models. Although, it is well know that aqueous solutions may exhibit unusual behavior; consequently, it has been decided to verify that the single phase liquid mixtures obtained with MixD indeed have the correct kinematic viscosity (using a more reliable model based on UNIFAC[8]); all mixtures were found to match the target viscosity and are reported in Table 2; these are all single liquid phase mixtures.

Table 2. Mixtures suitable for water-based insect repellent formulations. Units of measure are the same specified for Table 1.

Mixtures	x_1	δ	v	ρ	LC_{50}	T_{90}	**Cost**
2-propanol - water	0.24	42.00	1.31	0.87	0.52	661	0.92
ethanol - water	0.27	42.00	1.01	0.89	0.58	734	1.42
1-propanol - water	0.25	42.00	1.28	0.88	0.47	628	2.07

The presence of water in the formulations improves both the safety and the price. It is interesting to note that the mixture ethanol-water, with a composition of 27% (molar base) of ethanol corresponds to the one used in Autan® (29% of ethanol), but the design just performed reveals that it is not the cheapest alternative: 2-propanol with water (24% of 2-propanol) is the optimal solution with respect to the cost.

3.2. Sunscreen liquid formulations

The sun produces a wide range of electromagnetic radiation. Ultraviolet light is responsible for suntan and sunburn and increases the risk of skin damage. Sunscreens are cosmetic formulations that block UV rays. Consumers want a product which is effective against sunburns, prevents skin aging, is long lasting, is safe, has a good skin feeling and has a nice scent. Water resistant formulas are usually preferred; in addition, a spray product will be designed.

In order to have an effective protection against UV-A and UV-B rays, and prevention of skin aging, the active ingredients that may be used are many: UV-A and UV-B filters; antioxidants; insoluble pigments, since they are opaque to light so they provide a physical barrier for radiations. Since a waterproof formulation has to be designed, all chemicals involved have to be water insoluble; all the AIs chosen are oil-soluble substances. The AIs chosen are: avobenzone[9] and octyl salicylate[9] as UV-A and UV-B filters, respectively; α, β-carotene and vitamin A as antioxidants; titanium dioxide as an opacifying agent (it also acts like a thickener).

Since the performance criteria for a sunscreen are quite similar to those of an insect repellent (they both are personal care spray products), except for the activity, the target properties could be considered the same for these two products; therefore, similar constraints involving δ, v, ρ, LC_{50}, T_{90} are specified. A solvent mixture that can dissolve or disperse the AIs so that sedimentation is avoided and that can provide for the product end-use properties has to be designed; esters are largely used in personal care and in pharmaceutical applications for their interesting properties; they are oil-soluble substances so they perfectly fit the purpose of designing a waterproof product; in addition, they support the rapid and uniform spreading of the sensorially heavy UV filters. From the database, 97 esters has been retrieved, and they are employed in this case study. Considerations on the choice of the models are the same as in §3.1.

Table 3. Mixtures suitable for sunscreen formulations. 'MAcAl' and 'dimethprop-3-methbut' stand for methoxyacetaldehyde and dimethylpropyl 3-methylbutanoate. LC_{50} [mol/m^3].

Mixtures	x_1	δ	v	ρ	LC_{50}	T_{90}	**Cost**
MAcAl - 2,2-dimethylpropyl butanoate	0.89	18.95	0.53	0.83	3.63	1018	1.40
MAcAl - tert-butyl pentanoate	0.89	18.95	0.53	0.83	3.63	1018	1.40
MAcAl - isobutyl isopentanoate	0.89	18.93	0.48	0.83	3.65	879	1.40
MAcAl - 1,1-dimethprop-3-methbut.	0.91	18.91	0.52	0.83	3.86	847	1.41
MAcAl - 2,2- dimethprop-3-methbut.	0.91	18.92	0.53	0.83	3.80	940	1.41
MAcAl - isobutyl 3,3-dimethylbutanoate	0.91	18.92	0.53	0.83	3.80	940	1.41

The single phase mixtures matching the targets are listed in Table 3. Mixtures show very similar properties since methoxyacetaldehyde is always present in high concentrations and some of the second compounds in the mixtures are isomers with similar properties. Verification of the mixture properties calculated with the linear models is not necessary in this case, since esters are all polar and non-associating compounds, and their mixtures have negligible excess properties.
Since the costs of the designed mixtures are approximately the same, there is no reason to use the cost as the optimization criteria. The mixture suggested as the optimal is methoxyacetaldehyde and 1,1-dimethylpropyl 3-methylbutanoate, since it shows the highest LC_{50} value, which corresponds to the lowest toxicity value.
The necessity of additives can be now analyzed. Octocrylene can be used as a stabilizer; it also augments other UV absorption and improves their uniform skin coating[9]; it is an ester, therefore suitable for the formulation. Parabens are widely used as preservatives in the cosmetic and pharmaceutical industries; they prevent decomposition by microbial growth or by chemical changes. Also in sunscreens a fragrance can be added in order to enhance cosmetic properties; para-menth-3-yl phenylacetate[7] is a slightly viscous liquid with mild floral and extremely sweet and tenacious notes; iso-propyl salicylate[7] is an oily liquid, with a sweet ethereal herbaceous, yet quite tenacious scent with distinctly fruity character. They both are esters, therefore suitable for the formulation designed.

4. Conclusions and future work

The virtual PPD-lab has been introduced and the use of the resident models, methods and tools has been illustrated. A systematic methodology developed for formulation design has been highlighted through two case studies; this methodology employs the algorithm MixD which has been previously presented[3]. The significance of the PPD-lab is that the time and the effort in the development of formulated products can be drastically reduced. Two case studies dealing with personal care formulations have been shown. Future work is to enlarge the number and the complexity of products which can be designed and tested through the virtual PPD-lab.

Catalyst deactivation in reactive distillation

Rui M. Filipe[a], Henrique A. Matos[b] and Augusto Q. Novais[3]

Abstract

This work addresses the effect of catalyst deactivation in reactive distillation. A rigorous dynamic model developed in gPROMS is used to assess the impact in the column of the change in the catalyst activity. A model system of the olefin metathesis, wherein 2-pentene reacts to form 2-butene and 3-hexene was used to evaluate the column behavior and some output parameters, such as product purity and energy consumption. Strategies to overcome the deactivation are addressed through the use of different feed qualities and reboil ratios.

Keywords: reactive distillation, catalyst deactivation, modeling, simulation.

1. Introduction

Reactive distillation combines reaction and separation into one physical shell leading to potential economic and environmental gains (Malone and Doherty, 2000; Taylor and Krishna, 2000). This process intensification also leads to systems with significantly greener engineering attributes (Malone *et al.*, 2003).

In the authors' previous work, a framework combining feasible regions and optimization techniques has been developed for the design and multiobjective optimization of complex reactive distillation columns and reacting systems with variable degrees of relative volatilities (Filipe *et al.*, 2008b). This led to the consideration of reactive distillation columns with distributed feeds, many of them involving the combination of superheated and subcooled feeds. This combination was found to provide a source or a sink of heat at specified trays of the columns, which favors reaction while reducing the total reactive holdup requirements. It was also found that higher conversions could be obtained with the same reactive holdup by using these feed qualities outside the traditional range, which led to the consideration of using this technique to overcome catalyst deactivation during column operation.

Catalyst deactivation represents both an operational and a design problem, and has received little attention from the research community. Wang *et al.* (2003) address the control of reactive distillation columns when the production rate changes or the catalyst deactivates, and propose a control scheme able to maintain high purity and high conversion under such conditions. Catalyst deactivation reduces the reaction conversion achieved at each tray, which may limit column performance and product specifications. If deactivation is taken into account at the design stage, the operating conditions over the catalyst life-cycle may be assessed and preventive actions taken at an early stage.

In this work, the effects of the catalyst deactivation are investigated using the optimal design specifications obtained previously regarding feasibility and performance. Additionally, the manipulation of the feed quality and reboiler ratio were used to investigate how to tackle catalyst deactivation. With this aim, a rigorous dynamic model developed in gPROMS was used and applied to an illustrative example, i.e., the olefin metathesis system, wherein 2-pentene reacts to form 2-butene and 3-hexene.

2. Dynamic model

To investigate the dynamic behavior of a reactive distillation column with catalyst deactivation, a rigorous dynamic model has been developed using gPROMS language. The model was built modularly and allows for different number of trays and feeds, and feed qualities. Mass and energy balances are used at each element of the column. Pressure drop over the column is considered and calculated from the vapor flow speed and liquid height at each tray. Deviations from phase equilibrium can be accounted for through the built-in Murphree stage efficiency equation although they were neglected in this work. The physical properties are estimated using the gPROMS included package IPPFO for ideal systems. The coefficients used within IPPFO library were regressed using data from Aspen Plus. The reaction is considered to occur only on the liquid phase at specified trays of the column. Instead of specifying the catalyst amount, a reactive holdup amount is set on these trays.

Five control loops are used. The distillate and bottoms flowrate are manipulated to control reflux drum and reboiler levels, respectively. The pressure on the first tray is controlled through the energy removed in the condenser. The purity of the heavy component in the bottoms is controlled by manipulating the reboiler duty. Reflux ratio is manipulated to control the ratio D/F through the measurement of the distillate flow leaving the column. This control configuration allows the manipulation of the feed energy content by adjustment of the feed temperature while holding constant the reboil and D/F ratios, conditions previously established in the column design and optimization stages.

The design used in this work was obtained from the previously reported design and optimization framework (Filipe *et al.*, 2008a; Filipe *et al.*, 2008b) applied to the olefin metathesis system. All the RD column design details (Table 1) were transferred from the Aspen Plus simulations performed prior to gPROMS implementation. The availability of these design details from previous Aspen Plus runs proved valuable for the initialization of the simulations, which is always a major task when dealing with complex gPROMS models.

A good agreement between both models was achieved as shown in Table 1, with the largest difference being observed in the condenser and reboiler duty (6.6% and 5.5%). Nevertheless the temperatures at these sections of the column are the same in both models: 277 K and 341 K, respectively. Product purity refers to the amount of 2-butene in the distillate stream and 3-hexene in the bottoms stream, which is the same, due to the ratio D/F used (0.5) and the stoichiometry of the reaction.

3. Catalyst deactivation

Catalyst deactivation is simulated through the inclusion of a multiplication factor in the reaction rate constant, which varies between zero (no catalyst activity) and one (full catalyst activity). With this option, the variation of the catalyst activity during his life cycle can be simulated. For convenience, the variation of this factor will be mentioned as catalyst deactivation from now on.

Table 1. Case study details and results comparison

	Aspen	gPROMS
Number of stages	14	
Feed tray	8	
Reboil ratio	3.20	
Reflux ratio	6.02	6.22
Feed rate (mol/s)	5.56	
Condenser duty (kW)	-460.68	-491.27
Reboiler duty (kW)	256.58	270.57
Purity (mol %)	97.77	98.00
Reactive trays	6-10	
Reactive trays holdup (kmol)	4.97	
Feed temperature (K)	401 (q = -0.37)	
D/F	0.5	
Column diameter (m)	0.61	
Pressure at first tray (Pa)	101325	

A negative exponential decay over time is considered for catalyst activity, which decreases to 50% after 81 days of service (Figure 1). Purity is maintained above 90% until activity decreases below 33%, after which if falls steeply. Figure 2 shows that reboiler and condenser duties remain practically constant when catalyst deactivates, for the specified conditions (fixed reboil ratio and D/F).

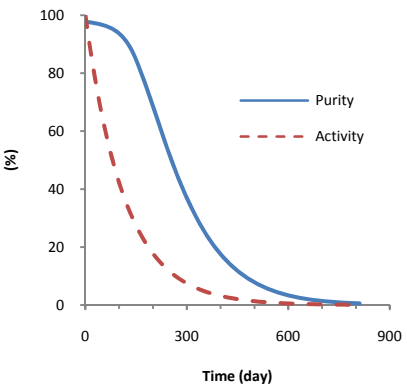

Figure 1. Variation of product purity and catalyst activity with time

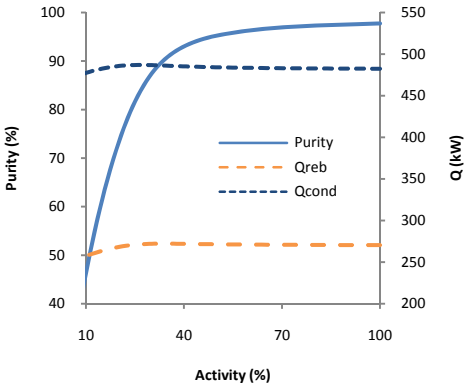

Figure 2. Variation of product purity, condenser and reboiler duty with catalyst activity

4. Influence of the feed quality

The use of feed qualities outside the traditional range has proved to be important in the reduction of the required total reactive holdup (Hoffmaster and Hauan, 2006; Filipe *et al.*, 2008b) and thus in attaining designs with lower cost indicator (Filipe *et al.*, 2009). Feed quality is related to the energy content of the feed through equation (1), where F is the feed flow, q the feed quality, and L_{n-1} and L_n the liquid entering and leaving the tray n, respectively.

$$L_n = L_{n-1} + q \cdot F \tag{1}$$

The direct specification of the feed quality is not possible in the model developed as it would involve the specification of the feed enthalpy, a dependent variable. In fact, the specification of the feed is made with values of temperature, pressure and composition which for a single component stream limit the conditions to below ($q > 1$) and above ($q < 0$) temperature's boiling point. A combination of two feeds with temperature above and below the boiling point with different contributions to the total flow could be used to obtain a mixed feed with quality comprised between $0 < q < 1$. Although possible, this strategy has not been used in this work. A variation of the feed temperature was used to assess the effect of the feed quality outside that range. The discontinuity observed in Figure 3 and 4 is due to the vaporization enthalpy contribution at the 2-pentene boiling point (310 K)

Figure 3 depicts the variation of the purity when the feed temperature varies between 273 K and 410 K. Although the gain obtained with the vaporized feed is notorious with an increase of over 2% in product purity, no apparent benefits result from overheating the vapor, as the change in product purity is marginal. On the contrary, changing the temperature under the boiling has a visible effect on purity.

Figure 4 shows that the reboiler duty remains practically unchanged, apart a small variation when the feed is vaporized. This behavior is justified by the fixed reboil ratio used and also to the feed being located near the middle of the column. The condenser has to remove all the extra energy added through the feed in order to maintain the constant pressure and, consequently, its duty increases with the feed temperature.

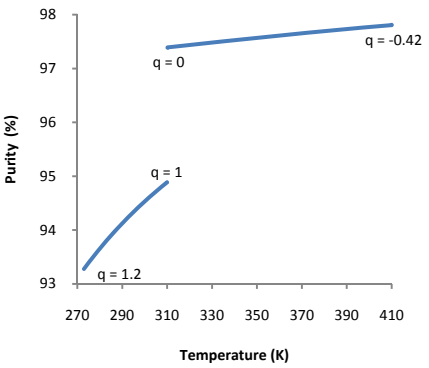

Figure 3. Variation of product purity with feed temperature

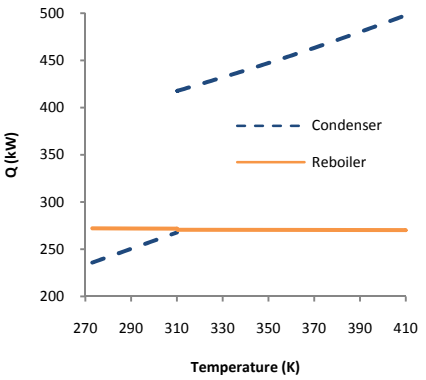

Figure 4. Variation of reboiler and condenser heat duty with feed temperature

The effect of the feed quality was also investigated for situations with partial deactivation of the catalyst. Figure 5 compares the evolution of the purity with the feed temperature for scenarios where catalyst has 50, 75 and 100% activity. The effect of feed temperature on purity is found to increase with the catalyst deactivation, highlighting the impact of the feed temperature on product purity, particularly for those situations where the catalyst has partially lost its activity. These results are also in accordance with the previous finding that reactive holdup can be reduced by manipulation of the feed quality (Hoffmaster and Hauan, 2006; Filipe *et al.*, 2008b). Furthermore, it explains the selection of the extreme feed quality values when minimizing the reactive holdup, if no other restriction is used (Filipe *et al.*, 2008b), since the purity will keep increasing.
Nevertheless, and for the present case, the effect of the feed quality is not strong enough to override large changes in catalyst activity, except when the feed boiling temperature is surpassed. The low reactive holdup associated with this design contributes to this difficulty, once it leaves a small margin to deal with further decreases in the already low catalyst availability. On-going research addresses optimal designs with higher reactive holdup, where a more marked influence of the feed quality is expected.

5. Influence of the reboil ratio

Since feed quality change is not enough to overcome the catalyst deactivation effect on the product purity, the effect of the manipulation of the reboil ratio was also studied. This variable provides an indirect way to vary the column energy supply. Temperature feed was adjusted from 401K to 320 K, with a decrease in purity of 0.54%, considered as not significant for the temperature differential involved.
Figure 6 depicts the effect of the reboiler ratio on product purity for different catalyst activities at a feed temperature of 320 K. The positive effect of increasing the reflux ratio is more noticeable for low activities. This effect has been previously noticed for the feed quality. The changes in the reboiler ratio are, therefore, found to be insufficient to achieve higher purities.

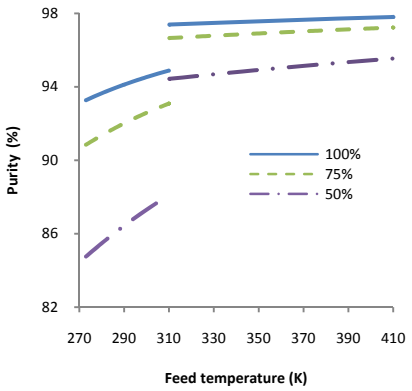

Figure 5. Variation of product purity with feed temperature for different catalyst activities

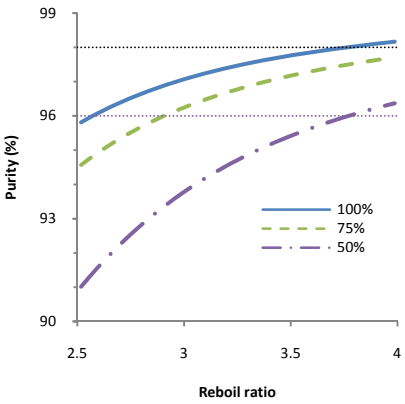

Figure 6. Variation of product purity with reboiler ratio for different catalyst activities (T_{feed} = 320 K)

However, the reboiler ratio can be used to handle catalyst deactivation for a larger period if a lower product purity specification is allowed. Figure 6 shows that 98% product purity can only be reached with full catalyst activity, within the reboiler ratios considered. Nevertheless, when a new specification of 96% is considered, all three scenarios of activity can reach the goal, although with different reboiler duties requirements, as seen in Table 2. An increase of 47% in reboiler duty is required when activity decays to 50%, indicating the need for a careful assessment of the right moment for catalyst replacement.

Table 2. Reboiler ratio and reboiler duty with catalyst activity for a 96% product purity specification

Catalyst activity (%)	Reboiler ratio	Reboiler duty (kW)
50	3.78	320.4
75	2.91	246.8
100	2.57	218.0

6. Conclusions and final remarks

This paper investigates the effect of catalyst deactivation in reactive distillation columns. A rigorous dynamic model developed in gPROMS is used to simulate the reduction of catalyst activity and assess its effects in column performance. The influence of the feed quality, i.e., the energy content of the feed, is also addressed and its positive effect verified. The impact of the feed was found to be small, especially for temperatures above the boiling temperature of the feed. Future work will investigate different design configurations for which a higher impact is expected.

Policies to overcome catalyst are also addressed with the manipulation of the reboiler ratio to enlarge the operation time of the column with the same catalyst load. It was found that for a lower product purity specification this can be an effective way to maintain product purity. Future work will focus on the optimization of the catalyst replacement policies, through the analysis of the costs involved.

Abstract

This paper presents an integrated framework comprising of two computer aided systems, ENVOP*Expert* and *SustainPro*, for sustainability assessment of chemical process plants. Analysis based on ENVOP*Expert* diagnoses the waste sources, identifies heuristic design alternatives and highlights trade-offs between the environmental and economic objectives. The Indicator model of *SustainPro* evaluates further these alternatives and screens them at an in-depth level through its sustainability metrics analysis to identify sustainable design alternatives. The application of the framework is illustrated through an ammonia production case study.

Keywords: sustainability; process design; intelligent system; metric-based analysis; indicators

1. Introduction

One of the major concerns facing the world today arises from increasing industrial activities that have lead to rapid depletion of non-renewable resources and increase in pollution. With the current emphasis on sustainability, much improvement is expected from the process industry to minimize raw material and energy usage and waste generation without compromising the economic value of the enterprise. Responding to these challenges requires a new insight into the characteristics of a sustainable system and a fundamental rethinking of how a production unit is to be designed, built and operated [1]. Various computational tools have been proposed to assist the process engineers in the decision-making to identify and evaluate sustainable design alternatives (those that improve a sub-set of sustainability metrics). An expert system, called ENVOP*Expert*, has been developed for waste minimization analysis of chemical processes [2]. Another tool is *SustainPro* which applies a set of mass and energy indicators for generation and evaluation of sustainable design alternatives [3]. In this paper, we propose an integrated framework comprising both of these for a comprehensive sustainability study. We illustrate the framework by solving a case study involving the ammonia production process based on synthesis gas route.

2. An Integrated Framework of ENVOP*Expert* and *SustainPro*

The two computer aided systems are integrated according to the framework shown in Figure 1. The procedure involves the following steps.

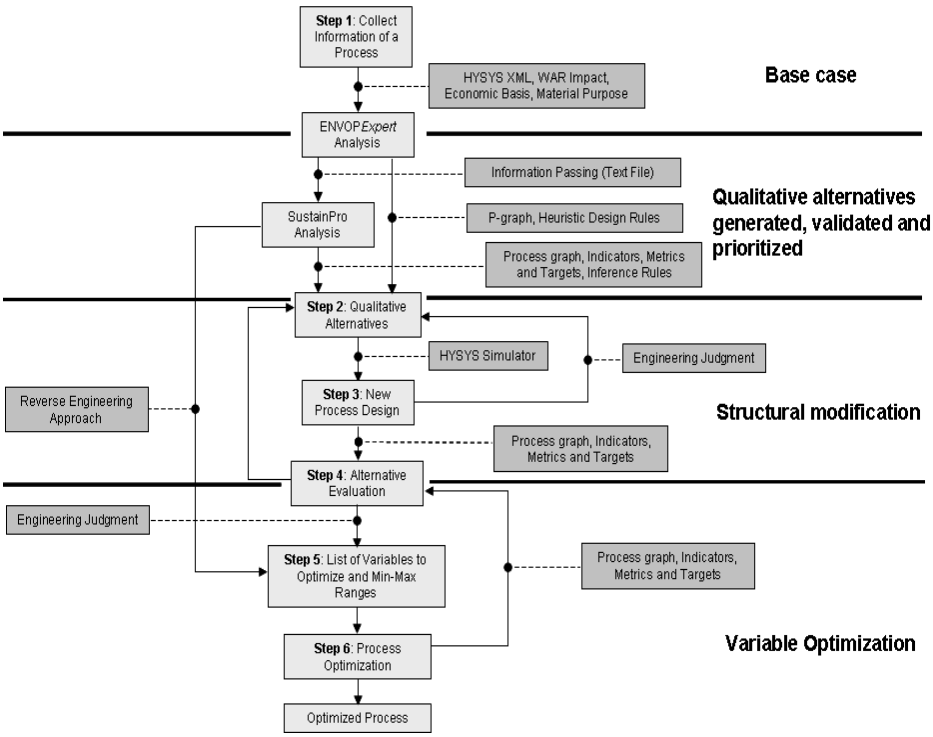

Figure 1: Integrated framework of ENVOP*Expert* and *SustainPro*

Step 1 − Process information representation

Information about the base process including the flowsheet, mass and energy balance information, material and stream classification, chemical environmental impact (WAR method) and economic data are specified. The flowsheet and material and energy balance information can be extracted from any process simulator (for example, HYSYS) in a XML format. This information is processed by ENVOP*Expert* to a suitable text file format decipherable by *SustainPro*.

Step 2 − Qualitative alternatives generation

Qualitative design modifications are identified by ENVOP*Expert* in two-step procedure: first a P-graph analysis is performed to identify the root cause of waste generation, next the hierarchical design method is used to generate heuristic alternatives. In parallel, a set of mass and energy indicators is calculated in *SustainPro* to identify the critical points in the process with respect to material accumulation and process economics. The most significant indicators are next identified using a sensitivity analysis method to propose design modifications (changes in design variables that improve targeted indicators, which in turn, improve a corresponding sub-set of sustainability metrics). The next step is to generate sustainable design alternatives (those that match the target indicators).Generally, the *SustainPro*'s alternatives are in-line with the suggestions of ENVOP*Expert*. However, the alternatives of *SustainPro* are more specific. For instance, using the material accumulation indicator, a high build-up of certain materials in a recycle stream can be diagnosed and hence suggestions for reducing this material

recycle can be proposed. Such specific suggestion cannot be inferred by ENVOP*Expert* as its analysis is purely based on qualitative reasoning.

Step 3 − New process design

The suggested new design alternatives are implemented to the base process. This is done by modifying the flowsheet of the simulator (HYSYS) followed by simulation of the new flowsheet to generate mass and energy balance data.

Step 4 − Alternative evaluation

The sustainability of the new alternatives are evaluated using *SustainPro*, where a set of sustainability and safety metrics, ([4] and [5]) are calculated and used for comparing the base and the new process. The indicators are again calculated for the new alternative to verify that the targets have been improved and the others have not been disturbed. This step is repeated for each design alternative.

Step 5 – Define the optimization problem

The new process alternative from step 4 is used as an initial estimate to further refine the search for the optimal sustainable process design. Thus, in this step, a list of process variables that can be manipulated is specified. *SustainPro* then screens these variables by prioritizing the ones that may significantly affect the process. The minimum and maximum ranges for optimizing these variables are also estimated based on reverse approach which uses sustainability metrics and other operational constraints.

Step 6 − Process variable optimization

Single or multi-objective optimization problem involving the selected process variables is solved. This is done through a simulation-optimization option within ENVOP*Expert*. The sustainability and safety metrics of the optimized process are calculated and compared with the base process using the *SustainPro* package.

3. Ammonia Production – Case Study

The developed framework has been applied on an ammonia production process based on synthesis gas route. The basic flowsheet of this case study is shown in Figure 2. A feed-gas stream containing nitrogen, hydrogen, and impurities (argon and methane) is passed through a multiple-bed catalytic reactor equipped with internal cooling. The products from the reactors are condensed using a coolant and then separated in a flash separator, where ammonia liquid is collected as product and the vapor mixture is recycled back to the reactors. To prevent the build-up of impurities within the process, a purge-gas stream is used, which becomes the only waste stream from this process. The step-by-step procedure employed to improve the sustainability of this process is described next.

Step 1 − Information of the process

Information about the process is obtained from a HYSYS simulation model. Here, a series of plug flow reactors is used as a representation model for the multi-bed reactor unit. The economic data, material and stream classifications and chemical environmental impacts are listed in Table 1.

Step 2 − Qualitative alternatives

Table 2 lists some of the qualitative suggestions identified by ENVOP*Expert* and *SustainPro*. As seen from the table, the two sets of alternatives complement each other.

Step 3 − New design process

Through the use of set of mass and energy *SustainPro* identified the critical paths in the process by performing a sensitivity analysis on the operational parameters related to these paths. This analysis pointed to the reduction of methane in the feed-gas stream as the most promising because of its effects on the targeted indicators. Following the

methodology described in [4], one possible separation process to reduce this impurity is to use a membrane. A specific membrane for this type of mixtures is reported in [5]. Hence, this alternative is implemented in the HYSYS model of the base process and a new simulation was carried out.

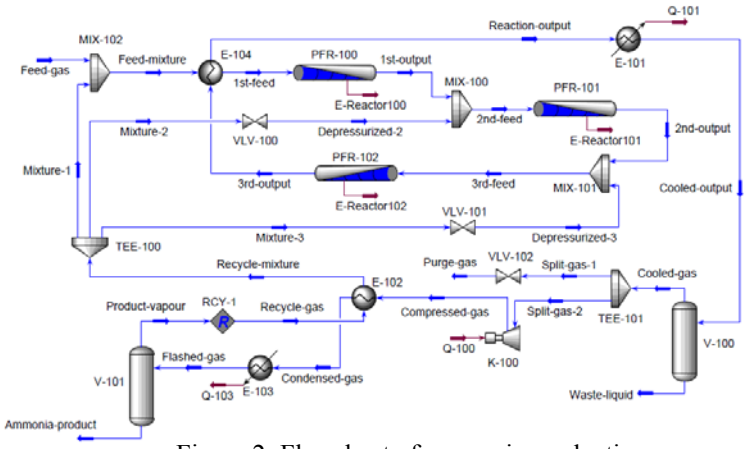

Figure 2: Flowsheet of ammonia production

Table 1: Ammonia process information

Stream	Status	Value/Cost	Material	Purpose	Env. Impact (mass basis)
Feed-gas	Feed	$ 0.13/kg	Methane	Impurity	0.0408
Purge-gas	Waste	$ 0.005/kg	Water	Utility	0.0
Ammonia-product	Product	$ 0.3/kg	Hydrogen	Raw material	0.0
Q-100	Energy	$ 0.07/kWh	Nitrogen	Raw material	0.0
Q-101	Energy	$ 0.006/kWh	Ammonia	Product	3.984
Q-103	Energy	$ 0.1/kWh	Argon	Impurity	0.0

Table 2: Qualitative alternatives

System	Qualitative Suggestions
ENVOP*Expert*	1) Prevent excessive feed of materials in the feed-gas stream, remove impurities (methane and argon) from feed-gas 2) Increase reactant conversion in the reactors 3) Recycle or recovery-recycle useful materials (nitrogen, hydrogen and ammonia) from purge-gas stream
SustainPro	1) Separate methane in the feed-gas stream before entering the process 2) Reduce the recycle of methane using a new separation process

Step 4 − Alternative evaluation

The new sustainability and safety metrics are calculated using the *SustainPro* and compared with the base case. Table 3 shows that the new alternative improves all the sustainability indicator metrics while maintaining the same safety index to their base values. Therefore, it is concluded that the new design is more sustainable.

Step 5 − -Define the optimization problem
Here, we consider feed and purge flowrates as the decision variables (i.e., two degree of freedoms). Using the reverse approach combined with sensitivity analysis, *SustainPro* verifies that manipulating the feed flowrate offers the best improvement to the process. The minimum and maximum range for the feed flowrate is found to be 1.22×10^5 < flowrate < 4×10^5 kg/h. This range is obtained by considering the maximum allowable profit loss (1%) and the constraints of the reactor performance.

Table 3: Selected sustainability metrics for the base and improved process

Metrics	Base	New	Improvement
Total Net Primary Energy Usage rate (GJ/y)	19336	18968	1.90%
% Total Net Primary Energy sourced from renewables	NA	NA	NA
Total Net Primary Energy Usage per Kg product (kJ/kg)	23.74	23.43	1.31%
Total Net Primary Energy Usage per unit value added (kJ/$)	0.012	0.011	8.33%
Total raw materials used per kg product (kg/kg)	1.23	1.21	1.63%
Total raw materials used per unit value added	6.14×10^{-4}	5.80×10^{-4}	5.54%
Fraction of raw materials recycled within company	NA	NA	NA
Net water consumed per unit mass of product (kg/kg)	7.92	7.76	2.02%
Net water consumed per unit value added	3.96×10^{-3}	3.71×10^{-3}	6.31%
WAR per kg product (impact/kg)	0.1541	0.1524	1.11%
Safety Index	26	26	0%
Profit ($/yr)	1.13×10^8	1.21×10^8	8.03%

Step 6 − Variables optimization
With the specified range, the feed flowrate is optimized using simulated annealing. A single objective problem involving profit maximization was considered. Table 4 lists the sustainability and safety metrics for two optimized process (local and global optima). As seen from the table, the profit reaches a maximum when operating near the maximum feed-gas flow. The other sustainability and safety metrics are also shown to be constant or slightly improved at this maximum flow. The only metric that becomes worse is the total energy used per year. However per kg of product, the energy consumption fraction is maintained constant, which means that to produce the same amount of product the energy spent is the same.

4. Conclusions

An integrated framework comprising of ENVOP*Expert* and *SustainPro* has been developed for sustainability analysis of chemical processes. The integrated analysis diagnoses the waste sources accurately, recommends design alternatives to improve the process and reduces the optimization space by screening the variables with most impact

on the process. The application of the framework has been illustrated on a continuous ammonia production process. Future work will include extension and application of the framework to cover batch process operations.

Table 4: Sustainability metrics for the optimized process

Metrics	Base	Local optima (Feed-gas = $3.55x10^5$ kg/h)	Global Optimal (Feed-gas = $3.97x10^5$ kg/h)
Total Net Primary Energy Usage rate (GJ/y)	19336	54792	61232
% Total Net Primary Energy sourced from renewables	NA	NA	NA
Total Net Primary Energy Usage per Kg product (kJ/kg)	23.74	23.44	23.42
Total Net Primary Energy Usage per unit value added (kJ/$)	0.012	0.011	0.011
Total raw materials used per kg product (kg/kg)	1.23	1.21	1.21
Total raw materials used per unit value added	$6.14x10^{-4}$	$5.81x10^{-4}$	$5.81x10^{-4}$
Fraction of raw materials recycled within company	NA	NA	NA
Net water consumed per unit mass of product (kg/kg)	7.92	7.76	7.76
Net water consumed per unit value added	$3.96x10^{-3}$	$3.70x10^{-3}$	$3.70x10^{-3}$
WAR per kg product (impact/kg)	0.1541	0.1524	0.1524
Safety Index	26	26	26
Profit ($/yr)	$1.13x10^8$	$3.51x10^8$	$3.93x10^8$

Automated design of batch water-allocation network

Hong-Guang Dong,[a] Li-Juan Li,[a] Rui-Jie Zhou[b]

[a]*School of Chemical Engineering, Dalian University of Technology, Dalian 116012, PRC*
[b]*Department of Economics, Dalian University of Technology, Dalian 116024, PRC*

Abstract

The mathematical technique presented in this work deals with one step design of batch water-allocation network (WAN), where batch schedules, water-reuse subsystems, and wastewater-treatment subsystems are all taken into account. In the first place, a flexible schedule model is introduced to represent the precedence order of all operations. Then, two novel superstructures incorporating all basic elements (i.e. states, tasks, equipment and time) are adopted to capture all production schemes and batch WAN configurations. Specifically, by adding novel components in the original superstructure, a series of optimal network structures with multistage splitting and mixing options which have never been contained within previous superstructure can be easily generated. Finally, a reliable optimization strategy, where deterministic and stochastic searching techniques are combined, is suggested to deal with the resulting mixed integer non-linear programming (MINLP) model. Two illustrative examples are presented to demonstrate the effectiveness of the proposed approach.

Keywords: superstructure, batch schedules, batch water-allocation network.

1. Introduction

In the past, the tasks of optimizing batch schedules, water reuse and wastewater treatment subsystems were performed individually. Cheng and Chang (2007) first developed an effective procedure to incorporate these three components into a single comprehensive model. However, in their study, the discrete-time model embedded was inflexible. In addition, not all possible network structures were included in their superstructure and this superstructure may fail to wholly reflect the essential relationship between units and corresponding operations. Finally, interactions between process schedules and batch WAN were not clearly addressed mathematically, which might result in solving the proposed model on a sequential basis. To circumvent these problems, Zhou et al. (2008) integrated batch schedules and WAN into a simultaneous optimization model based on continuous time representation and the modified state space concept. Although the relationship between operations and units was addressed by the STN (Kondili, 1993) and SEN (Smith, 1996) extensions of the original state space framework (Bagajewicz and Manousiouthakis, 1992), yet assigning a fixed mixer and splitter to each unit during the whole time horizon inevitability leads to the preclusion of a class of optimal network structures, where the best cost-optimal scheme may actually lies. Finally, the continuous time formulation is unable to express the sequence of all operations and the optimization strategy has to be executed interactively between different components. Given these shortages, there is therefore a need to develop a more comprehensive design method for optimizing the batch WANs.

2. Superstructures

2.1. Superstructure for batch production

A novel superstructure has been introduced in this work to represent batch productions. (see Figure 1). In the first place, all material states embedded in distribution network (DN block) are classified into three groups-raw materials, intermediate products and final products, all of which are further divided into two parts: material states to be consumed/sold and produced/bought. Then, through the process operators (OP block), each water-using unit is illustrated as a block with many sub-blocks which correspond to operations performed at certain event points. Finally, all material states and units are connected through streams to reflect the material flows and a reference axis of time is set to identify the starting and ending points of each operation.

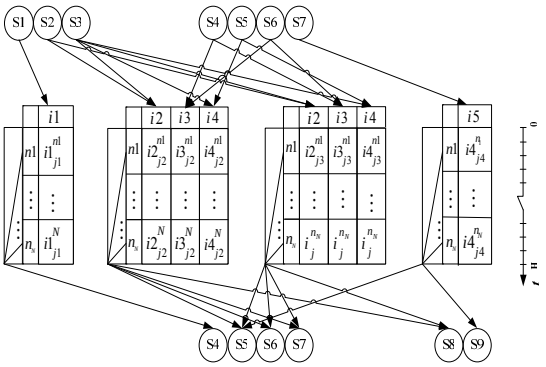

Figure.1. Superstructure for batch production.

2.2. Superstructure for WAN

In the previous superstructure (Zhou et al. 2008), the splitting and mixing can only take place in DN where a one-to-one correspondence between mixers/splitters and water users is ensured, and the possibilities that streams bypass water users without mass exchange were completely ruled out. As a result, streams can only mix once before entering the water user and in the same way they are only allowed to split once after leaving the water user. To overcome these deficiencies, we have developed a comprehensive STS superstructure for optimizing batch WAN.

The improved state-space superstructure for batch WAN is also viewed as two inter-connected blocks (see Figure 2). One is referred to as the distribution network (DN), in which all connections between units and junctions are embedded. The other is the so-called process operators (OP), which can be further divided into two sub-blocks, i.e., units and junctions. Detailed explanations of our superstructure are described in the sequel. In one time interval, while all input streams to DN are allowed to connect all exits leading to OP block or the environment, only inputs from junctions are allowed to split into several branches. Likewise, more than one input is allowed to mix before all junctions. Finally, in any time interval, splitting of inputs from units and mixing of streams before units are forbidden. As for OP, each unit is illustrated as a block with many sub-blocks which correspond to operations performed at certain event points. Furthermore, the optimal number and the corresponding assignment of units to junctions are not fixed a priori, thus being subjected to optimization process. It is worthy of note, that junctions can provide increased flexibility in formulating network

structures with multistage mixing/splitting options, which can never be captured by other frameworks. Specifically, all mixed inputs to DN block have further opportunities to match with other possible streams at all junctions and, if necessary, such looping procedure within junctions can be carried out for arbitrary times.

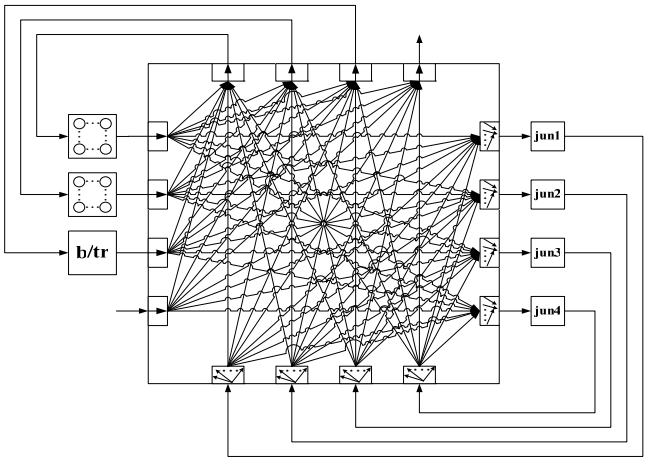

Figure.2. Superstructure for WAN.

3. Mathematical Model

Due to the length of this paper, only parts of the constraints are presented as follows.

3.1. Models for Batch schedules

3.1.1. Material balances

$$ST_{s,n} = ST_s^{in} - \sum_{i \in I_s} \rho_{s,i}^c \sum_{j \in J_i} B_{i,j,n} + r_{s,n} - d_{s,n} \qquad \forall s \in S, n \in N (n = n_1) \qquad (1)$$

$$ST_{s,n} = ST_{s,n-1} - \sum_{i \in I_s} \rho_{s,i}^c \sum_{j \in J_i} B_{i,j,n} + \sum_{i \in I_s} \rho_{s,i}^p \sum_{j \in J_i} B_{i,j,n} + r_{s,n} - d_{s,n} \qquad \forall s \in S, n \in N (n > n_1) \qquad (2)$$

$$ST_{s,N} = ST_s^{in} \qquad \forall s \in S \qquad (3)$$

Constraint 3 expresses that the amount of each state at the starting and ending times of any operation cycle should be kept identical.

3.1.2. Duration constraints

$$T_{i_j^n}^f = T_{i_j^n}^s + \alpha_{i,j} \cdot wv(i, n) + \beta_{i,j} \cdot b_{i_j^n} \qquad \forall i \in I,\ j \in J_i,\ n \in N \qquad (4)$$

$$B_{i_j^n} / B_{i,j} \le b_{i_j^n} < \left(B_{i_j^n} + B_{i,j} \right) / B_{i,j} \qquad \forall i \in I,\ j \in J_i,\ n \in N \qquad (5)$$

$$T_{i_j^n}^s = \chi_{i_j^n} \cdot \Delta t \qquad \forall i \in I,\ j \in J_i,\ n \in N \qquad (6)$$

$$T_{i_j^n}^f = \varphi_{i_j^n} \cdot \Delta t \qquad \forall i \in I,\ j \in J_i,\ n \in N \qquad (7)$$

where $\alpha_{i,j}$ and $\beta_{i,j}$ denote respectively the constant and each variable term of processing time; $B_{i,j}$ and $b_{i_j^n}$ are assumed, respectively, to be the amount processed at each variable term and the number of variable terms needed; Δt represents the length of each variable interval. Constraints 4-7 show that the processing time of each operation is made up of two parts: fixed term and variable terms.

3.2. Model for WAN

3.2.1. Mass and flow balances of each operation

$$f_{u,t}^{in} = \sum_{u' \in U} fs_{u',u,t} \qquad \forall u \in U, t \in T \qquad (8)$$

$$f_{u,t}^{in} \cdot c_{u,k,t}^{in} = \sum_{u' \in U} fs_{u',u,t} \cdot cs_{u',k,t} + \sum_{jun \in JUN} fs_{jun,u,t} \qquad \forall u \in U, k \in K, t \in T \qquad (9)$$

$$f_{u,t}^{out} = \sum_{u' \in U} fs_{u,u',t} + \sum_{jun \in JUN} fs_{u,jun,t} \qquad \forall u \in U, t \in T \qquad (10)$$

$$c_{u,k,t}^{out} = cs_{u,k,t} \qquad \forall u \in U, k \in K, t \in T \qquad (11)$$

3.2.2. Mass and flow balances of each unit

$$f_{j,t}^{in} = \sum_{i_j^n \in I_j^n} f_{i_j^n,t}^{in} \qquad \forall j \in J, t \in T \qquad (12)$$

$$f_{j,t}^{out} = \sum_{i_j^n \in I_j^n} f_{i_j^n,t}^{out} \qquad \forall j \in J, t \in T \qquad (13)$$

$$c_{j,k,t}^{in} = \sum_{i_j^n \in I_j^n} c_{i_j^n,k,t}^{in} \qquad \forall j \in J, k \in K, t \in T \qquad (14)$$

$$c_{j,k,t}^{out} = \sum_{i_j^n \in I_j^n} c_{i_j^n,k,t}^{out} \qquad \forall j \in J, k \in K, t \in T \qquad (15)$$

3.3. Objective function

The criterion of this study is the minimizing of cost, which can be expressed as follows:

$$Obj = (total\ income - purchasing\ cost) - (cost\ of\ fresh\ water + cost\ of\ water\ treatment + cost\ of\ buffer\ tanks + cost\ of\ junctions) \qquad (16)$$

4. Application examples

4.1. Example 1

The first example presented was originally solved simultaneously based on discrete-time representation by Cheng and Chang (2007). All the data used can be found in the original work. In a latter study, when network complexity was taken into account, Zhou et al. (2008) obtained a batch WAH design, of which the profit of batch production and cost of network were found to be 1366.7 and 388.31 units respectively. In the present study, On the basis of a time of horizon of 4 hr, the most appropriate production scheme and network configuration are presented in Figures 3. It can be found that while the schedule scheme is the same as the former study, the network configuration has subjected to a major transformation, as the multistage mixing/splitting stream from Jun1-Jun2 can be clearly identified. The corresponding cost of network in a production cycle can be reduced to 377.01 units, which represents a 3% improvement. This can be attributed to the fact that by allowing multistage mixing/splitting, the economic trade-off issues in WAH design can be carried out effectively. Specifically, the costs of freshwater supply, wastewater treatment, buffer tanks, junctions and pipelines were found to be 123.33, 201.68, 0 and 52 units respectively. As evident from the network structure, buffer tank is not embedded in the optimal network configuration and this can explain that buffer tanks are not necessary in some batch WAN if optimal production sequences and operating policies of water flows are adopted. Finally, it can be observed that the introduction of junctions allows a higher integration of the overall batch WAN, since only 2 junctions and 14 pipelines are needed.

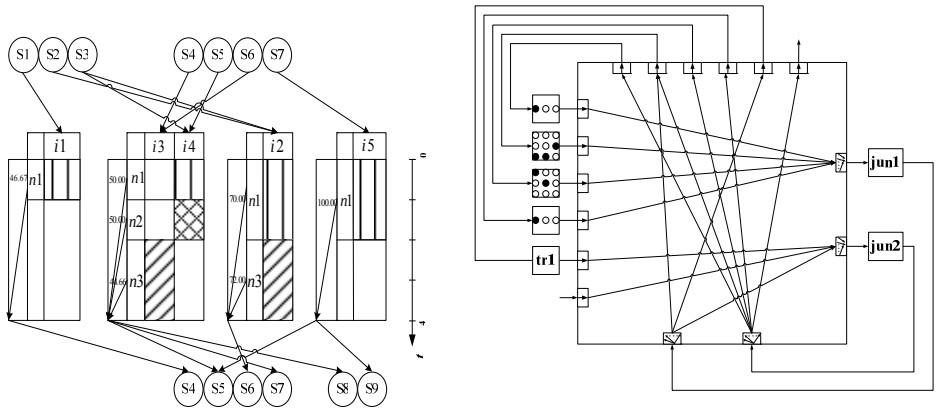

Figure.3. Optimal production scheme and network configuration for Case I

4.2. Example 2

In this example, multi-contaminant system design options are incorporated. Consider the process presented by Zhou et al. In this study, the removal ratios of tr1 and tr2 are chosen to be 0.9, 0.85, 0.9 and 0.95, 0.9, 0.95 respectively; the corresponding cost is set to 0.75 and 1 respectively. The resulting schedule results and its corresponding network are shown in Figure 4 and 5. Notice that the rewards of production and cost of network can be found to be 2108.57 and 333.95 units respectively. The freshwater and wastewater treatment costs in this case are 121.71 and 78.03 units respectively, while the costs of buffer tanks, junctions and pipelines are 67.21 and 67 units respectively. It can be concluded from this example that multistage mixing/splitting is indeed a desirable fashion and such methods enable cost-optimal designs of complex and large scale multi-contaminant systems.

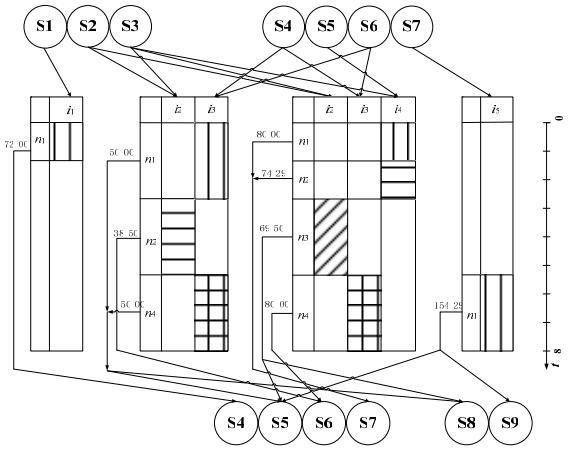

Figure.4. Optimal production scheme for Case II

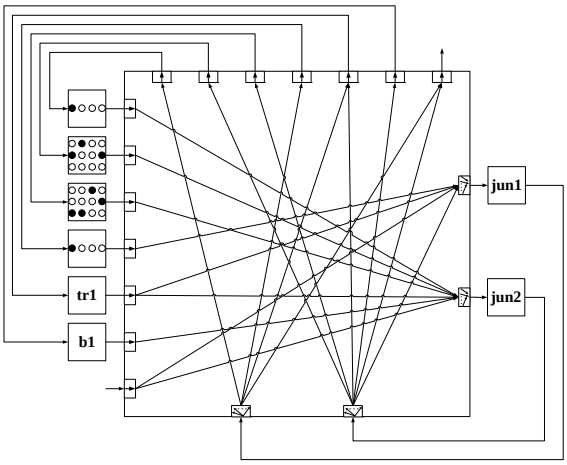

Figure.5. Optimal network configuration for Case II

5. Conclusions

Two superstructures have been presented in this study to formulate a MINLP model for one step design of batch WAN. The advantage of this approach is that not only all possible alternative network topologies can be captured, but the sequential order of all operations as well, can also be properly addressed. To ensure the quality and efficiency of the solutions, a hybrid optimization strategy integrating DICOPT and EA search techniques is developed. Finally, two examples dealt with single- and multi-contaminant WAN are presented to demonstrate the feasibility and effectiveness of the proposed automated design method.

Abstract
A design framework for the evaluation of multi-bed/multi-step Pressure Swing Adsorption (PSA) cycles for CO_2 capture is introduced. The framework addresses the need to have a compact and effective representation of cycle configurations. This is necessary for the development and implementation of a flowsheet design framework for the synthesis of PSA cycles. Cycle configurations can be assessed through multi-criteria optimisation to take into account the trade-offs between conflicting aspect of the performance. The effect of cycle configuration has been investigated for 5 multi-step/multi-bed PSA cycles from the literature.

Keywords: Pressure Swing Adsorption, CO_2 Capture, Design, Multi-objective Optimisation

1. Design of Pressure Swing Adsorption Cycles for CO_2 Capture

The need to stabilise levels of greenhouse gases in the atmosphere motivates the development of more efficient CO_2 capture technologies. Pressure swing adsorption (PSA) is the most efficient separation option for middle scale operations [1]. PSA is a cyclic separation process whose main steps are adsorption, at high pressure (P_H), and regeneration of the adsorbent, at low pressure (P_L). During the adsorption step, the less strongly (or less rapidly) adsorbed species pass through the bed and are collected as a *light* product (LP). The *heavy* product (HP) consists of the adsorbed species removed during desorption step. Besides these basic steps, others have been introduced to improve the efficiency of separation. Originally, PSA was designed to provide a high purity stream of the light product (LP). However, CO_2 is the most preferably adsorbed species on the majority of adsorbents used. Advances in adsorbent materials and more complex cycle configurations have proven PSA to be efficient and economically viable for CO_2 capture [2]. However, the design of complex PSA cycles still remains mainly an experimental effort due to the complexity of the simulation. The need to develop automated tools for the synthesis of optimal PSA cycles has been noted [3, 4].

This paper describes the key elements for the development of a multi-criteria design framework for the generation and evaluation of multi-bed/multi-step PSA/VSA (vacuum swing adsorption) cycles for CO_2 capture. Specifically, we describe a compact representation of cycle configurations and the use of multi-objective optimisation to compare the performance of different cycles. A compact representation of the cycles enables the use of the cycle configuration as a design variable in an optimisation framework. The ability of the framework to distinguish between different cycle configurations is demonstrated for 5 multi-bed/multi-step vacuum swing adsorption (VSA) cycles, originally proposed in [5]. A VSA cycle is a PSA cycle where the low pressure achieved during the blowdown step is sub-atmospheric to allow a deeper regeneration of the adsorbent.

2. Compact Cycle Representation

A flowsheet design framework should be able to identify the best cycle configuration to perform the desired separation according to the criteria specified by the designer. In Fig.1, a flowchart of the framework is proposed. The first step is the generation of a cycle configuration, c, which satisfies the requirements of the designer. Then, the set of operating conditions, $\overline{x}$, which affect the performance for this configuration is identified. Potential operating variables are cycle time, dimension of the beds, feed rates. The actual set of design variables, and their bounds, will depend on the configuration generated. Next, the operating variables, $\overline{x}$, for cycle c are optimised using multiple objectives. The performance of the configuration is then fed back to the generator of cycles and taken into account when generating new configurations. The information the designer needs to provide are the problem of interest (e.g. mixture of gas to be separated, the desired products) and the physical properties needed to simulate the operation. Furthermore, the designer has to give indication about the design space to be investigated, regarding both the relevant cycle configurations and the operative conditions.

The performance of the cycle, for instance in terms of purity and recovery, is defined by the cycle configuration (sequence **S** of steps used, bed interconnections) and operating variables, but not by the number of beds (N_B) used to perform the cycle: all the beds will undergo the given sequence of steps in an identical manner and at cyclic steady state they all behave in an identical way. On the other hand, the number of beds is necessary to evaluate capital and operating costs of the cycle. Once the sequence of steps **S** which provides the desired product has been chosen, the minimum number of beds needed can be determined using the method proposed by Smith and Westerberg in [3]. The cost and the number of beds, should be taken into account in the evaluation of cycle c.

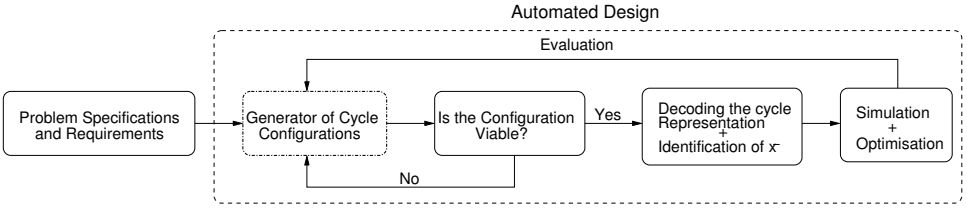

Figure 1: Diagram representing the elements of the ideal automated design framework for PSA cycles. According to the specification introduced by the designer, a viable cycle configuration, c, is generated. Then, the operating variables, $\overline{x}$, which determine the performance of c are identified. The optimal performance of c, in the design space defined by $\overline{x}$, is determined. The performance criteria are then fed back to the cycle generator so as to take it into account when generating new cycles.

The essential elements of a cycle configuration are the sequence **S** and the number (N_S) of steps, the number of products (N_P), the map of interconnections (between beds, feed tanks and product tanks), the pressure profile and the direction of the flow (co-current or counter-current with respect to the adsorption step) in each step.

One of the most critical decisions when developing automated design tools for a particular class of problems is the choice of the search space, or, equivalently, of a representation [6]. The representation needs to contain enough details for the implementation of the simulation and to cover the desired design space; it also has to be managed with ease by the generator of configurations. We propose, therefore, a compact mathematical representation of cycle configurations. The key idea motivating the representation we propose, is that, to synthesise new, more efficient, cycles, we need to think of cycles not as sequences of known steps (e.g. adsorption with feed, desorption etc.), but to allow for all the possible bed interconnections to be explored. Since all the beds undergo the same sequence, **S**, we can describe the whole cycle using only one bed. The connections implemented in a cycle can

be represented in a matrix, C, which has to specify, at each step, the step or steps from which the bed is receiving its inlet; it also has to indicate the steps from which products are withdrawn. Each row of C corresponds to the "receiving step", including product withdrawals, and each column to its "sources". The bed can act as a source at each step, as well as the feed tank. The number of receiving units (N_U) is therefore the summation of the number of steps (N_S) and the number of products (N_P). The number of sources (N_{in}) is given by the number of steps plus 1, the feed. If N_C is the maximum number of units feeding a single unit, the dimension of the matrix C will be $N_U \times N_C$. The representations of the cycles investigated in this paper are presented, in this compact form, in Table 1, together with the graphical visualisation of the cycles.

The matrix C describes in a compact way not only the map of interconnections in the cycle, but also information about pressure profiles and position of mixers and splitters. Once the output/input streams are specified, also the pressure profiles are: if both an input and an output streams are present, the pressure will remain constant (as in adsorption and desorption); if no input is fed to the bed, then the pressure will go down as the bed releases its content (as in the blowdown step); if no output stream leaves the bed, the pressure will increase during the step (as during pressurisation). The simulator can also deduce from the information in C when to include mixers (if a unit is receiving more than one stream, the incoming streams need to be mixed before been fed) and splitters (if a stream, or a mixture of streams, feeds more than one unit, splitters are needed). The information that the generator of configurations needs to produce are N_S, N_P, the matrix C and a vector $\overline{f}$ describing the direction of the flow for each step. $\overline{f}$ can be a vector of N_S elements, where $\overline{f}_i$ is 1 if the flow in step i is cocurrent with respect to the adsorption step, -1 otherwise.

The representation is general enough to represent all viable cycle configurations. However, it may also represent cycles that are not meaningful. It is therefore necessary for the designer to include some rules to guarantee that the configurations generated are viable. For example, one might want to specify the maximum number of steps that can be included, or that the first step must receive from the feed by imposing $C(1,1)$=-1, and the last step (N_S) is a pressurisation by specifying that $\forall(i,j) \in \{1,..,N_U\}\ C(i,j) \in \{-1,1,...N_S-1)\}$. Section 3.1 illustrates the rules used to generate the cycles investigated in this article. Besides imposing the viability of the cycles generated, the designer might want to indicate which interconnections need to be included in the cycles and which are to be avoided: for example, pressure equalization steps are usually not included when vacuum swing cycles are used, as no compression work has to be recovered. This can easily be imposed to the matrix C, requiring that a bed which is undergoing blowdown cannot feed a bed which is undergoing pressurisation. All of the above specification can be implemented by imposing some conditions on the generation of C. However, the rules should not be overspecifying the problem so that only known configurations are explored.

3. Case Study

We present the effect of cycle configuration on four 5-step cycles, originally proposed in [5], for the separation of CO_2 from flue gases. We also include the 4 bed/4-step cycle [2, 7]. All the cycles are illustrated in Table 1. The feed is a typical stack effluent at 575 K, containing 15% of CO_2, 75% N_2 and 10% of H_2O. The adsorbent used is a K-promoted hydrotalcite-like compounds (K-HTlcs). The performance of a PSA cycle needs to be evaluated when cyclic steady state has been reached. This can be evaluated via the dynamic simulation of the operation, which is described by a set of differential equations.

A simplified model, based on a series of CSTRs (continuous stirred tank reactors) for each bed, has been used to reduce computational costs involved with the simulation.

Table 1: Illustration of all the cycles investigated in this study. In the second column each cycle is represented in a compact way, in the second column the schematics of the cycle. The feed is indicated by "-1". The "-" entries in C corresponds to a 0 value in the actual computer representation.

A good correspondence between our results and those of the more rigorous model used by Reynolds et al. [2] has been achieved using 6 CSTRs to simulate each bed [7]. The linear driving force (LDF) model has been used to describe the mass transfer in the solid phase [1]. All data used are from [5]. The details of the equations used have been provided in [7]. We achieved a faster convergence to cyclic steady state (CSS) by adopting the unibed approach [8].

3.1. Generation of configurations

In all cycles investigated here, the first step is adsorption with the feed, and that the last step is a pressurisation with the light product. The second step is *heavy reflux*, where the bed, at high pressure, receives a purge gas, rich in the heavy component, to the feed end. This heavy purge gas can come from step *III*, which is always a blowdown, or from step *IV*. Step *IV* is a *light reflux* step, during which the CO_2 is desorbed at low pressure using the output stream of step *I* as purge gas. The output of step *II* can either be recycled at the feed end of step *I*, or might be taken as a part of the light product and used to pressurise step *V*. The heavy product is withdrawn from the step, between *III* and *IV*, which is not feeding step *II*. All the steps are counter-current with respect to the first.

4. Results

The design problem is the simultaneous optimisation of CO_2 recovery (R) and purity (P) of the product in the design space defined by the cycle time (t_c), the purge-to-feed ratio (γ), the pressure ratio ($\pi_T = P_H/P_L$) and the throughput of the operation (θ). θ is the amount of feed fed to one reactor during the adsorption step (step *I*) divided by the cycle time and the mass of adsorbent in one column. The analysis of the cycles has been made with respect to the same parameters used in [2, 5]. The value of the high pressure has been kept constant, $P_H = 1.36\,\text{atm}$. The only constraint is the evaluation of R and P at cyclic steady state, which is identified by dynamic simulation.

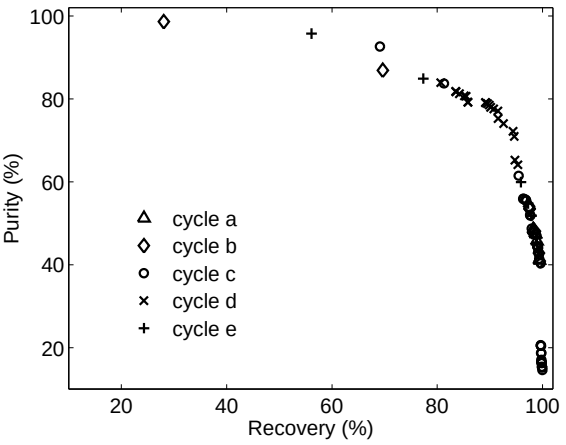

Figure 2: The Pareto set obtained by identifying the set of non-dominated points from the union of the individual Pareto sets obtained for each cycle configuration investigated. The aim is to show how the best performance of different cycles compare.

For the multi-objective optimisation, a multi-objective genetic algorithm (MOGA) has been used [7, 9]. The Pareto sets, consisting of equally optimal trade-offs between P and R, have been obtained using a crossover rate of 0.7, a mutation rate 0.01, a tournament size 2, a population size of 70, and 50 generations. Using a large population size, we obtain a reliable approximation to the Pareto front, as the statistical analysis carried out in [9] showed.

A Pareto set of each cycle configuration has been generated. The overall set of non-dominated points, from the set of points defined by the union of the individual Pareto sets, is shown in fig.2. The cycle configuration which corresponds to each point in this set is shown in the legend. Our results are qualitatively coherent with the conclusions by Reynolds et al. [5]. However, we did not replicate their

results quantitatively as our models differ. All 5-step configurations outperformed the 4-step cycle. The latter could only achieve a product purity of 60%. This result justifies the investigation of cycles where also the heavy recovery step is included (step *II* in all the 5-step cycles).

Comparing the results from cycle *b* and cycle *c*, the effect of the management of the output of the heavy recovery step (step *II*) can be deduced: when this is mixed with the output of step *I*, as in cycle *b*, lower recoveries are achieved as some CO_2 can be lost in the light product. The higher values of P have been achieved by cycle *b*. By comparing cycle *b* and cycle *c* on one side, and cycle *d* and cycle *e* on the other, we can understand the effect of the different arrangements for the input to step *II* and the heavy product. When the purge for the heavy recovery step comes from the blowdown (as in cycle *b* and cycle *c*), higher purity and higher recoveries can be achieved, as it becomes evident looking at both extremes of the Pareto set. However, the Pareto set suggests that the best trade-offs between P and R are achieved by cycle *d*, which dominates the region where the Pareto set bends. This analysis would encourage the cycle-generator in the design framework to propose new cycles which keep the characteristics of cycle *d* and cycle *b*, maintaining what they have in common (input to step *I* and *II*), and proposing intermediate arrangements of the input to step *II* and the heavy product, in which the two cycles differ.

5. Conclusion

A multi-criteria design framework for the generation and evaluation of multi-bed/multi-step PSA cycles for CO_2 capture is proposed. A compact representation of the cycles has been introduced, a necessary component for the development of the flowsheet design framework. The representation has been illustrated through the presentation of 5 multi-step/multi-bed cycles. These 5 cycles have been solved using a multi-objective optimisation tool. An overall Pareto set has been generated which allows us to understand the effect of different cycle configurations as well as to gain insight on how to improve the performance by manipulating the configuration.

Ethylene Separation by Feed-Splitting from Light Gases

Daniel Salerno[a], Harvey Arellano-Garcia[a], Günter Wozny[a]

[a] *Chair of Process Dynamics and Operations, Sekr, KWT-9, Berlin Institute of Technology, Strasse des 17 Juni135, D-10623, Berlin, Germany*

Abstract

Separation of ethylene from light gas mixture is one of the most energy intensive separations in petrochemical processes, which uses distillation columns up to 100 m tall and containing over 100 trays due the very small differences in the relative volatilities and very large reflux ratios and also due to the need for sub-ambient temperatures. In recognition of these costs, several attempts have been made in the past to develop processes with less energy and equipment costs. In distillation columns with condenser temperatures significantly below room temperature, such as in ethylene separation towers, it is essential to minimize the expensive energy requirements of the refrigeration cycle that produces the tower reflux. In this work, a solution has been found by expanding the gaseous distillate to decrease its temperature. Moreover, additional solutions applied to conventional ethylene fractionation columns have been implemented here in order to study this behavior. In this contribution, an outlet stream of an Oxidative Coupling of Methane (OCM) reactor, which has been previously stripped of its CO_2 content, is also introduced in a demethanizer tower to remove almost all of its CH_4 content before entering the ethylene fractionating column. Then, it is cooled exchanging its heat with the distillate stream of the ethylene tower, warming the distillate. The main goal is to reduce the condenser heat duty. This objective is achieved reducing a significant amount of heat required by the condenser, maintaining the mandatory product purity. Due to this improvement, it was also possible to reduce the reboiler heat in almost the same percentage amount that is achieved with the condenser. In addition, the reflux of ethylene column decreases. The sensitivity analysis and the corresponding simulations results will be discussed in order to show the efficiency of the presented approach. These results have also been used for the design of the pilot plant which is now being built at our department. The final design for the OCM process will also be presented.

Keywords: distillation, ethylene separation, energy saving, process simulation.

1. Introduction

Due to the large natural gas reserves worldwide, methane appears to be the cheapest and most available carbon source for the gas-based petrochemical industry. The development of a simple and commercially advantageous process for the direct conversion of natural gas to more easily transportable products was desired. Catalytic reaction for the direct conversion of natural gas to ethane and ethylene offered a new route for ethylene production. Among the numerous attempts for direct conversion, the oxidative coupling of methane (OCM) to C_2 hydrocarbons still remains one of the potential routes.[1-2] Regardless of the technology used in the production of ethylene, the process that follows its production is to separate the reaction products.

Distillation is by far the most common separation technique in the chemical process industry accounting for 90% to 95% of the separations.[3] Distillation columns are a major energy user in a petrochemical plants, and therefore, it is necessary to save as much as possible the energy demand for this towers, specially the heat expenses used in condensers and reboilers, because of the evaporation steps involved. Typically, more than half of the process heat distributed to plant operations ends up in the reboilers of distillation columns. By this, high-level energy is fed at the base of the column and about the same amount of energy is released at the top, unfortunately at a much lower temperature level. The difference between the two Gibbs energies can be seen as the necessary energy investment to reverse the mixing entropy and to separate the components of a given feed by a distillation process.[4] To find a solution to this problem some researchers have proposed alternatives focused on the feed-splitting concept.[5] In the conventional distillation operation for ethylene-ethane separation, as typified in Figure 1, low-temperature distillation column has been the preferred technology for several decades. However, this binary separation process consumes about 36 percent of the refrigeration energy required in, for example, an ethylene plant.[6]

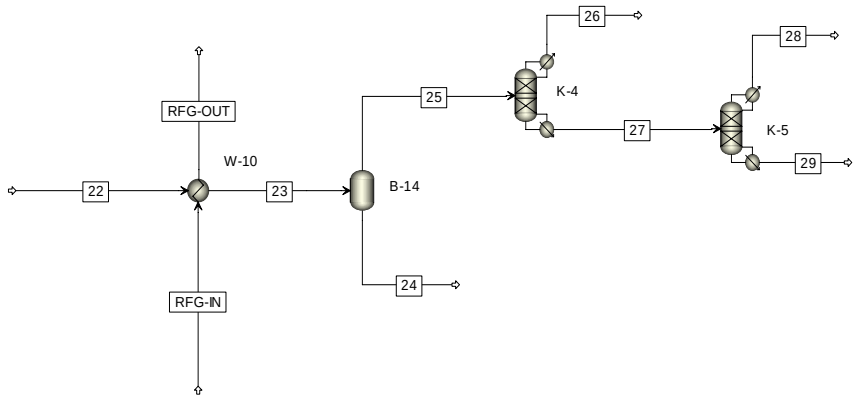

Figure 1 Conventional Ethylene Separation System

The C_2 splitter is commonly operated at high-pressure, utilizing closed-cycle propylene refrigeration, which is incorporated with the refrigeration systems serving other parts of the plant. The desired objectives for any ethylene separation process are to obtain a high-purity ethylene product combined with a high percentage recovery of the ethylene. The conventional distillation technology can accomplish both of these objectives. The main goal of this study is to reduce de amount of energy required by the reboiler in the ethylene-ethane column by partially precooling the feed(s) by the distillate, using a scheme symmetrical to that employed for warm columns.

2. Brief description of the OCM process

The complete process consists of three main sections: reaction, purification and separation section. Due to novel process design strategies, the downstream alternatives will also improve the reaction part and the catalyst design as well by means of for instance maximum carbon dioxide concentration for the reaction product. Figure 2 shows the flowsheet for this process.

2.1. Reaction section

The reactor is continuously fed with natural gas and oxygen. The feed gas is preheated to 700 °C and will catalytic partial oxidized at pressure of 0.5 MPa. The Reactor is jacked cooled to operating temperature of 750 ° C. The exothermic reaction heat has to be removed while steam is produced. The reaction products are compressed in a multi-compaction section to 3.5 MPa and cooled down to 40 °C later on. This stream is fed to the following purification section.

2.2. Purification section

In this section the carbon dioxide is removed by an amine scrubber and the following sodium hydroxide scrubber. The first scrubber is based on an absorption process with mono ethanolamine solutions (MEA) as detergents. The concentration of carbon dioxide is reduced from approximately 60 mol% to 10 mol% in this section. In the next following scrubber the carbon dioxide will be removed completely.

2.3. Separation section

This section consists of two cryogenic distillation columns. The first one is the demethanizer and the unconsumed methane is separated from the product stream. The product stream consists of ethane and ethylene that is separated in the deethanizer. The heat requirement Q of a single rectification column can be minimized best by effective heat exchange between the warm products and the cold feed, and also by efficient insulation of the column. Furthermore, the operational reflux ratio R should be kept as small as possible; optimum ratios are in the range of $R = 1.05 - 1.1\ R\text{min}$.[7] Soave has shown that in a cold tower, if the enthalpy of the feed is decreased by precooling with the distillate, the final result is a decrease in the condenser and reboiler duties; his study was applied to a demethanizer column of a "cold box" of an ethylene plant. In the present work the feed-splitting principle to an ethylene-ethane distillation tower is applied, using the steady-state Aspen Plus® simulation tool for the calculation and study of this ethylene column.

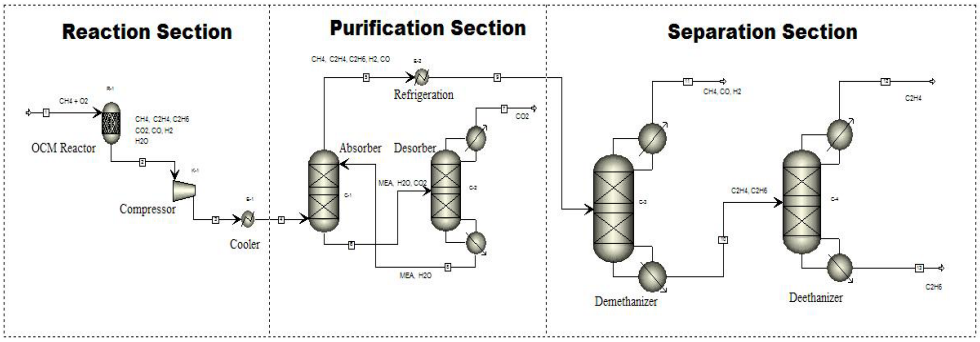

Figure 2 Flowsheet of the OCM Process

3. Simulation models

The first simulation model had the same schematic shown in figure 1. The data on the feed to the demethanizer column are reported in Table 1. Starting point is the outlet stream of an OCM reactor, in which all the contents of CO_2 are removed, introduced in a demethanizer tower to remove most of its CH_4 content before entering to the ethylene-ethane fractionating column. Both columns were modeled using rate-based calculations. With this approach, mass and heat transfer between the phases flowing each other is

assumed, based on the two-film theory (AspenONE Process Engineering webinar, 2008). Three alternative solutions of feed configurations are studied, and each one has to guarantee a distillate with at least 95% weight of ethylene.

Table 1 Demethanizer Column Feed

Property	Value	Flow rate (kg/hr)	
T (°C)	-23.000	H_2	9.870
P (bar)	32.000	CO	35.160
F (kg/hr)	442.319	CH_4	330.010
		C_2H_4	51.040
		C_2H_6	16.220
		H_2O	0.019

In order to reduce the condenser and reboiler duty different solutions of feed configuration to the ethylene-ethane column were proposed for improving its performance with the feed-splitting technique. In the first one (Figure 3) the feed is pre-cooled with the cool stream from the condenser, were a warmer distillate is obtained. The feed temperature to the ethylene-ethane column decreased, the minimum reflux ratio and the condenser duty also decreases.

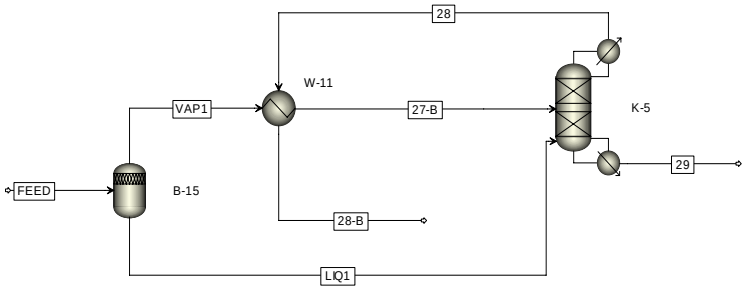

Figure 3 Alternative 1 for the Ethylene-Ethane Column

In the second one (Figure 4), part of the feed to the ethylene-ethane column is flashed, at constant pressure lowering its temperature, and consequently vaporizing certain amount of the stream. The vapor phase goes to the heat exchanger, decreasing its temperature a little more, and then is adiabatically flashed again to generate a second liquid stream which feeds the column K-5.

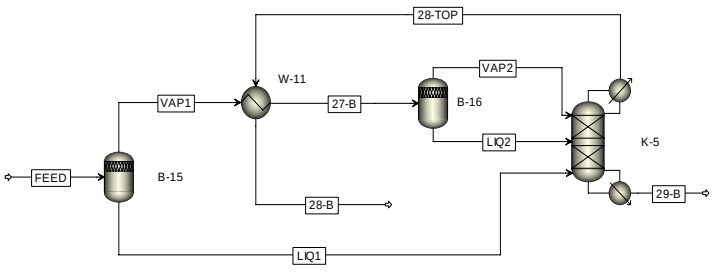

Figure 4 Alternative 2 for the Ethylene-Ethane Column

In the last alternative (Figure 5) only a fraction of the vapor phase is precooled. This fraction has to be determined by sensitivity analysis, making sure to maintain the quality specifications of the desired ethylene product at the top of this column.

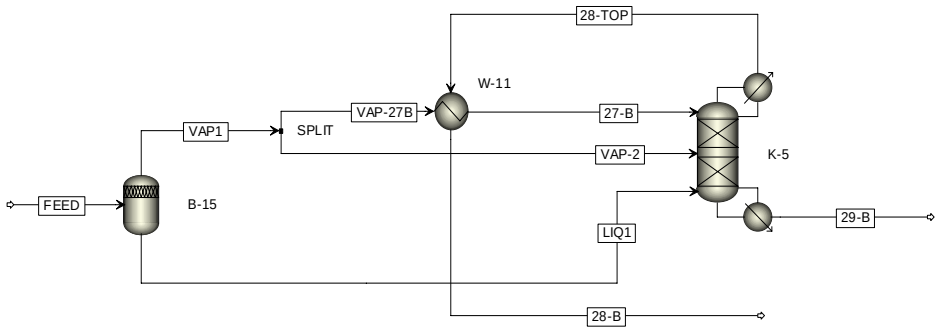

Figure 5 Alternative 3 for the Ethylene-Ethane Column

In all three cases the liquid phase obtained from the first flash is fed directly to the column, taking into account that this phase has a flow rate that is too low for good heat-exchange performance with the distillate. Also with these three studied configurations it was necessary to find the best feed trays. This can be done by changing the position of each feed stream one at a time. For all the simulations of the precooler the hot/cold outlet temperature approach was also kept constant.

4. Results and Discussions

To properly evaluate the simulation results the comparisons were made with the conventional separation ethylene-ethane column (K-5 from figure 1). Table 2 shows the duty values for condenser, reboiler, and flow rate of ethylene at the top of this column. Table 3 shows the ethylene recovery results for all the four cases studied.

Table 2 Ethylene-Ethane Column Results

Case Studied	Heat Duty (kW)		C_2H_4 flow (kg/hr)
	Condenser	Reboiler	
Conventional	-127.962	131.523	47.763
Alternative 1	-96.647	100.528	48.401
Alternative 2	-96.262	95.702	49.637
Alternative 3	-96.630	96.084	48.455

Table 3 Ethylene Recovery Results

Case Studied	Ethylene Flow (kg/h)		
	Total Column Feed	Top	Recovery
Conventional	50.266	47.763	0.9502
Alternative 1	50.464	48.401	0.9591
Alternative 2	50.463	49.637	0.9836
Alternative 3	50.464	48.455	0.9602

Comparing the conventional and the alternative 1 case, there is a substantial decrease in the condenser and boiler duties, around 30%, while at the same time the C_2H_4 product increases. Further improvements, alternative 2, lead to a greater ethylene recovery, small decrease in condenser duty and more substantial decrease in the reboiler duty (around 5%). When applying the feed-splitting concept to the ethylene-ethane column (K-5), both the condenser duty and the reboiler duty decrease under the same operating conditions (pressure, number of theoretical stages of the column, internals type, feed flow rate and composition). It can be observed that the condenser values decreases with each improved alternative, until a further splitting of the vapor phase can't be reached. In alternative 3, the 93.4% of the feed to the column was flashed into vapor phase being subjected to precooling. Comparing the results shown in Table 3 we can see the improvement in the flow rate of ethylene product at the top of the column K-5, therefore, alternative 2 shows the best performance in case of ethylene recovery.

5. Conclusions

The goal of significantly reduce the heat duty required by the condenser has been achieved by almost 25% and simultaneously has been reduced (27.2%) the amount of heat duty required by the reboiler. If the flow to the W-11 heat exchanger is not divided, there will be an increase of the ethylene recovery at the top of the K-5 tower. With this feed-splitting concept 98% of the initially ethylene can be recovered. Considering the data reported in Table 2, the advantages of applying the feed-splitting concept in a pilot plant is highly profitable, in order to save as much energy as possibly and reduce the expenses and optimizing resources. The sensitivity analysis and the corresponding simulations results show the efficiency of the presented approach. These results will be used also for the design of the pilot plant which is now being built at our department using the results of these simulation specifications.

Abstract

In the present study, we propose an optimization model for the minimization of capital and operating costs in a supercritical methanol biodiesel plant, considering alternative process schemes together with the convenience or not to use a cosolvent in the chemical reaction. A rigorous process simulation model, based on a group contribution equation of state is integrated with a successive quadratic programming algorithm to solve the nonlinear problem. Optimization results show that noncatalytic biodiesel production with supercritical methanol can be economically competitive with conventional catalyzed production.

Keywords: biodiesel, supercritical, transesterification, optimization.

1. Introduction

Biodiesel is comprised of esters of short chain alcohols made from renewable biological sources, such as vegetable oils, and it can be used as an alternative diesel fuel. Biodiesel can considerably reduce emissions, it is biodegradable and nontoxic. However, raw material and production costs are the main concern for commercialization of this product. Most of the conventional methods for biodiesel production use a basic or acid catalyst (Freedman et al., 1984, Fukuda et al., 2001, Lotero et al., 2005) and more recently, enzimes (Watanabe et al., 2000; Varma and Madras, 2007). While conventional catalytic transesterification of oils gives several byproducts, the single phase supercritical transesterification takes place at high pressures and temperature, not requiring the use of a catalyst. This feature makes the process not sensitive to water and free fatty acid content in the feed, avoiding the need for a pre-treatment step (Kusdiana and Saka, 2004; Cao et al., 2005) and additional separation steps downstream the reactor. Furthermore, free fatty acids in the feed oil are esterified simultaneously. Reaction time takes seconds to minutes in supercritical processes while catalyzed transesterification takes minutes to hours. The absence of pretreatment, soap removal and catalyst removal can significantly reduce the capital cost of a biodiesel plant. However, the need for high pressures and temperatures can be associated to high operating costs for the supercritical process. Therefore, development of reliable simulation and optimization models is required for the design of economically feasible supercritical biodiesel production processes.

In this work, we develop an optimization model for the minimization of capital and operating costs in a supercritical methanol biodiesel plant, based on rigorous process models, nonlinear programming techniques and thermodynamic predictions with a Group Contribution Equation of State with Association (Gross., 1996; Ferreira et al., 2004). Thermodynamic predictions have in turn been checked with available

experimental equilibrium data from the literature and data obtained in our group laboratory (Hegel et al., 2007). We have formulated a nonlinear programming (NLP) problem for an 80,000 ton/y biodiesel plant, using soybean oil and methanol as raw materials. The model allows exploring different plant capacities and alternative productions schemes by solving different NLPs, together with the convenience of including or not a co-solvent in the chemical reaction. Numerical results confirm that non-catalytic biodiesel production with supercritical methanol is economically competitive with conventional catalyzed production.

2. Thermodynamic modeling of supercritical soybean oil transesterification

Thermodynamic modeling of phase equilibrium of the reactants and reaction products in the two phase region and the determination of the homogeneous region are required for a reliable reactor design. Furthermore, the design of the downstream separation train requires the accurate prediction of the distribution of components between phases in the heterogeneous region (Espinosa et al., 2007, Diaz et al., 2008).

Binary and ternary systems including reactants and reaction products and water have been studied at different operating conditions. Binary interaction parameters have been taken from the literature (Espinosa et al. 2000; Ferreira et al., 2004; Andreatta et al., 2008). Figure 1 shows a good agreement between the Group Contribution Equation of State (GCA-EoS) estimations when compared to experimental data on LLE of the ternary methanol + methyl oleate + glycerol by Negi et al. (2006) at 333 K and atmospheric pressure. Reliable phase equilibria predictions of this mixture are especially important to identify operating conditions in the first separator that assure high recovery and purity of methanol in the vapor phase. Our study concludes that three phases in equilibrium (two liquid phases and one vapor phase) are necessary in order to obtain methanol rich vapor phase while glycerol and methyl esters remain in the liquid phases. The existence of two liquid phases in the first separator has been impose as a restriction in the mathematical model.

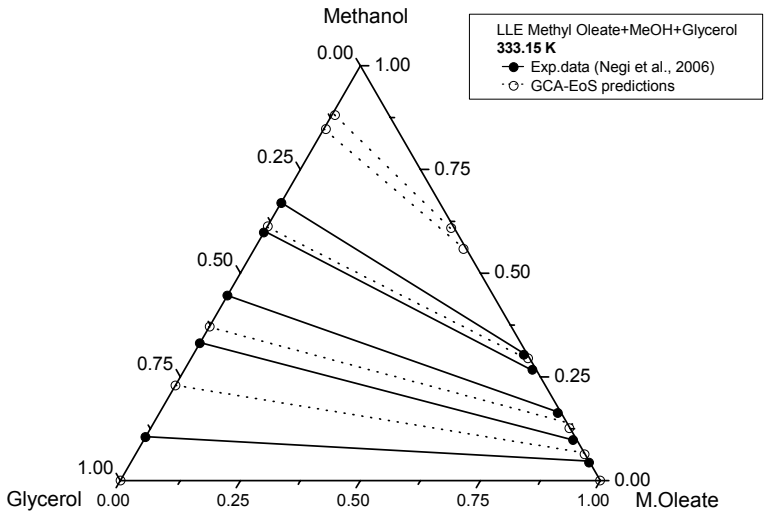

Figure 1. Ternary phase equilibria for the reaction products (methyl oleate and glycerol) and excess methanol at 333.15 K and one bar. Experimental data (Negi et al., 2006) and GCA-EoS predictions

3. Optimization Model

The optimization model for the noncatalytic transesterification of soybean oil with methanol at high pressure includes reliable thermodynamic predictions with the GCA-EoS equation of state and alternative schemes indicated as discontinuous lines in Fig. 2.

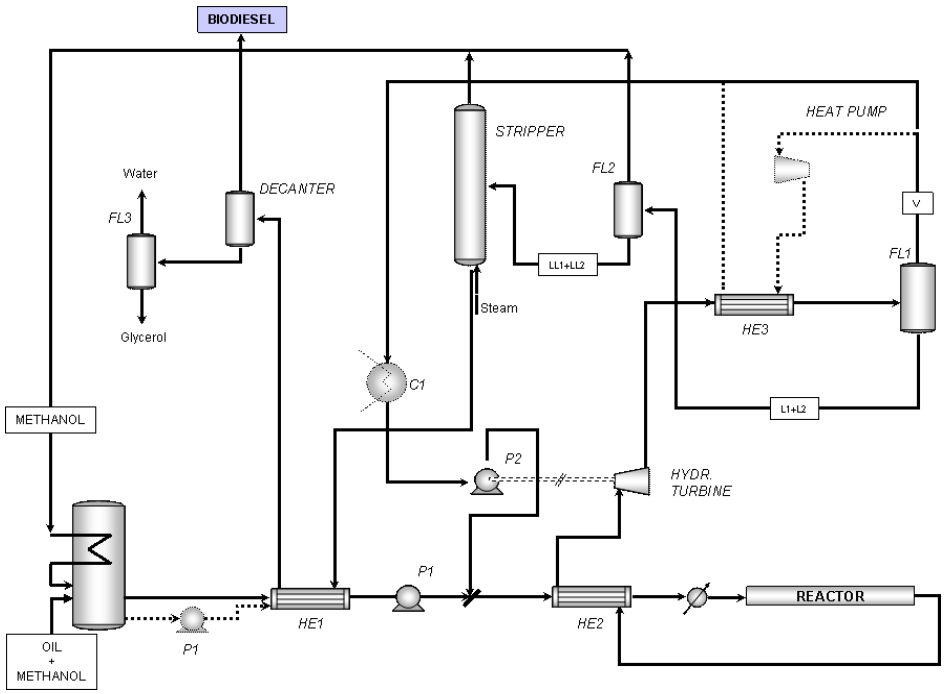

Figure 2. Superstructure of supercritical biodiesel production plant

We have formulated a nonlinear programming (NLP) problem for each analyzed process scheme, for an 80,000 ton/y biodiesel plant. The objective is the minimization of capital and operating costs for a supercritical methanol plant considering a project life of ten years. Capital cost correlations have been implemented from Ulrich (1984), Peters and Timmerhaus (1991) and Institut Français du Pétrole (1981).

Operating costs correspond to steam and cooling water requirement in heat exchangers, and electrical consumption for pumps and compressors. Optimization variables are the operating pressure in the supercritical reactor and in the first methanol recovery unit (FL1), pressure change in the heat pump, inlet steam flowrate in the stripper and distillate to feed ratio in this unit. The process model includes mass and energy balances in equipment, design equations, thermodynamic equilibrium equations (GCA-EoS) and recycle convergence equations as nonlinear equalities. Inequality constraints impose the existence of two liquid phases in the 1st separator, aqueous and organic phases, to provide high methanol recovery in the recycle stream with low glycerol content. A minimum methanol recovery of 90% and maximum glycerol mass concentration of 1 % in this stream are required. Additionally, constraints on maximum water content in the recycled methanol from the top of the stripper, products purity specification of 99 wt% for methyl oleate (biodiesel) and product purity specification above 95wt% for glycerol are imposed. Product specifications, as required by European norms (EN 14214), have been also included as additional constraints in the optimization model. The resulting

nonlinear programming problem has been solved with a Successive Quadratic Programming (SQP) algorithm (Biegler et al., 1985).

4. Discussion of Results

Based on experimental results (Hegel et al., 2007) operating pressure in the reactor has been taken from 98 to 110 bar to ensure around 100% oil conversion to biodiesel, at 570 K. Following Kusdiana and Saka (2001) experimental results, the reaction has been modeled as first order and rate equations have been included in the optimization model. The supercritical transesterification reaction is carried out in a tubular reactor with 24 to 1 methanol/oil molar ratio. The possibility to use propane as a co-solvent (also to obtain 100% conversion at lower pressures), as suggested by Cao et al. (2005) has been considered, taking a molar propane/methanol ratio of 0.05 in the reactor. As compared to these authors' results, we have obtained a slightly higher residence time in the reactor (13.59 against 10 min) and slightly lower residence time with the process without co-solvent (13.59 against 15.37). Process variables, equipment energy consumption and biodiesel composition in the final product are shown in Table 1 for supercritical processes with and without co-solvent.

Table 1. Main variables of the supercritical biodiesel process

Variable	C3/Meth=0.00	C3/Meth=0.05
Separator Pressure, FL1 (bar)	6	6.5
Pres. change Heat Pump (bar)	3	9.5
Reactor pressure (bar)	100	106
Methanol recovery in recycle (%)	93	95
Glycerol in recycle (wt%)	0.3	0.6
Biodiesel in recycle (wt%)	0.2	0.3
Biodiesel purity (wt%)	99.9	99.8
Methanol in Biodiesel (wt%)	0.07	0.1
Glycerol in Biodiesel (ppm)	76	97
Water in Biodiesel (ppm)	473	395
Tubular Reactor Volume (m^3)	25	31
Reactor Tubes Length (m)	28	30
Reactor Residence Time (min)	15.4	13.6
Feed Pump Power, P1 (kW)	99.8	99.9
Compressor Power, HP* (kW)	116.6	337.0
Heat in Heat Pump (kW)	2362.3	2956.6
Hidraulic Turbine Power (kW)	69.9	75.2
Recycle Pump Power, HP[a] (kW)	61.7	69.8

[a] HP: Heat Pump

It can be noted that optimal operating pressure for the first separator is 6 bar, which ensures LLV equilibrium at the conditions determined in the heat pump (150ºC to

160ºC) and a pressure change of 3 bar has been determined in the heat pump. However, when propane is used as a co-solvent, this pressure change is not enough to completely condense the propane + methanol mixture. Therefore, one alternative is the addition of external cooling, as this mixture has its bubble point around 363 K, which is too low to heat the feed to the first separator. Another alternative is to increase the upper bound on pressure change in the heat pump, which reduces the latent heat of vaporization of the condensing methanol + propane mixture, avoiding the requirement of additional cooling. The propane/methanol mixture must be subcooled to avoid cavitations in the pump. Biodiesel purity is above 99%wt in both cases, as required. The feed pump and the compressor have the main energy consumption. The integration between the hydraulic turbine and the recycle pump has been possible in the analyzed cases.
Table 2 shows optimal cost values with and without propane used as co-solvent in a 0.05 molar ratio to methanol. In cost calculations, investment cost has been annualized considering a project life of ten years and soybean oil price as 60 US$/t. When operating with a co-solvent both operating and capital costs are higher due to the need for compression at higher pressure in the heat pump compressor of the methanol-propane recycle. However, as mentioned earlier, the reaction kinetics is increased when propane is used as cosolvent, reducing the residence time in the reactor. The last column in Table 2 shows results for a process scheme with no heat pump. As compared to the one with heat pump, it can be seen that operating costs have increased in 470 % due to higher steam requirement for heating the feed to the first separator. Capital costs are a slightly lower because there is no need for a compressor and the biodiesel production cost has increased in almost 4 %.

Table 2. Cost comparison for the plant with and without the use of a co-solvent

Costs	24-to-1, HPump C3/Meth=0.	24-to-1, HPump C3/Meth=0.05	40-to-1, HPump C3/Meth=0.	40-to-1, no HPump C3/Meth=0.
Operating (US$/h)	34.32	55.81	50.08	284.89
Operating (US$/t biodiesel)	3.41	5.56	4.98	28.23
Capital (US$/t biodiesel)	4.66	5.88	5.15	4.47
Plant (US$)	2,287,826	2,876,631	2,526,000	2,195,050
Production Cost (US$/t biodiesel)	598.98	608.55	626.32	650.72

5. Conclusions

Different alternatives to supercritical biodiesel production have been studied in the present work by formulating nonlinear programming problems based on rigorous process models and thermodynamic predictions for each process scheme. Numerical results indicate that the use of propane as co-solvent slightly reduces the residence time in the reactor but increases both production and capital costs. Operating costs are significantly reduced considering the use of a heat pump scheme, making the supercritical biodiesel production economically competitive with conventional catalytic production and providing additional advantages that include no need for feed treatment, catalyst and soap removal.

[2]*College of Chemical Engineering and Materials Science, Zhejiang University of Technology, Hangzhou 310014, China*

Abstract

The Generalized Disjunctive Programming (GDP) has been proposed as an alternative to the mixed integer nonlinear programming (MINLP) for applications in process synthesis. It is straightforward in conditional modelling. Besides, it can reduce the complexity of the NLP sub-problems. In this paper, a nested method combining heuristic algorithm and gradient-based optimizer is proposed to solve the GDPs. It is generally a two-layer method, where the heuristic algorithm such as Tabu Search (TS) or Genetic Algorithm (GA) performs master iterations in the outer loop dealing with the logical variables of GDPs, and a gradient-based NLP solver such as Sequential Quadratic Programming (SQP) is applied in the inner layer dealing with the sub-NLP problems. In each call by the outer-layer heuristic algorithm, a set of logic values is specified and passed to the inner-layer. The general GDP model can thus be transformed into a reduced NLP sub-problem by automatically eliminating a number of equations based on the logic disjunction, nonlinear ones in some cases. After the execution of the gradient-based NLP solver, the result of each NLP sub-problem is returned to the outer-layer for further iterations. The heuristic method is responsible to find the global optimum of logic variables. Good performance has been demonstrated by applying the combined method into process synthesis such as heat exchanger networks (HEN) and the integrated water systems.

Keywords: process synthesis, generalized disjunctive programming, nested method.

1. Introduction

The synthesis of process network problems involving discrete variables are usually formulated as Mixed Integer Nonlinear Programming (MINLP) models. In the past decade however, researchers have presented Generalized Disjunctive Programming (GDP) as an alternative modelling method for MINLP.[1] Compared with MINLP, the GDP model is more intuitive and straightforward. Besides, it reduces the complexity of the generated sub-NLP problems, when the Boolean variables are specified.

A number of deterministic methods which used to solve the MINLP have been adapted to solve the GDP problems.[2] Although these algorithms have the advantage of fast convergence, it is well known that global optimality cannot be guaranteed for non-convex models; or in other words, the global optimization relies on the mathematical form of the handled problem.[3] In contrast to the inherent flaw of deterministic methods on global optimization, the heuristic algorithms are born to have advantage on this

* : Corresponding author. E-mail: xichen@iipc.zju.edu.cn

issue. Methods that can be categorized into heuristic algorithms include simulated annealing,[4] tabu search[5,6] and genetic algorithm,[7] etc. For example, Tabu search has already been applied to solve chemical process optimization problems[8].

Combining deterministic and heuristic algorithms, the idea of hybrid method has also been proposed for global optimization with fast convergence.[9] In this paper we will propose a nested framework combining heuristic and gradient-based methods to solve the GDP problems. Numerical results of several typical process synthesis problems which are formulated as GDP are also given.

2. Nested heuristic and gradient-based method

2.1. The decomposition strategy of nested method

The general form of the GDP model is as follows:

$$
\begin{aligned}
&Min \quad Z=\sum_k c_k + f(x) \\
&s.t. \quad g(x) \le 0 \\
&\quad \begin{bmatrix} Y_k \\ h_{1k}(x) \le 0 \\ c_k = \gamma_k \end{bmatrix} \vee \begin{bmatrix} \neg Y_k \\ h_{2k}(x) \le 0 \\ c_k = 0 \end{bmatrix} \quad k \in D \qquad \text{(GDP)} \\
&\quad \Omega(Y)=\text{True} \\
&\quad x \in R^n, c \in R^m, Y \in \{true, false\}^m
\end{aligned}
$$

The GDP model allows conditional modelling of equations by using Boolean variables. When Y_k, the Boolean variable denote the existence of a unit and is false, the continuous variables in the second block are usually set to be zero. As soon as a set of Boolean variables' value is specified, the GDP model will be transformed into a NLP sub-problem. Equations belonging to the inactivated terms will be eliminated, and variables corresponding to the non-existing units usually will be set to zero and maybe also removed from the NLP sub-problem. With the reduction in dimension and avoidance of singularities, the NLP sub-problem can always be solved efficiently.

Here we propose a nested method, involving two layers of sub-solver: in the outer loop a heuristic algorithm such as TS or GA performs the master iterations, dealing with the Boolean variables only; in the inner layer, a gradient-based NLP solver such as Sequential Quadratic Programming (SQP) is applied, to solve the reduced NLP sub-problems when the Boolean variables are specified. This method decomposes the GDP model into two layers, as is shown in Fig 1. The heuristic algorithm solves a combinatorial optimization problem, which has no explicit mathematical formulations. And it's responsible for iteratively locating the value of Boolean variables to escape from being trapped in a local optimum and therefore reach global optimality of the GDP problem. In each call by the outer loop, a set of Boolean values is passed to the inner layer, producing a reduced NLP problem to be solved by the inner gradient-based NLP solver. The sets is defined as: $S1=\{m|Y_m=true\}$ and $S2=\{n|Y_n=false\}$.

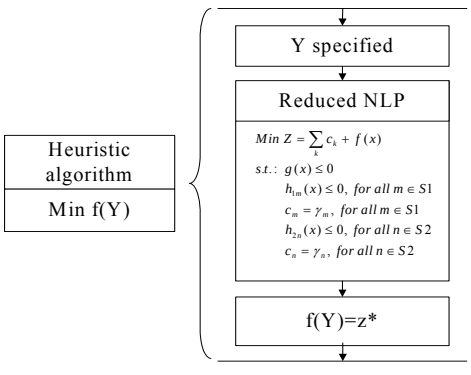

Fig 1 Structure of the nested method

Next we look at the GDP model and the nested method from a somewhat different viewpoint. After a set of Boolean values is

specified, a sub-network is produced from the postulated superstructure, with the "false-value" units disappeared. Reflected in the mathematical formulation, the GDP problem is transformed into a NLP problem with a reduction in both the equation and variable dimensions. Therefore, each Boolean value, when denoting the existence of a unit, possesses two sorts of members: variables and equations (relations of variables). When this unit is selected in the reduced NLP, the variables belonging to this unit will be present, so do the relations of these variables; otherwise, the variables corresponding to the non-existing unit will be set to zero and removed from the produced NLP.

This idea is quite similar to the Objected-Oriented Programming (OOP) idea in the computer programming language, C++. When an object is created, it means all the class members belonging to this object are created in the computer memory. The GDP model then can be transformed as follows:

$$
\begin{aligned}
Min \quad & Z = \sum_k \mathrm{Unit}_k.c_k + f(\mathrm{Unit}.x) \\
s.t. \quad & \mathrm{g}(\mathrm{Unit}.x) \le 0 \\
& \begin{bmatrix} \mathrm{unit}_k \\ h_{1k}(\mathrm{Unit}.x) \le 0 \\ \mathrm{Unit}_k.c_k = \gamma_k \end{bmatrix} \quad \mathrm{k} \in \mathrm{D} \\
& \Omega(\mathrm{unit}_k) = \mathrm{True} \\
& x \in \mathrm{R}^n, c \in R^m, \mathrm{unit}_k \in \{true, false\}^m
\end{aligned}
$$

Here we use the "." operator to indicate the "belong-to" relationship. Generally every continuous variable belongs to a unit or another. In the disjunctive part, instead of non-existing continuous variables being set to zero, the second block of equations usually does not exist at all. The g(.) functions which will hold irrespective of the disjunctive values, are usually used for mass and enthalpy balance. If certain unit doesn't exist, relevant variables in the g(.) should also be removed from the sub-NLP. The conditional modelling of equations has been discussed by the original GDP model. The conditional selection and removal of variables can be accomplished through logical operators in the equation itself. For example, in the HENS case, the heat balance at each stage can be implemented like this: $(T_{i,k} - T_{i,k+1})Fcp_i = \sum_{unit_{i,j}=true} Q_{i,j,k}$. The variable $Q_{i,j,k}$ will be activated only when the $unit_{i,j,k}$ is selected.

This variant will produce a better sub-NLP than the original GDP, in that the sub-NLP will have fewer variables and avoid singularities effectively. However, both models can be solved by the nested method proposed in this paper.

2.2. The heuristic algorithm in the outer layer

Both Genetic Algorithm (GA) and Tabu Search (TS) have been implemented to perform the outer loop of the GDP solver. Due to space limitation, only the results and discussion of The Tabu Search method will be presented.

Tabu Search (TS) is a meta-heuristic method which employs neighbourhood search to explore the solution space and prevent it from being trapped in a local optimum. Define a set neighbourhood $\mathrm{NY_k}$ as follows:

$$
NY_k = \{ y' \left| \sum_{m=1}^{M} \left| y'_m - y_m \right| = k \right\}, k \in N^+
$$

where M is the number of disjunctions, y is the current solution, and y' is one of its neighbours. The definition of the NY_k means that its element y' is exactly k bits different from the current solution. From the viewpoint of configuration, a neighbour is different from the current one in k unit's presence or absence.

As for the tabu and aspiration criteria, all the past current solutions and the local optimums (which are defined by no improvement for L iterations) will be kept for tabu use. There is also a probability p=2% to aspire a tabu point as a candidate for the selection of the next current solution. Besides, almost all the parameters used are initialized depending on the number of disjunctions, such as the maximum iteration "MaxIterCount", the maximum iteration defining a global solution to be found "MaxIterNoImprove", the length of the tabu lists, etc.

2.3. The gradient-based optimizer in the inner layer

With Boolean variables specified in the outer loop, the GDP model is branched into a typical NLP sub-problem through conditional modelling of equations. This is a typical optimization problem which is solved for the best operating levels for a given structure. Numerous solution techniques have been developed so far to solve the constrained NLP problems. For example, Sequential Quadratic Programming (SQP) accomplishes this by optimizing a sequence of quadratic programming (QP) sub-problems iteratively. The global solution of the GDP problems relies on the global solution of the sub-NLP directly. For the nested method, since the GDP's conditional modelling has greatly reduced the complexity of the NLP problem, and the same set of Boolean variables may be revisited by the outer loop, global optimization of the generated NLP becomes attainable for most problems. And for the NLP problems of examples in chapter III, produced when the global structure are given, the successful ratio of global optimization are all above 95%.

3. Test problems and numerical results

In this section we will apply the proposed nested method to two typical process synthesis problems: a HENS problem and a water treatment network problem. The program of the nested method is implemented with Microsoft Visual Studio 6.0 for the heuristic part and General Algebraic Modelling System (GAMS) for the inner NLP part. The execution of the program is run on an Intel 2.8 G Hz, 3.0G memory, PC, with Windows Server 2003. The nested method adopts the Tabu search in the outer layer and the SNOPT in the inner layer.

Case 1: HENS example

The first case to be studied is a Heat Exchanger Network Synthesis (HENS) problem, cited from Example 5 in Zamora and Grossmann's paper.[10] It involves 3 hot and 2 cold streams, steam and cooling water, and no stream splits. We reformulate it in a GDP model and then solve it by the nested method. The starting configuration is constructed assuming that the coolers and heaters all exist and no exchangers are present, which is an intuitive and feasible structure as listed in the second row of Table 1. As for the TS's parameters, the "MaxIterNoImprove" is same as the number of disjunctions, ND. The maximum number of different bits defining a neighbour K is half of ND, which is relatively large because the logical constraints are quite strict. The iterative process of the proposed method is given in Table 1. As can be seen, after 8 iterations, the nested method finds the global optimal solution and after ND iterations of no improvement for this solution, the method exits with the objective value of 82042.91.

The results of the nested method are listed in Table 2. The second column indicates the successful times to reach the global optimality among 30 runs. The third column gives an average count of the actually used NLP runs, which is highly relevant with the computation time. The forth column shows the ratio r of the actually used NLP count to the possible NLP count on average, which is 2^{23} here. The fifth column shows the major iteration count to reach the solved best solution versus the actually used iterations on

average. These three columns highly reveal the performance of the heuristic method looking for the optimal structure, and therefore the global solution.

Table 1: Iterative process for Case 1

Iteration No.	Boolean variables (0/1)	Objective value	Feasibility
0	000000000000000000011111	95415.23	Yes
1	000000000000010000011101	84189.18	Yes
2	000000000000001000011101	84189.18	Yes
3	000100000000001000011101	87639.28	Yes
4	000010000100011000011101	92573.90	Yes
5	000010000000001000011101	95039.28	Yes
6	000010000000001010011101	92830.18	Yes
7	000010000000001010011001	85431.14	Yes
8	000000000000001010011001	82042.91	Yes
……	……		

Table 2: Performance data for Case 1

No. of Disjunction	Global runs	Average NLP Count	Average Ratio r	Average Major iteration	Average time (s)
23	26/30	1210	1/6933	8/31	106

Case 2: WUTN example

Case 2 is a water network problem consisting of three effluent streams with three contaminants and three treatment units, which is adapted from published examples of Wang and Smith[11] and Gunaratnam.[12] It is complicated in that it involves highly nonlinear terms in the objective function and bilinear terms in the constraints.

The objective function consists of (1) the capital cost of the treatment units; (2) the operating cost of the treatment units; (3) the piping cost. The cost of a pipe $Cost_{i,j}^{pipe}$ is calculated as follows:

$$F_{i,j} = A_{i,j} v_{i,j} / 3600$$

$$Cost_{i,j}^{pipe} = (a A_{i,j} + b Y_{i,j}) d_{i,j}$$

where the flow rate F is in t/h, the cross-sectional area A in m^2, the distance d between the units is in m, and the velocity v in m/s, a=3603.4, b=124.46. The objective function is as follows:

$$Total\,cost = \sum_{j \in TU} Cap\,cost_j + \sum_{j \in TU} Oper\,cost_j + \sum_{k \in U} cost_{k,w}^{pipe} + \sum_{i \in PU, j \in TU} cost_{i,j}^{pipe} + \sum_{j \in TU} cost_{j,j}^{pipe}$$

The economic and other process data can be found in Gunaratnam's paper.[12] Besides, the velocity of the flows in each pipe is constrained to be 1m/s and the flow rate of each stream, if it exists, must be above 0.5 t/h.

As can been seen above, this example has 21 Boolean variables: 6 denote the existence of discharge pipes for each unit, 9 for pipes from 3 process units to 3 treatment units and 6 for treatment units interconnections.

Existing methods for water treatment networks always rely on the insights into the water networks, such as at least one of the contaminants must reach a maximum outlet concentration level, and then decompose the original complex models. Here however we apply the nested method to solve this problem without employing any engineering insights, just to examine its performance, and the starting Boolean variables are randomly generated. As for the TS's parameters, the "MaxIterNoImprove" is 1/3 of disjunctions, ND, and maximum number of different bits defining a neighbour K is also 1/3 of ND. The performance data for case 2 is listed in Table 3.

Table 3: Results of Case 2

No. of	Global	Average NLP	Average	Average Major	Average

Disjunction	runs	Count	Ratio r	iteration	time (s)
21	43/50	1227	1/1709	6/13	272

The objective of the solution is 482688.97 and the corresponding configuration is illustrated in Fig 2. To check the global optimality, 10 runs have been repeated by strengthening the TS search ability, which cost more than 7000 NLP counts and 1900 seconds in each run. Starting from 10 sets of random Boolean values all tests reached this same solution.

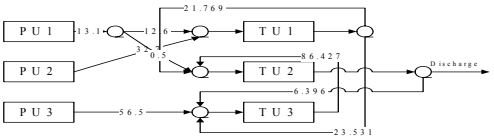

Fig 2: Global optimum solution structure for Case 2

4. Conclusion

In this paper, a nested framework combining general-purpose heuristic algorithm and gradient-based NLP solvers is proposed to solve the GDP model. It avoids the complexity and incapability of deterministic methods for global optimization, while performs quite well to solve different process synthesis problems. An Objected-Oriented viewpoint is also introduced to offer better understanding of not only the GDP model but also the proposed method.

Abstract

This paper introduces a new method on calculating the Molecular Weight Distribution (MWD) of free radical polymerization, termed the Sequential Variable Decoupling (SVD) method. The original model of MWD calculation in free radical polymerization is based on fundamental reaction mechanism and diffusion controlled reaction rate coefficients, resulting in a group of large scale differential algebraic equations (DAEs). However the traditional DAEs solvers always require huge computer memory to solve this kind of model simultaneously, making it impossible to implement on a normal PC. The SVD method decomposes the large DAEs model into a small scale DAEs model and a series of small scale ordinary differential equations (ODEs) models. This decomposition reduces computer memory greatly and makes it executable on a normal PC. As an example, the SVD method has been used to calculate the MWD of methyl methacrylate (MMA) homopolymerization with good precision. To further reduce computation time cost, techniques with variable step size in the numerical integration along time and chain length of the polymers are also proposed. By using the methods, the computational efficiency is improved by 8.2 times at a cost of increasing the relative error only by 0.56%.
Keywords: free radical polymerization, molecular weight distribution, sequential variable decoupling method.

1. Introduction

The Molecular Weight Distribution (MWD) of free radical polymers is the major factor that determines the end-use properties of polymers. A general and precise method that predicts MWD based on the operation parameters is very helpful. For a typical polymerization process, the range of molecular weight is from 10^3 to 10^5 or even more. Therefore, the models of polymerization are always large in scale, which presents difficulties while solving these models.

In the previous research, a great diversity of methods have been introduced, such as lumping method[1], passage to continuous variable method, the method of moments[2], the discrete Galerkin h-p-method[3], the Monte-Carlo method[4][5][8]. All these methods

* : Corresponding author. E-mail: xichen@iipc.zju.edu.cn
* : Corresponding author. E-mail: yaozhen@iipc.zju.edu.cn

include simplifying assumptions which help reduce equations, but at the same time reduce its precise and limit its application area[6][7].
In the first part of our paper, we introduce a general model of MWD calculation. Our model of free radical polymerization is based on the fundamental reactions mechanisms, including material balance equations, the volume relations, and chemical kinetic expressions thermodynamic properties. In the second part, we will introduce the Variable Decoupling Sequential Method, to decompose the original large scale DAEs model into small scale DAEs with a series of small scale ODEs sequential model. Finally, we will discuss the solver for this specific model, and we will optimize the compute process, which will improve the algorithm efficiency greatly.

2. Model decomposition of MWD calculation

2.1. Model I, Original model
The kinetics of typical free-radical homo-polymerization initiated by mono-functional initiators could be described by the following reactions: initiation, propagation, transfer and termination by combination and disproportion. A modified Stickler-Panke-Hamielec (SPH)[9] Model based on free-volume theory is used in this work. Here we only take the case of mono-functional initiators and bulk polymerization into account for simplicity. Equations, describing the whole model of free radical polymerizations, contain both ODEs and algebraic ones, the so-called large scale DAEs. The dimension of the ODEs group depends on the maximum value of the chain length. However, theoretically the chain length will grow to infinite, which make it impossible to solve this large scale DAEs. Therefore it is necessary to implement the moment method to convert the infinite item into finite item.

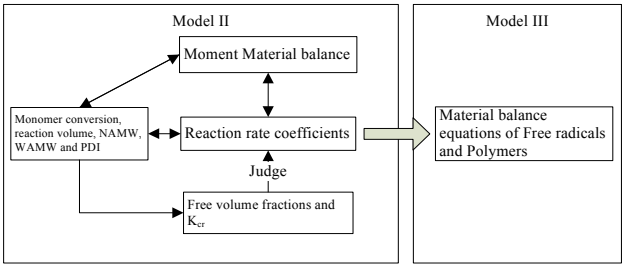

Fig.1 Structure of Model II and its relationship with Model III

2.2. Model II, Moment model
By using the moment method, we replace the ODEs of free radicals and polymers, the infinite items, with the ODEs of j^{th} moment of free radicals and polymers, whose dimension is limited.
The j^{th} moment of free radicals and polymers are defined as follows:

$$\lambda_j = \sum_{m=1}^{\infty} n^j R_n^{\bullet} \tag{1}$$

$$\mu_j = \sum_{m=1}^{\infty} n^j P_n \tag{2}$$

The moment model also contains the SPH model which is the same with model I.
And it also contains ordinary differential equations and algebraic equations, so this model is a DAEs model. However, it is a small scale DAEs group. It only contains 13 ordinary differential equations and 11 algebraic equations.
However, by solving this small DAEs group, we can only obtain the time-evolution of moment. In this case, we still can not simply derive the MWD since the concentration of polymers and free radicals with different chain lengths are not available. But with the solution of the small DAEs, we know the time-evolution of the moments, the reaction

coefficients k, the reaction volume V and other algebraic variables. Then, we can treat these variables as known variables, and solve the ODEs of free radicals and polymers to calculate the MWD, and this is the model III.

2.3. Model III, MWD calculation

Since the sums of free radicals and polymers of all chain length, are 0^{th} moments of free radicals and polymers, so the equations of free radicals and polymers can be converted into the following:

$$\frac{1}{V}\frac{d(R_1^\bullet \cdot V)}{dt} = k_i I^\bullet M - k_p M R_1^\bullet + k_{tr,M} M\lambda_0 - (k_{tc} + k_{td}) R_1^\bullet \lambda_0 + k_{tr,P}(P_1\lambda_0 - R_1^\bullet \mu_0) \tag{3}$$

$$\frac{1}{V}\frac{d(R_n^\bullet \cdot V)}{dt} = k_p R_{n-1}^\bullet M - k_p R_n^\bullet M - k_{tr,M} R_n^\bullet M - k_{tr,I} R_n^\bullet I_2 + k_{tr,P}(P_n\lambda_0 - R_n^\bullet \mu_0) - (k_{tc} + k_{td}) R_n^\bullet \lambda_0 \quad (n=2, \ldots, CL_{max}) \tag{4}$$

$$\frac{1}{V}\frac{d(P_n V)}{dt} = k_{tr,M} R_n^\bullet M + k_{tr,I} R_n^\bullet I_2 + k_{tr,P}(R_n^\bullet \mu_0 - P_n\lambda_0) + k_{td} R_n^\bullet \lambda_0 + \frac{1}{2} k_{tc} \sum_{s=1}^{n-1} R_s^\bullet R_{n-s}^\bullet \quad (n=2, \ldots, CL_{max}) \tag{5}$$

In the above equations, we can get the time-evolution of k_i, k_p, $k_{tr,m}$, $k_{tr,I}$, $k_{tr,P}$, k_{tc}, k_{td}. I_2, $I^\bullet$, M, λ_0, μ_0, V from the solution of the small DAEs group in Model II. The concentrations of polymers and free-radicals with different chain lengths, which represent MWD, can be obtained by solving the ordinary equations (3) (4) (5). This relationship is represented in Fig.1. From this figure, it is easy to conclude that by solving model II and III sequentially, we can finish calculating MWD. And also the maximum of chain lengths that are taken into consideration can be very large with our solver represent in the next chapter.

3. Sequential Variable Decoupling method with control on truncation error

3.1. Decomposition of Model III with Sequential Variable Decoupling method

In the equations (3) (4) (5), the model III is still quite large in scale. And with the present ODEs solver, it will take quite large computer memory to solve this model simultaneously, which makes it not applicable on a personal computer. And we have tried to solve the ODEs directly, and a computer with 4GB memory can only solve the maximum chain length of 2000, which is far from sufficient for MWD predication.

In the equations (3) (4) (5), we can find that, for a specific chain length, the equations of polymers and free radicals do not contain any information from bigger chain lengths' components, which means we can solve the whole model sequentially, from small chain length

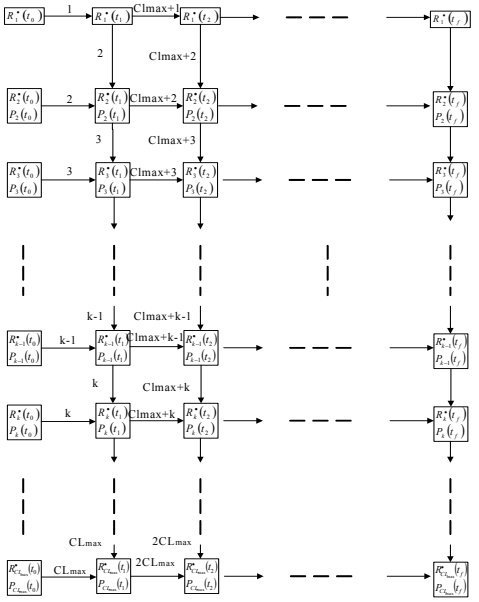

Fig.2 Structure of Decoupled Sequential Model

to big chain length components, thus the large scale ODEs group is decoupled into lots of such units sequential models. Fig.2 shows this structure, the structure of decoupled sequential model. In the Fig.2, the simulation is from the initial moment t_0 to the final moment t_f, and the whole period is sampled into several discrete points.

Since that we can solve $R_k^\bullet$ and $P_k^\bullet$, from k=1 to k=CL_{max}, sequentially, we can save lots of computer memory and make this model solvable on a personal computer. This is the key idea of the sequential variable decoupling method. The CL_{max} represents the maximum of the chain lengths that need to be considered.

However, problem rises while solving this model. Since the model III has become a large scale sequential model, if we implement traditional ODE solver on it, the computation time is quite long. And the sequential model needs synchronization on the steps among different chain lengths which make this model inflexible. So later in this chapter will discuss the optimization of this computation process.

3.2. Mechanism of variable step size

The Fig.2, the structure of decoupled sequential model, also shows the discretization of the whole reaction period, thus the whole reaction period is divided into many steps between discrete points. How to divide this period is an important issue for the computation. Here, we use first order backward differentiation formula (BDF) to solve these ODEs. Since the step size decides the efficiency and the accuracy of the algorithm, a mechanism determining the appropriate step size is very essential.

The Gear's BDF algorithm introduced a method to estimate the error of numerical integration. Here we use the first order method and build an error estimator. The step size of the numerical integration is determined by the error and error tolerance. Each model has a specific requirement on the accuracy. For this model, 10% relative error is acceptable. For each iteration, the mechanism is described as follows:

(1) Use the old step size *h* to calculate a new step.

(2) Run the error estimator to estimate the error for this step

(3) If the error is smaller than the tolerance, then increase the step size and go to next step (1); if not, reduce the step size and calculate this step again, also go to (1), and this step is the feedback and the control on the step size to maintain the error within the tolerance.

3.3. Variable step size on time scale

Fig.2 shows the structure of the sequential ODEs group. It denotes that, at each step of numerical integration, the method will calculate the polymers and free radicals fractions for all chain lengths. To ensure this synchronization, the step sizes for a certain step, of all variables, must be the same, which means, it needs to choose the minimal step size to satisfy the accuracy requirement of all variables. If one variable's accuracy is violated, the whole step needs to be calculated again.

3.4. Variable step size with chain length

In the error estimator mentioned above, there is a variable α calculated to represent the sensitivity towards the step size. For this specific model, we find that the α increases with the chain length, which means, for a certain step, the variables that represent larger chain length polymers and free radicals are more inert than the variables that represent smaller chain length polymers and free radicals.

Because the large chain length polymers and free radicals are always inert, and according to their accuracy requirement, their step size can be further amplified. At each

even step we set a transition point. The calculation of the variables for the chain length larger than this point is skipped on this step. The step size of the variables of the chain length larger than this point is twice the size of the variables of the chain length smaller than this point. For the variables of small chain length, their step size is still determined by the feedback control mechanism. We decide the transition point in this way: if the α of the polymer variable for a certain chain length is very large, we can conclude that from this chain length on, the polymer and free radicals are inert, so this point is the transition point.

4. Results and Discussion

4.1. MWD results from model III with constant step size

Here we implement an example of MMA homopolymerization, the 0.3% (weight fraction) AIBN at 90□ for 30 minutes. First we solve the Model II by DAEs solver, and generate the time-evolution of the moments, the reaction rates *k*, the reaction volume *V*, which are the inputs of model III.

By applying the Sequential Variable Decoupling method, we can calculate the very wide chain length range. In our example, we calculate the MWD with maximum chain length of 5×10^4, which is sufficient for polymer design.

Here the step size is constant, and in order to decide an appropriate step size, a comparison between different step sizes is needed. The comparison among step size of 0.5 min, 0.1 min and 0.01min is show in Tab.1. From the comparison, we know that the step size of 0.1min is optimal for this model, because the accuracy improvement for the step size from 0.5min to 0.1min is quite significant, but the accuracy improvement for the step size from 0.1min to 0.01min is not so significant and the maximum relative error between 0.1min and 0.01min is within the accuracy requirement 10%. So here for the constant step size the 0.1 min step size is an optimal one. And for the later discuss, we take the results of the calculation with step size 0.01min as the standard data for comparison.

Tab.1 Comparison of MWD calculations

Step size	Compute time (s)	Maximum relative error with step size=0.01min(%)
0.5min constant	292.38	50.2%
0.1 min constant	769.26	9.01%
Feedback control on time	138.17	9.86%
Step Size variable with Chain length	94.13	9.57%
0.01min consant	5324.78	

4.2. Variable step size on time scale

The result of the calculation is quite positive, by applying the feedback control, the efficiency improved by 5.6 times, which means it only takes 18.0% computation time of the constant step size method with a step size of 0.1min, and the maximum relative error is 9.86% comparing to 9.01% for the result of 0.1min. The comparison is also shown in Tab.1. Since the MWD is constituted of tens of thousands

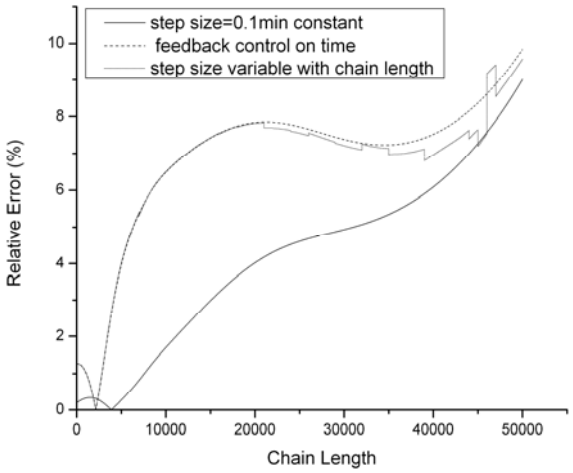

Fig.4 Relative error comparison of different methods

variables, and the accuracy of the calculation should be represent as a distribution of the relative error, it is show in Fig.4.

4.3. Variable step size on chain length

The result of calculation is positive too. The comparison is also contained in Tab.1. And the relative error distribution and its comparison with the relative error of feedback control on time scale, is in Fig.4. The time cost further decreased by 31.9% and the relative error do not increase noticeably.

5. Conclusion

This paper introduced a novel method on MWD calculation. We decompose the large scale DAEs model into a group of small scale sequential ODEs, which make the MWD solvable on a normal PC. We further discuss the improvement of computational process by varying step size on both time scale and chain length, which greatly reduces the time at a cost of little deterioration in accuracy.

Global Optimization of Nonconvex Generalized Disjunctive Programs

Juan P. Ruiz, Ignacio E. Grossmann
Carnegie Mellon University, 5000 Forbes Ave. , Pittsburgh 15213, United States

Abstract

This paper is concerned with the global optimization of Bilinear and Concave Generalized Disjunctive Programs. The efficiency of methods to solve these problems relies heavily on their capability for predicting strong lower bounds that in turn depend on the strength of their relaxations. The major objective of this work is to propose a procedure to find such relaxations. We first present a framework for obtaining a hierarchy of linear relaxations for nonconvex Generalized Disjunctive Programs (GDP), that combines the linear relaxations proposed in literature for nonconvex MINLPs with the results in the work of Sawaya & Grossmann [1], to obtain relaxations for the case of Linear GDPs. We further exploit the theory behind Disjunctive Programming to guide the generation of better relaxations more efficiently. We show through a set of examples how these new relaxations can strengthen substantially the lower bounds for the global optimum leading to an improvement in the performance when used within a spatial branch and bound framework.

Keywords: Global Optimization, Generalized Disjunctive Programming, Convex Relaxations, Bilinear GDP, Concave GDP

1. Introduction

Generalized Disjunctive Programming (GDP), developed by Raman and Grossmann [2], has been proposed as a framework that facilitates the modeling of discrete-continuous optimization problems by allowing the use of algebraic and logical equations that are expressed in terms of Boolean and continuous variables. In order to take advantage of the existing MILP/MINLP solvers, GDPs are often reformulated as MILP/MINLP problems by using either the Big-M (BM), or the Convex Hull (CH) [3] reformulation. However, these reformulations are not unique and may have associated relaxations that are not very tight, consequently having an adverse effect on the efficiency of the algorithm that is used. In nonconvex GDP problems the direct application of traditional algorithms to solve the reformulated MINLPs may correspond

to a local optimum. Therefore, specialized algorithms should be used in order to find the global optimum [4]. Nonconvex GDP problems with bilinear and concave constraints are of particular interest since these arise in many applications [5,6]. To tackle these problems, Lee and Grossmann [7] proposed a global optimization method that first relaxes the bilinear terms by using the convex envelopes of McCormick [8] and the concave terms by using linear under estimators. The convex hull [9] is then applied to each disjunction and used within a spatial branch and bound technique. A major question is whether one might be able to obtain stronger lower bounds to enhance the efficiency for globally optimizing GDP problems. Sawaya and Grossmann [1] have recently established new connections between Linear GDP and the Disjunctive Programming theory by Balas [10]. As a result, a family of tighter reformulations has been identified. These are obtained by performing a sequence of basic steps on the original disjunctive set (i.e. each basic step is characterized by generating a new set of disjunctions by intersecting the former), bringing it to a form closer to the Disjunctive Normal Form (DNF), and hence tightening its discrete relaxation [9]. In this work we build on the work by Sawaya and Grossmann [1] exploiting the new hierarchy of relaxations in order to solve more efficiently nonconvex GDP problems.

2. Background

The general structure of a nonconvex GDP can be represented as follows [2,3,6]

$$
\begin{aligned}
&Min\ Z = f(x) + \sum_{k \in K} c_k \\
&s.t. \quad g^l(x) \le 0 \qquad\qquad l \in L \\
&\bigvee_{i \in D_k} \begin{bmatrix} Y_{ik} \\ r_{ik}^j(x) \le 0 \quad j \in J_{ik} \\ c_k = \gamma_{ik}(x) \end{bmatrix} \qquad k \in K \qquad\qquad (GDP_{NC}) \\
&\Omega(Y) = True \\
&x^{lo} \le x \le x^{up} \\
&x \in R^n, c_k \in R^1, Y_{ik} \in \{True, False\}
\end{aligned}
$$

where $f : R^n \to R^1$ is a function of the continuous variables x in the objective function, $g^l : R^n \to R^1$, $l \in L$, belongs to the set of global constraints. The disjunctions $k \in K$, are composed of a number of terms $i \in D_k$, that are connected by the OR operator . In each term there is a Boolean variable Y_{ik}, a set of inequalities $r_{ik}^j(x) \le 0$, $r_{ik}^j : R^n \to R^1$, $j \in J_{ik}$ and a cost variable c_k. If Y_{ik} is true then $r_{ik}^j(x) \le 0$ and $c_k = \gamma_{ik}(x)$ are enforced, otherwise they are ignored. Also, $\Omega(Y) = True$ are logic propositions for the Boolean

variables. As indicated in Sawaya and Grossmann [1], we assume that the logic constraints $\underset{i\in D_k}{\vee} Y_{ik}$ are contained in $\Omega(Y) = True$. In a nonconvex GDP, f, r_{ik}, γ_{ik} and/or g^l are nonconvex functions. In this work we aim at solving two particular nonconvex GDP cases, namely, bilinear GDPs (GDP_B) and concave GDPs (GDP_{Co}). A GDP_B is a nonconvex GDP where some of the functions f, r_{ik}, γ_{ik} and/or g^l are bilinear, whereas a GDP_{Co} is a nonconvex GDP where some of the functions f, r_{ik}, γ_{ik} and g^l are concave.

3. Methodology to obtain strong relaxations

In this section we present a general framework to obtain a hierarchy of continuous linear relaxations for the nonconvex GDP problem (GDP_{NC}) that can serve as a basis for predicting tight lower bounds of the global optimum. This framework will be presented for general nonconvex GDP problems, although it will later be only applied to the bilinear and concave case (i.e. GDP_B and GDP_{Co}). Without loss of generality we can consider in (GDP_{NC}) f to be a linear function of x. Hence, we can represent it as $d^T x$.

Let us define the following sets:

$L_c := \{ l \in L \mid g^l(x) \text{ is convex} \}$, $L_{nc} := \{ l \in L \mid g^l(x) \text{ is nonconvex} \}$, $J_{cik} := \{ j \in J_{ik}, i \in D_k, k \in K \mid r^j_{ik}(x) \text{ is convex} \}$, $J_{ncik} := \{ j \in J_{ik}, i \in D_k, k \in K \mid r^j_{ik}(x) \text{ is nonconvex} \}$, $D_{cik} := \{ i \in D_k, k \in K \mid \gamma_{ik}(x) \text{ is convex} \}$, $D_{ncik} := \{ i \in D_k, k \in K \mid \gamma_{ik}(x) \text{ is nonconvex} \}$

In the first step of this approach we replace each nonconvex function with a valid linear over/under estimator. Generalizing,

$g^l(x) \le 0$ is replaced by $A^l_g x \le b^l_g$, $l \in L_{nc}$, $r^j{}_{ik}(x) \le 0$ is replaced by $A^j_{rik} x \le b^j_{rik}$, $j \in J_{ncik}$, $i \in D_k$, $k \in K$ and $c_k = \gamma_{ik}(x)$ is replaced by $A_{\gamma ik}(x, c_k) \le b_{\gamma ik}$, $i \in D_{ncik}$, $k \in K$

Note that the dimensions of the matrices, A^l_g, A^l_{rik}, $A_{\gamma ik}$, and the right hand side vectors, b^l_g, b^j_{rik}, $b_{\gamma ik}$, depend on the particular under/over estimators that are chosen.

Similarly, we replace each convex inequality with a valid linear outer-approximation,

$g^l(x) \le 0$ is replaced by $A^l_g x \le b^l_g$, $l \in L_c$, $r^j{}_{ik}(x) \le 0$ is replaced by $A^j_{rik} x \le b^j_{rik}$, $j \in J_{cik}$, $i \in D_k$, $k \in K$ and $c_k = \gamma_{ik}(x)$, is replaced by $A_{\gamma ik}(x, c_k) \le b_{\gamma ik}$, $i \in D_{cik}$, $k \in K$

Note that the dimensions of the matrices, A^l_g, A^l_{rik}, $A_{\gamma ik}$ and the vectors b^l_{rik}, b^l_g, $b_{\gamma ik}$ depend on the polyhedral outer-approximation technique that is chosen [4].

Replacing the nonconvex functions in (GDP_{NC}) by the corresponding under/over estimators and outer-approximations, leads to the following Linear GDP:

$$
\begin{aligned}
&\underset{\cdot}{Min}\ Z^L = d^T x + \sum_{k \in K} c_k \\
&s.t.\quad A_g^l x \le b_g^l \qquad\qquad l \in L \\
&\bigvee_{i \in D_k} \begin{bmatrix} Y_{ik} \\ A_{rik}^j x \le b_{rik}^j \quad j \in J_{ik} \\ A_{\gamma ik}(x, c_k) \le b_{\gamma ik} \end{bmatrix} \qquad k \in K \qquad\qquad (GDP_{RLP}) \\
&\Omega(Y) = True \\
&x^{lo} \le x \le x^{up} \\
&x \in R^n, c_k \in R^1, Y_{ik} \in \{True, False\}
\end{aligned}
$$

In order to predict strong lower bounds for the global optimum of (GDP_{NC}), as the second step in this approach, we consider the hierarchy of relaxations for (GDP_{RLP}) from the work of Sawaya & Grossmann [1]. These authors proved that any Linear Generalized Disjunctive Program (LGDP) that involves Boolean and continuous variables can be equivalently formulated as a Disjunctive Program that only involves continuous variables. Hence, Disjunctive Programming Theory can be used to solve Linear GDPs. One important result in Disjunctive Programming Theory, as presented in the work of Balas [9], is that we can systematically generate a set of equivalent DP formulations going from the CNF to the DNF by using an operation called "basic step" which preserves regularity (See Theorem 2.1 [9]). Although the formulations obtained after the application of basic steps on the disjunctive sets are equivalent, their *continuous relaxations* are not. As described in Theorem 4.3 [9], the application of a basic step on a disjunctive set leads to a new disjunctive set whose relaxation is at least as tight, if not tighter, as the former. Consider now the linear relaxation of (GDP_{NC}), namely (GDP_{RLP0}), which is equivalent to (GDP_{RLP}). We introduce the subscript i to indicate the number of basic steps that has been applied to the initial Linear GDP relaxation (GDP_{RLP0}) that is obtained by the under/over estimation of the nonconvex terms from (GDP_{NC}). Then we can show that:

$$h - rel\, GDP_{RLP0} \supseteq h - rel\, GDP_{RLP1} \supseteq ..h - rel\, GDP_{RLPi} .. \supseteq h - rel\, GDP_{RLPt} \supseteq GDP_{NC}$$

where *h-rel* GDP_{RLPi} is the convex hull relaxation of GDP_{RLPi} (Lee and Grossmann [2])
We can then establish the following proposition.

PROPOSITION: The lower bounds for the global optimum obey the following relationship: $Z_{RLP0} \le Z_{RLP1} \le .. Z_{RLPi} \ldots \le Z_{RLPt} \le Z_{NC}$ where Z_{RLP0} , Z_{RLP1} ,.. Z_{RLPi} , Z_{RLPt} are the optimal solutions of the hull-relaxations of problems GDP_{RLP0} , GDP_{RLP1},.. GDP_{RLPi} .., GDP_{RLPt} respectively and Z_{NC} is the optimal solution of GDP_{NC}.

In order to implement the basic steps more efficiently we developed a set of rules based on Theorem 4.5 [9] which exploits the particular structure of the problems.

4. Numerical Results and Conclusions

In order to test the performance of the framework to generate strong relaxations we used 5 examples. Example 1 deals with the optimal selection of two reactors with bilinear constraints in the demand. Example 2 deals with the optimal selection of two reactors whose investment costs are given by a concave univariate function. Example 3 deals with the optimization of a Heat Exchanger Network with discontinuous investment costs for the exchangers and can be represented by a nonconvex GDP with bilinear and concave constraints [8]. Example 4 deals with the optimization of a Wastewater Treatment Network whose associated nonconvex GDP formulation is a bilinear GDP . Finally, example 5 is a Pooling Design problem that can be also represented as a bilinear GDP [7]. Table 3 summarizes the characteristics and size of the examples, and Table 4 shows the computational performance of the Lee and Grossmann [7] relaxation and the one proposed in this work.

Table 3 Characteristics and size at example problems

	Bilinear Terms	Concave functions	Discrete Variables	Continuous Variables
Example 1	1	0	2	3
Example 2	0	2	2	5
Example 3	4	9	9	8
Example 2	36	0	9	114
Example 3	24	0	9	76

Table 4 Performance of proposed framework

	Global Optimum	Lower Bound (Lee & Grossmann Relaxation)	Lower Bound (Proposed Relaxation)	Best Lower Bound
Example 1	-1.01	-1.28	-1.10	-1.10
Example 2	6.31	5.65	6.08	6.08
Example 3	114384.78	91671.18	94925.77	97858.86
Example 4	1214.87	400.66	431.9	431.9
Example 5	-4640	-5515	-5468	-5241

All the examples show an improvement in the lower bound which is a direct indication of the reduction of the relaxed feasible region. The column “Best Lower Bound” in the Table 4 represents the MIP solution of the Linear GDP after the relaxation of the nonconvex terms/functions (i.e. bilinear terms and concave terms). This ultimately represents the best lower bound attainable by the application of the basic steps (i.e. the solution of the hull relaxation of the DNF of GDP_{RLP0}). Clearly, this can be used as an indicator of the performance of our set of rules to apply basic steps (e.g. note that Examples 1, 2 and 4 reach this limit). A further indication of tightening is shown in Table 5 where numerical results of the branch and bound algorithm proposed are

presented. As it can be seen the number of nodes that the spatial branch and bound algorithm needs to visit before finding the global solution is significantly reduced in Examples 1, 3 and 4. In Examples 2 and 5 the performance is not altered significantly.

Table 5 Performance of proposed methodology

		Global Optimization Technique using Lee & Grossmann Relaxation			Global Optimization Technique using Proposed Relaxation		
	Global Optimum	Nodes	Bound contract. (% Avg)	CPU Time (sec)	Nodes	Bound contract. (% Avg)	CPU Time (sec)
Example 1	-1.01	5	35	2.1	1	38	1.4
Example 2	6.31	1	33	1.0	1	33	1.0
Example 3	114384.78	13	85	11.0	1	99	6.0
Example 4	1214.87	450	8	217	227	16	139
Example 5	-4640	502	1	268	497	1	285

Abstract

Computer-Aided Mixture Design for product development can take advantage from equilibrium modelling. Systems composed by triacylglycerols (TAG) mixtures are widely used for many applications (foods, cosmetics, pharmaceutical and lubricants) and their end-use properties are very close related to phase behaviour (melting and crystallization). Such molecules can have different polymorphisms in solid state, leading to a lack of intersolubility and consequently formation of multiple solid phases. This work has implemented the solid-liquid equilibrium for TAG mixtures in a two step approach: stability tests and equilibrium compositions computations for two phase mixtures. The Michelsen's method for stability analysis was adapted to cope with polymorphisms and was successful for phase-split detection. Melting curves for mixtures composed by 9 TAGs in different compositions and molecular structures were simulated revealing good agreement with physical background for such systems. Further implementations of other initialization independents stability tests and robust optimization techniques show, therefore, a great potential for use as auxiliary computational framework for match improved mixtures in structured lipids research.

Keywords: triacylglycerols, polymorphisms, solid-liquid equilibrium, CAMD.

1. Introduction

Knowledge of phase equilibrium calculations has been widely applied in chemical process design, simulation and optimization. However, equilibrium calculations have also a great potential to be applied in product design, as many products have their properties directly related to phase behaviour in multi-component mixtures.

In chemical industry, phase behaviour plays an important role in the product functionality of many products: paints, rubber, plastic composites, agglomerated powders, extruded products, foams and foods (Bruin; Jongen, 2003). Phase equilibrium calculations are very useful in food industry for product design and fat-based foods are particular examples where phase behavior directly affects product requirements. The solid fat content and melting profile of such products influences the texture; the mouthfeel related to this texture and to its destruction during mastication is the key factor to final product quality and appreciation by the consumer (Bruin, 1999).

Vegetable oils and fats (natural or modified) are the main raw materials for these fat-based foods. Control of melting and solidification behaviour of such systems is therefore essential for manufacturing these products (Bruin; Jongen, 2003). Despite the importance for the design of fat-based foods with improved chemical, physical and nutritional properties, the use of phase equilibrium calculations remains still unsolved in

such systems, due to their complex nature. In fact, fats and oils are lipids systems composed mainly by triacylglycerols (TAG) molecules. For computing solid fat content, up to 1990, mainly empirical calculation methods were available (Wesdorp, 1990). Such empirical approaches limit the application range and provide no fundamental understanding of phase behaviour of TAG systems. After 1990, experimental data on fatty systems (Liang *et al*., 2003; Inoue *et al*., 2004; Zhou and Hartel, 2006; Zhang *et al*., 2007) were published along with some discussions about general TAG phase equilibrium modelling (Wesdorp, 1990; Won, 1993; Himawan *et al*., 2006).

However, a robust and general methodology to cope with the complexity of the problem is still unsolved. One reason is that fats and oils are multi-component mixtures of different triacylglycerols that can crystallize in 3 different polymorphisms (a, ß' and ß). At these solid states, such molecules have limited miscibility, leading to the formation of several solid phases. Similar problems can be found in oil industry as precipitation of waxes in pipelines due to solid phase behavior of n-alkanes (Lucia *et al*., 2005).

2. Molecular Structures and Polymorphisms

2.1. Triacylglycerol structure and fatty acids

Triacylglycerol molecules (TAGs) are responsible for more than 95% of vegetable oils composition. They are made by three fatty acids sterified to a glycerol backbone, as illustrate in Figure 1.

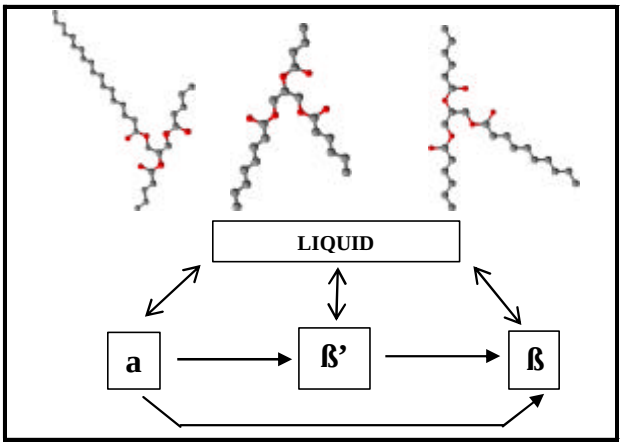

Figure 1: Triacylglycerol structures and state transitions.

Figure 1 shows a large variety of molecules according to the type of the 3 fatty acids attached to the glycerol. The carbon chain length, the number of double bounds and even the position of fatty acid in the three possible positions directly affect melting point, melting enthalpy, viscosity and solid miscibility in mixtures. As consequence, equilibrium between different species in liquid multi-solid phases is directly affected by these molecular issues.

2.2. Polymorphisms

TAG molecules present basically three different polymorphisms (Figure 1): unstable a, metastable ß' and stable ß, each one corresponding to a solid crystalline arrangement (Sato, 2001). Differences in molecular packing affect important properties related to solidification and melting behaviour, such as melting points and enthalpy of fusion

(molecule level), Gibbs energy, melting ranges and solid content (mixture level) as well as subjective properties related to fat crystal networks in edible products, as texture and spreadability.

3. Multi-phase Multi-Component Solid Liquid Equilibrium

3.1. General Modelling

Computing phase equilibrium is the solution of a nonlinear programming (NLP) problem searching for the global minimization of the total Gibbs energy subject to material balance constraints that can be also represented as an equivalent set of nonlinear equations. Experimental and theoretical backgrounds allow considering liquid and alpha solid phases as ideal (Wesdorp, 1990; Bruin, 1999; Himawan *et al*., 2006). Thus, only ß' and ß solid phases need description with an excess Gibbs free-energy model. The Margules equations are used in this work. Interaction parameters for the model were obtained by using the isomorphism based correlations, as illustrated by Wesdorp (90).

3.2. Stability Analysis

As the number of phases coexisting in equilibrium is not known *a priori*, the flash calculation is performed in two steps: stability analysis and calculation of phase fraction and equilibrium compositions. McDonald and Floudas (1997) demonstrated that while one can use global optimization to solve the NLP problem, it is computationally more efficient to use a two-stage approach, since the dimensionality of the global optimization problem in phase stability is less than that of the full equilibrium problem.

Stability tests concern the evaluation if a phase can split in two other phases, given T, P and overall composition. In this work, we use the tangent plane criterion for stability problem, presented by Michelsen (1982a,b): a necessary and sufficient condition for stability of a mixture at fixed temperature, pressure and overall composition (**z**) is that the Gibbs energy surface be at no point below the plane tangent to the surface at **z**. This condition for n components mixture is expressed as follows:

$$D(x) = m(x) - m_0 - \sum_{i=1}^{n} \left(\frac{\partial m}{\partial x_i} \right)_0 (x_i - z_i) \geq 0 \quad \forall x_i \tag{1}$$

Where $m(x) = \sum_{i=1}^{n} x_i \ln x_i + g^E(x)$ and $g^E(x) = G^E / RT$ is the reduced molar excess Gibbs energy. The subscript zero indicates evaluation at $x = z$. D(x) is the tangent plane distance function, which represents that if there is any possible trial phase with composition x to be added with negative value of D(x), it is possible to have a negative variation of Gibbs free energy (initial phase is unstable and splits). As all of the minima in D(x) are located in the interior of the permissible region ($x_i = 0$, ? $x_i = 1$) (Michelsen, 1982a), the value of D(x) will be nonnegative if it is nonnegative at all stationary points.

For achieving stationary points, Michelsen proposed an iteration procedure from a several initial guesses. The adaptation of this method to cope with polymorphisms is done by increasing the number of initial guesses: one pure phase of each component in each polymorphism and mixtures with compositions evaluated as an average of the mixtures already present (Wesdorp, 1990), leading to a 3n+4 initial guesses.

4. Results

Table 1 shows some stability tests performed in a mixture composed by 4 mono-TAGs formed by the fatty acids Palmitic, Stearic, Myristic and Oleic. The overall composition

(Z) and their physical state, temperature, stationary points and tangent plane distance are shown together with the physical state of the new phase that will be formed in case of instability (most negative value of tangent plane distance).

Table 1: Stability tests in a four component TAG systems.

Feed (Z1,Z2,Z3,Z4)	Temperature (°C)	Stationary Points (x1,x2,x3,x4)	D(x)/RT	Phase Split

Systems composed by 9 triacylglycerols were used to simulate melting curves. They contain saturated as well as unsaturated molecules with different chain lengths. Mixture 1 is composed by the followings TAGs: MMM, PPP, SSS, OOO, PPS, PSP, SSM, MMP and MMS. Figure 2 shows the melting curves for mixture 1 at three solid states. It can be noted that as molecules in a state have the lowest melting points, the a curve lies below the two other curves. For ß' and ß curves, there is a region (between 20°C and 55°C) where the behavior is inverted (ß curves below ß' curve), highlighting that solid liquid equilibrium can clarify different behaviors in TAG systems. For ß' and ß equilibrium, initial compositions given by stability analysis were used.

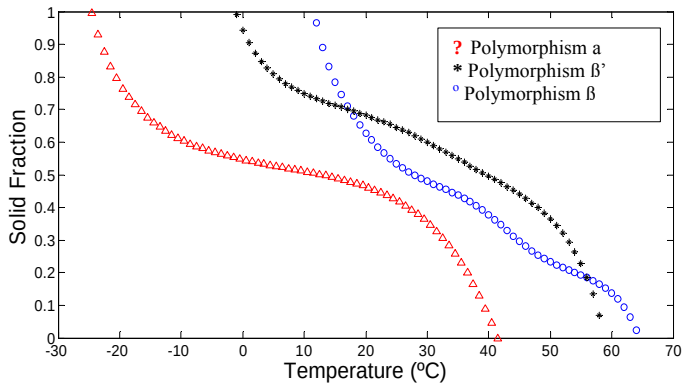

Figure 2: Melting curves for 3 polymorphic states (Mixture 1).

In Figure 3, mixture 1 was simulated using two different compositions, both in ß form: Composition 1 is [0.05;0.05;0.2;0.3;0.06;0.1;0.05;0.05;0.14] while composition 2 is [0.1;0.1;0.1;0.5;0.05;0.05;0.03;0.03;0.03]; therefore, in composition 2 half of the system is made by TAG OOO (formed by three oleic acids), which is highly unsaturated (low melting points). Thus, it can be observed the large influence of these unsaturations in the melting profile of the mixture (lower solid contents for all temperature range).
Resolution of solid-liquid equilibrium can also give useful information about the influence of TAG structures in the melting profile of the mixtures. In order to achieve this, mixture 1 was modified: TAG MMM (14:0) was substituted for LLL (12:0)-mixture 2 and for CCC (10:0)-mixture 3. As the carbon number decreases, the melting points are lower (for same degree of unsaturations); thus, a lower solid fraction for a given temperature is expected, what can be observed in Figure 4. This is true especially between 0°C and 20°C: in the final regions of solidification (more than 80 % of solid) and final region of melting (more than 70 % of liquid), the curves are very similar. Even in the middle regions, the difference is not large as the structure of these mixtures is quite similar. However, the curves reveal the sensibility of the model even for small changes in molecular structures.

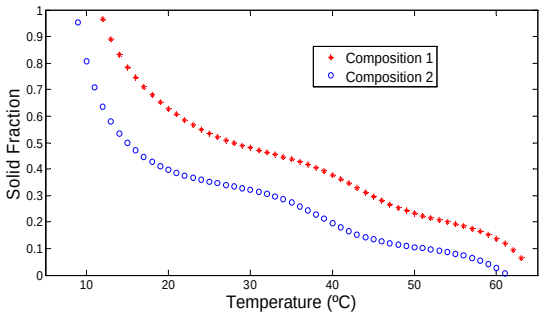

Figure 3: Influence of composition in melting curves (mixture 1; ß state).

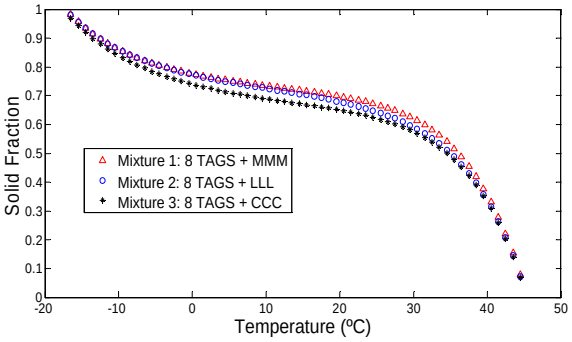

Figure 4: Melting curves for 3 mixtures differing of one TAG.

5. Conclusions

Melting and solidification behavior of triacylglycerol mixtures has a great importance for quality assessment of many products. The resolution of solid-liquid equilibrium with polymorphisms for triacylglycerol systems reveals useful information about melting and solidification profile of these complex mixtures. The effect of changes in mixture

composition or small changes in molecular structures can be observed by solid fractions in different temperatures. The technique has showed potential use for theoretical predictive capacity for new mixtures. However, the very large numbers of possible molecules that can be formed by fatty acids in a glycerol backbone requires the use of simulated melting curves coupled with optimization techniques in a Computer Aided Mixture Design environment for triacylglycerols. Besides this, other stability methods (as interval methods) must be tested in order to compare its robustness and the independence of phase split detection in relation to initialization, for using in multi-solid phase problems. Further DSC curves simulations can also be assessed by SLE, and experimental curves can be used as model validation.

The move towards the molecular level for product design is a major trend and challenge for Process System Engineering (PSE) in the future (Grossmann and Westerberg, 2000) and lipid-based products can take advantage of thermodynamic modelling of their phase behavior, allowing to achieve new products with improved functional properties and sustainability principles, as natural resources of triacylglycerols and fatty acids are renewable and provide alternative products using glycerol structure.

Abstract

The final goal of this research is to establish a systematic design method of T-shaped microreactors (T-MRs) with secondary flow using a reduced-order model (ROM). In this paper, a ROM which combines computational fluid dynamics (CFD) model and multi-resolution lamellar model is developed. Multi-resolution lamellar model is constructed from the *N* kinds of lamellar models with different width of layers. In each lamellar model, thin multi-layers of two fluids are arrayed alternately at the entrance of the mixing channel to express the increased material interface, and the concentration profiles in the flow direction are estimated by a reaction diffusion simulation between thin layers under the assumption of plug flow. The developed ROM requires the minimum number of CFD pre-simulations to extract model parameters such as weighting coefficients for superimposing different lamellar models. The main findings are: 1) the complicated mass transport processes of T-MRs obtained by 3-D CFD model is well captured by the ROM of 2-D, which is constructed from multi-resolution lamellas, and 2) the computational time based on the ROM is shortened to one-third of that based on just CFD model.

Keywords: microreactors, design, model order reduction, computational fluid dynamics.

1. Introduction

Microreactors can achieve the higher yield and selectivity of a product owing to their advantages of rapid mixing, high heat transfer rate, and precise residence time control. Although various microreactors have been proposed so far, their design depends on trial and error. Unless this situation is improved, the design period cannot be shortened. In the previous work by the authors, the microreactor design method based on computational fluid dynamics (CFD) model was proposed. CFD simulation provides the highly accurate detailed information on temperature and concentration distributions in microreactors without conducting experiments. However, it is not very practical to repeat CFD simulation for designing microreactors because of its heavy computational load. From this viewpoint, model reduction is required to obtain computationally tractable and physically meaningful models.

The secondary flows appear at the junction of T-shaped microreactors (T-MRs) under high throughput operation, increase the contact area between the mixing species, and accelerate the mixing rate (Bothe et al., 2006). The efficient mixing of T-MRs is confirmed through CFD simulation, whose main conditions and results are shown in Fig. 1. In order to efficiently design T-MRs, it is not practical to directly apply CFD

simulation to the T-MR design problems. The development of a reduced-order model (ROM) of T-MRs with secondary flow is effective in reducing the computational time for designing the T-MRs. This paper shows results of study toward the final goal of establishing a ROM-based design approach of T-MRs.

2. T-shaped microreactor (T-MR)

The fluid dynamics around the junction of T-MRs is complicated due to the generation of secondary flow, and it is difficult to analyze it without CFD simulation. As shown in Fig. 1, the concentration distribution greatly changes from the cross section ① to ③. On the other hand, there are few differences between concentration distributions on cross sections ③ and ④. This simulation result suggests that the complicated flow develops and becomes laminar along the mixing channel of T-MRs and that the convective mixing changes to the diffusion mixing.

In this research, the CFD model and the lamellar model are used as ROM. Diffusion and reactions in the mixing channel are modeled as reaction-diffusion simulations between thin layers. The two-dimensional concentration distributions on the cross sections are modeled as the one-dimensional distributions with two kinds of thin layers arrayed alternately at the entrance of the mixing channel as shown in Fig. 2. Thinner layers cause more rapid mixing. The concentration profiles under laminar flow condition in the flow direction are estimated by the lamellar model based on the reaction-diffusion simulations. As the first step of building the lamellar model, CFD simulation of mixing and reaction around the junction of the T-MR with secondary flow is conducted. Then, the lamellar model, which can estimate concentration profiles along the mixing channel, is constructed. Equation (1) is the governing equation of reaction-diffusion simulation under the assumptions of uniform flow and no axial diffusion.

$$u\frac{\partial C_i}{\partial x} = D\frac{\partial^2 C_i}{\partial y^2} + r_i \tag{1}$$

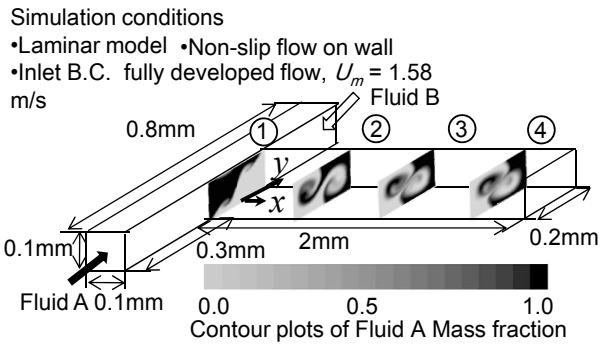

Fig. 1 Simulation conditions and results.

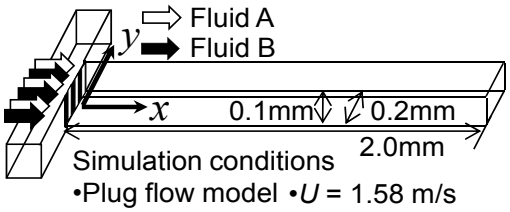

Fig. 2 Simulation of diffusion and reactions between the thin layers.

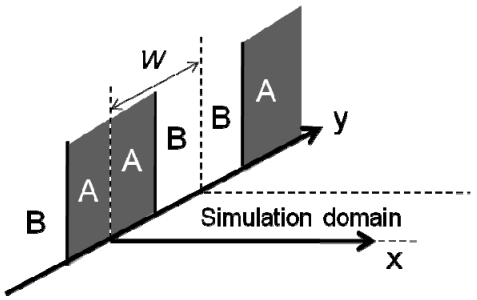

Fig. 3 Reaction-diffusion simulation domain.

where C_i denotes concentration of material i, x the position in the flow direction, y the position in the direction perpendicular to the flow direction, u flow velocity, D diffusion coefficient, and r_i reaction rate of material i. Equation (2) shows the boundary conditions of the reaction-diffusion simulation when width of layers is equal to W as shown in Fig. 3.

$$\text{B. C.} \quad \begin{aligned} &\frac{\partial C_i}{\partial y} = 0 && \text{at } y = 0, W \\ &C_A = C_{A0}, C_B = 0 && \text{at } x = 0, 0 < y \le W/2 \\ &C_A = 0, C_B = C_{B0} && \text{at } x = 0, W/2 < y < W \end{aligned} \tag{2}$$

where C_{i0} denotes concentration of material i at the entrance of mixing channel. The diffusional mixing and reactions in one-dimensional concentration distribution with single width of layers are analyzed by solving Eq. (1) under the boundary conditions shown in Eq. (2). In this research, Eq. (1) is solved with gPROMS®. However, the concentration distributions on the cross sections of T-MRs cannot be modeled with the arrayed layers having the same width because they consist of various scales of segregation. In order to express the concentration distributions, the lamellar model is constructed from the N kinds of reaction-diffusion simulations with single width of layers. In each simulation, the width of layers is different from those in the other simulations. The profiles of mass fractions of the lamellar model are given by Eq. (3):

$$F_{\mathrm{LM}}(i,x) = \sum_{n=1}^{N} a_n f_n(i,x) \tag{3}$$

$F_{LM}(i, x)$ denotes mass fraction of material i at position x in the flow direction. $f_n(i, x)$ denotes mass fraction of material i at position x in the flow direction in n-th reaction-diffusion simulation, where the width of layers is equal to W_n. a_n denotes the weighting coefficient of the result of n-th reaction-diffusion simulation. The values of weighting coefficients are determined as the solution of the minimization problem defined by Eq. (4):

$$\min_{a_n} \quad J = \frac{\sum_{i,k} \sqrt{\left(F_{CFD}(i, x_k) - F_{LM}(i, x_k)\right)^2}}{I\ K} \qquad \text{s. t.} \quad 0 \le a_n \le 1, \quad \sum_{n=1}^{N} a_n = 1 \tag{4}$$

J is the mean absolute error of mass fractions between the result of CFD simulation and the result estimated by the lamellar model. $F_{CFD}(i, x_k)$ denotes the CFD simulation result of mass fraction of material i at position x_k in the flow direction. I denotes the number of chemical species. K denotes the number of points in the flow direction for calculating the errors of mass fractions. The positions in the flow direction for calculating the errors of mass fractions have to be chosen. It is difficult to express the convective mixing and reaction with reaction-diffusion simulations between thin layers. Therefore, the positions for calculating the errors of mass fractions have to be where there is little effect of secondary flow on mixing and reactions.

3. Case study

The validity of the lamellar model is confirmed through a case study. At first, the lamellar model of the T-MR is constructed from the result of CFD simulation analyzing T-MR with 2 mm long mixing channel as shown Fig. 1. Then, the profiles of mass fractions between 2 mm and 10 mm in the mixing channel length are estimated by the constructed lamellar model. The estimated profiles are compared with the results of CFD simulation of mixing and reaction in the TMR with 10 mm long mixing channel. As the reaction system, the following competitive-consecutive reaction scheme is considered.

$$\begin{aligned} &\mathrm{A} + \mathrm{B} \rightarrow \mathrm{R} \quad && r_1 = k_1 C_A C_B \quad && k_1 = 18\ \mathrm{m^3/(kgmol \cdot s)} \\ &\mathrm{B} + \mathrm{R} \rightarrow \mathrm{S} \quad && r_2 = k_2 C_B C_R \quad && k_2 = 15\ \mathrm{m^3/(kgmol \cdot s)} \end{aligned} \tag{5}$$

The physical properties of Fluids A, B, R, and S are same with those of water at 300 K. Molecular weights of A, B, R, and S equal to 18, 18, 36, and 54 respectively. The positions x_k selected to calculate J are given at intervals of 0.1 mm between x_k = 1.3 mm and x_k = 2.0 mm. The solution of the minimization problem defined by Eq. (4) is found through comparing the values of J among all combinations of values of weighting coefficients, which are assumed to range from 0 to 1 at the 0.05 interval.

The lamellar model based on five kinds of reaction-diffusion simulations, i.e. N = 5, W_1 = 1 μm, W_2 = 6 μm, W_3 = 15 μm, W_4 = 50 μm, and W_5 = 100 μm, is abbreviated as LM-5. In addition, the lamellar model based on single width layers, i.e. N = 1 and W_1 = 6 μm, is abbreviated as LM-1. The width of layers of the LM-1 is determined so that the value of J is the smallest of all lamellar models when N = 1. The profiles of mass

fraction R of LM-5 (F_R LM-5), LM-1 (F_R LM-1), and CFD simulation result (F_R CFD) are plotted in Fig. 4. In addition, the values of J and J^*, the mean absolute error of mass fractions between 2 mm and 10 mm in the mixing channel length, are listed in Table 1. J^* is calculated by Eq. (6):

$$J^* = \frac{\sum_{i,k^*} \sqrt{\left(F_{\mathrm{CFD}}(i, x_{k^*}) - F_{\mathrm{LM}}(i, x_{k^*})\right)^2}}{I\ K^*} \tag{6}$$

The positions x_k^* selected to calculate J^* are given at intervals of 1 mm between $x_k^* = 2$ mm and $x_k^* = 10$ mm. K^* denotes the number of the selected positions to calculate J^*. The weighting coefficients of LM-5 are listed in Table 2.

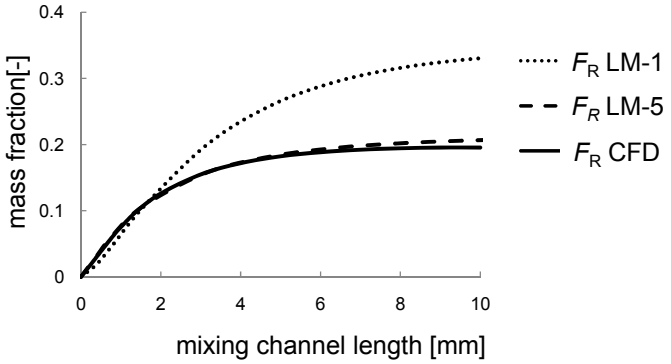

Fig. 4 Estimation results.

Table 1 Values of J and J^*

	LM-1	LM-5
$J \times 10^3$	4.53	2.04
$J^* \times 10^2$	8.76	0.95

Table 2 Weighting coefficients

n	W_n	a_n
1	1 μm	0.30
2	6 μm	0.20
3	15 μm	0.05
4	50 μm	0.20
5	100 μm	0.25

In Fig. 4, the profiles of F_R LM-5 (dashed line) and F_R CFD (solid line) are very similar between 2 mm and 10 mm in the mixing channel length, though the profile of F_R LM-1 (dotted line) is quite different from the others. Figure 4 clarifies that the model accuracy of LM-5 is much better that of LM-1. In addition, Table 1 shows that values of J and J^* of LM-5 are smaller than those of LM-1. That is, the model accuracy of the lamellar model is improved by using various kinds of widths of layers. Table 2 shows that various widths of layers are used in LM-5 to express the concentration distributions on the cross sections.

4. Conclusions

In this research, the ROM of T-MRs, which is based on the CFD model and the multi-resolution lamellar model, is proposed. The lamellar model is constructed from the results of the reaction-diffusion simulations to minimize the mean absolute error of mass fractions, J. Through the case study, it is confirmed that the lamellar model can estimate the profiles of mass fractions in the mixing channel of T-MRs accurately.

Novel Molecular Design Technique using Property Operators based on Signature Descriptors

Nishanth G. Chemmangattuvalappil, Charles C. Solvason,
Susilpa Bommareddy, Mario R. Eden
Department of Chemical Engineering, Auburn University, Auburn, AL 36849, USA

Abstract

In this work, we are introducing an algorithm that uses molecular signature descriptors for reverse problem formulations. This algorithm utilizes molecular property operators based on signatures for solving the reverse problem of obtaining the molecular structures corresponding to the property targets estimated during the process design step. The algorithm allows property models based on different Topological indices (TI) and group contribution models to be represented on the same property platform.

Keywords: Molecular design, Signature description, Reverse problem.

1. Introduction

1.1. Reverse problem formulation

Reverse problem formulation (RPF) is a technique used to reduce the complexity of integrated process and product design problems (Eden et al., 2004). The complexity of such problems is due to the non-linearity of property models. To overcome this issue, the single forward problem is broken down into two reverse problems. The first reverse problem provides the property targets to achieve optimum process performance and the second reverse problem is used to generate the molecular structures that meet the property targets. To track properties, property operators are used which are functions of the original properties tailored to obey linear mixing rules. The normalized property operator, Ω_{js} is obtained by dividing it by a reference value (Shelley and El-Halwagi, 2000). If $\psi_j(P_{js})$ is the property operator of the j^{th} property P_{js} of stream s, x_s is the fractional contribution, N_s is the number of streams:

$$\Omega_{js} = \frac{\sum_{s=1}^{N_S} x_s \psi_j(P_{js})}{\psi_j^{ref}} \qquad (1)$$

1.2. Molecular signature descriptors

Molecular signature is a molecular descriptor used for representing the atoms in a molecule using the extended valancies to a pre-defined height (Visco *et al.,* 2002, Faulon *et al.,* 2003a). If G is a molecular graph and x is an atom of G, the atomic signature of height h of x is a canonical representation of the sub graph of G containing all atoms that are at a distance h from x. The detailed procedure for generating signature can be found in the work published by Visco *et al.* (2002) and Faulon *et al.* (2003a). Since atomic signatures up to a given height are of finite size, any molecule can be uniquely represented with its atomic signatures. The signature of a molecule is defined

as the linear combination of its atomic signatures (Visco *et al.,* 2002, Faulon *et al.,* 2003a). The signatures produce meaningful QSPR/QSARs and accuracy of these descriptors is comparable to the existing TIs (Visco *et al.,* 2002, Faulon *et al.,* 2003a). The reason for this correlation is that many of the TIs can be derived from the molecular signature. Faulon *et al.,* (2003a) have provided the relationship between TIs and signatures:

$$TI(G) = k \cdot {}^{h}\alpha_G \cdot TI(root({}^{h}\Sigma)) \tag{2}$$

Here, k is a constant, ${}^{h}\alpha_G$ is the vector of occurrences of atomic signature of height h and TI(root (${}^{h}\Sigma$)) is the vector of TI values calculated for each root of atomic signature.

2. Reverse problem formulation using molecular signatures

Since many existing QSPR expressions can be reformulated in terms of molecular signatures, algorithms based on signatures will be able to track a wide variety of property targets. In addition, algorithms are available to obtain the molecular structures once the solution to RPF is available as signatures (Faulon *et al.,* 2003b).

2.1. General problem statement

Identify the non-cyclic molecules with the best dominant property, which also satisfy a set of property constraints. The first step is to identify the QSAR/QSPR expressions corresponding to all the given properties/activities. In the next step, identify the heights of molecular signature corresponding to the TIs used in QSPR. If θ is the property function of property *P,* the property operator corresponding to *P* is estimated as follows:

$$\theta = f(TI) \tag{3}$$

$$TI = \sum_{i=1}^{N} {}^{h}\alpha_i \cdot TI(root({}^{h}\Sigma)) = \sum_{i=1}^{N} {}^{h}\alpha_i L_i \tag{4}$$

$$\psi(P) = \sum_{i=1}^{N} x_i L_i \tag{5}$$

The dominant property, which is expressed in terms of the occurrences of atomic signatures, can be maximized or minimized subject to the property constraints. If Ω_j is the property operator corresponding to the dominant property and Ω_{ij} is the normalized property operator of molecule *i*, an optimization problem can be formulated as follows:

$$Max / Min \ \ \Omega_j \tag{6}$$

$$\Omega_j^{\min} \le \Omega_j \le \Omega_j^{\max} \tag{7}$$

To ensure that the molecule will be formed without any free bonds, the *handshaking lemma* from graph theory is used (Trinajstic, 1992). For a graph without any circuits, if *D* is the number of degrees of each vertex *i* and *V* is the number of vertices:

$$\sum_{i=1}^{N} D(i) = 2(V-1) \tag{8}$$

In order to differentiate between different types of atoms, vertex coloring has been used. The coloring function has to be selected based on the types of atoms and the nature of the final molecule. For instance, in the design of an alkane molecule, the coloring function is the degree of carbon atoms at all levels. The coloring should start from the root atom to all atoms up to level *h-1*. An example is shown below:

C(C(CC(CCC))CC(C(C)C(CC)C))→ C3(C3(C1C4(CCC))C1C4(C2(C)C3(CC)C1))

In a complete molecule, since each edge is shared by two vertices, the colors of the edge that joins the two vertices must be the same for both vertices. However, the order of colors will be different for both the vertices since the reading of color has to start from the root. For instance, consider the signatures, C1(C2) and C2(C1). Here, the reading of colors is 1→2 in the first signature where as it is 2→1 for the second signature. The presence of both edges ensured that there is a linking between the vertices. While writing the atomic signature, only one atom is being described by relating it to its neighboring atoms at different levels of neighborhood. Therefore, every color sequence of edges between two heights must be complemented by another signature having one edge with the same colors in the reverse order. If $(l_i \rightarrow l_j)_h$ is one coloring sequence $l_i \rightarrow l_j$ at a level *h,* then:

$$\sum (l_i \rightarrow l_j)_h = \sum (l_j \rightarrow l_i)_h \tag{9}$$

If the color sequence in one signature is $l_i \rightarrow l_j$ with $i=j$, then, there must be another signature present in the set of signatures with the same color sequence to complement the previous one. If η is the number of color sequences $l_i \rightarrow l_j$ on one signature with $i=j$ and x is the number of such color sequences and K is an integer, then:

$$\sum_{i=j} \eta_i x_i = 2K \tag{10}$$

In order to form a connected tree, it must be ensured that the total number of signatures, where the degree of the vertex at a higher level is more than the degree at a lower level should be less than the total number of vertices with the higher degree. If n_i is the number of child vertices with a higher degree than the parent vertex, i and j represents the child and parent colors:

$$\sum x_i n_i \leq \sum x_j \tag{11}$$

The dominant property function can be maximized or minimized subjected to the constraints. The signatures obtained will form the best molecule. In order to form other feasible molecules, integer cuts can be used. The algorithm developed by Faulon *et al.* (2003b) can be used to enumerate the molecules from the identified signatures.

2.2. Expression of group contribution (GC) models with signatures

In GCM, the property function of a compound is estimated as the sum of property contributions of all the molecular groups present in the molecular structure. The molecular signatures of sufficient height can be used to re-write GC expressions. This transformation will allow us to solve the property models based on TIs and GC models simultaneously. The height and number of the signature used to write the molecular groups in the GC model depends on the number of atoms and the nature of final molecule. Consider the design of a molecule with amine and alkyl groups. The maximum number of amine groups on each alkyl group and attached carbon atom on

each amine group is limited to one. The potential groups available in GCM are (Marrero and Gani, 2001):

CH_2 NH_2 CH_2NH_2 $CHNH_2$ CNH_2 CH_3 CH_2 CH C

The root atom on every signature can be colored with two numbers - the first color is the number of neighboring C atoms and the second color is the number of neighboring N atoms. Signature of height 2 is required for complete coloring. All signatures with root N can be used to re-write different amine groups. If the neighboring C atom of an N root has three neighbors, then, the root N atom will be equivalent to a CNH_2 group. Similarly, all N root signatures can be assigned the property contributions of CH_2NH_2 and $CHNH_2$ groups based on the colors of their nearest neighbors. The signatures with root C atoms will form the alkyl groups. Here, the signatures with root C atom having N in any of its nearest neighbor should not be considered as a group since that signature has been taken care of in the amine groups. For the rest of the signatures with root C, property contributions can be assigned based on the numbers of neighboring C atoms.

2.3. Property models with different signature heights

In a molecular design problem with multiple property constraints, different TIs may be describing different properties of interest. It is also possible to have one QSAR/QSPR containing different TIs. If the signature heights of the TIs are different, the signatures corresponding to the largest height have to be enumerated first and the number of signatures of smaller height can be obtained from the higher signatures. Consider the situation where QSPR is based on both zero and first order connectivity indices. The corresponding signatures are of heights one and two respectively. The property operator for property *Y* can be written in terms of signatures as follows:

$$Y = a_0{}^0\chi + a_1{}^1\chi \tag{12}$$

$$f(Y) = \sum_i L_i{}^1\alpha_i + \sum_j L_j{}^2\alpha_j \tag{13}$$

If the height of the largest signature of interest is *h* and height of the lower signature is *h-m,* then the total number of each *h-m* level signatures can be obtained by adding the *h* level signatures under same color at level *h-m*. For example, if the signatures of interest are N1(C), N2(CC) and N3(CCC) which are signatures with height one. Now, signatures of height two with root vertex N can be divided into three sets S_1, S_2 and S_3. The elements in these sets are signatures of height two with N vertex and vertex color 1, 2 and 3 respectively. The occurrences of signature N1(C) can be obtained as follows:

$$N(C):\ {}^1\alpha_{N(C)} = \sum_{S_1} {}^2\alpha_i \tag{14}$$

The number of occurrences of other signatures of height one is similarly estimated.

3. Case Study: Design of alkyl substituent for a fungicide

The optimal substituent selection for dialkyldithiolanylidenemalonate (DD), which was originally solved by Raman and Maranas (1998) has been reworked here. The target properties are affinity (*log* (V_E)), mobility (*log* (μ)) and retention (*log* [*R/(1-R)*]). These properties are correlated to hydrophobic factor (Uchida, 1980), which is correlated to a first order molecular connectivity index (Murray *et al.,* 1975). In this work, an additional property constraint of toxicity (LC_{50}) is included. The GCM can be used to

predict LC_{50} (Martin and Young, 2001). The property models are shown in Table 1. The objective of this case study is to identify the alkyl substituents of DD that give maximum affinity subject to the constraints based on mobility, retention and toxicity. The first order connectivity index can be re-written in terms of molecular signatures of height two (Visco *et al.,* 2002) according to Eq. 15:

$$ {}^{1}\chi = \sum_{i=1}^{K_G}\left(\frac{1}{2} \sum_{u \in {}^{l}V_2({}^{h}\chi_i)} \left[\deg(u) \deg({}^{-1}\nu_\sigma(u)) \right]^{-\frac{1}{2}} \right) x_i = \sum_{i=1}^{K_G} L_i x_i \qquad (15) $$

It is possible to form 65 signatures of height 2 with three signatures are corresponding to the CH_3- group, nine signatures corresponding to the CH_2- group, nineteen corresponding to the CH- group and thirty-four corresponding to the C- group. The property targets and the normalized property operators are shown in Table 1. The molecular design problem can be written in terms of signatures using Eqs. 16-19.

Table 1. Property operators and targets

Property	*Property model*	*Property operator*	*Ref.*	*L.B.*	*U.B.*
Mobility	$-0.6984({}^{1}\chi) + 2.0143$	$1.432(2.0143 - \log(\mu))$	1	-0.3	0.3
Retention	$0.787({}^{1}\chi) - 2$	$1.271\left(\log\left(\frac{R}{1-R} \right) + 2 \right)$	1	-0.3	1.0
LC50	$\exp\left(-\sum_{i=1}^{N} n_i \alpha_i \right)$	$-\log(LC_{50})$	1	-	0.04
Affinity	$0.5751({}^{1}\chi) - 0.2942$	$1.739(\log(V_E) + 0.2942)$	1	-	-

$$ Max\, \Omega_{V_E} \qquad (16) $$

$$ 2.455 \le \sum_{i=1}^{65} h_i x_i \le 3.314 \quad \text{(Includes the constraints on mobility and retention)} \qquad (17) $$

$$ 3.129 \le \sum_{i=1}^{3} c_1 x_i + \sum_{i=4}^{12} c_2 x_i + \sum_{i=13}^{31} c_3 x_i + \sum_{i=32}^{65} c_4 x_i \quad \text{(Constraint on LC50)} \qquad (18) $$

$$ \sum_{i=1}^{3} x_i + 2\sum_{i=4}^{12} x_i + 3\sum_{i=13}^{31} x_i + 4\sum_{i=32}^{65} x_i = 2\left[\left(\sum_{i=1}^{65} x_i \right) - 1 \right] \quad \text{(Handshaking Lemma)} \qquad (19) $$

To differentiate among different types of carbon atoms, the vertices are colored with the degree of each carbon atom. Equation 9 is applied to ensure that the signatures will complement each other. For illustration, one of the equations from Eq. 9 is shown:

$$ x_1 = x_4 + x_5 + x_6 \qquad (20) $$

Here, x_1, x_4, x_5 and x_6 are the occurrences of the signatures C1(C2(C)), C2(C2(C)C1), C2(C3(CC)C1) and C2(C4(CCC)C1). Equation 10 is used to ensure the consistency of signatures with same color sequence on same edges. An example is shown in Eq. 21:

$$x_4 + 2x_7 + x_8 + x_9 = 2K \quad (21)$$

Equation 11 ensures that the number of any color in the child level would not exceed the total number of that color when it is in parent level. One example is shown in Eq.22:

$$2x_{11} < \sum_{3\rightarrow 2} x_i \quad (22)$$

Here, x_{11} is the number of occurrences of the signature C2(C3(CC)C3(CC)). Since this signature contains two 2→3 color sequences, the total number of signatures with 3→2 sequence should be more than two times x_{11} to ensure the connected graph. Equations 16-22 are solved and the molecular structures are enumerated from the signatures using the algorithm provided by Faulon *et al.* (2003b). The solution and the estimated properties are shown in Table 2. This is the same solution as found by Raman and Maranas (1998). There are only four feasible solutions while the fifth solution in the original work is no longer valid because of the additional constraint on toxicity.

Table 2. Final solution

Affinity	Mobility	Retention	Toxicity	R_1	R_2
				methyl	3-methyl-butyl
1.608	-0.296	0.603	0.035	methyl	2-pentyl
				ethyl	*sec*-butyl
				methyl	*iso*-pentyl
1.586	-0.269	0.574	0.035	ethyl	*iso*-butyl
				n-propyl	*iso*-propyl
1.535	-0.207	0.503	0.040	methyl	2-methyl-2-butyl
1.504	-0.169	0.460	0.040	*iso*-propyl	*iso*-propyl

4. Conclusions

In this work, the molecular signature descriptors have been included in the RPF framework. The developed algorithm can include different QSAR/QSPR expressions based on multiple TIs thereby increasing the applicability of RPF. GC methods can be coupled with TI based expressions in the new algorithm. Since all property models are expressed as a function of occurrences of signatures, the problem can be solved for a single descriptor even if the TIs are described with signatures of different heights.

Process integration aspects of the design of a gas separation system for the upgrade of crude Synthetic Natural Gas (SNG) to grid quality in a wood to methane process

Martin Gassner, François Maréchal

Laboratory for Industrial Energy Systems, Ecole Polytechnique Fédérale de Lausanne, CH – 1015 Lausanne, Switzerland

Abstract

The present paper investigates the prospects of process integration of the biogenic production of crude synthetic natural gas (SNG) and its upgrade to grid quality. At the example of a separation by means of a membrane cascade, a holistic design approach targeting the overall process performances is presented. Compared to a design obtained from an isolated approach, it is shown that a considerable reduction of the size and cost of the separation system is possible if a tight process integration is considered in the system design.

Keywords: SNG, process integration, CO2 separation, membrane system design

1. Introduction

Among the possible routes for producing fuels from biomass, thermochemical processing is one of the most promising options since a complete conversion of lignocellulosic biomass is achieved. In these processes, the reactive steps are performed at high temperature and a viable process integration is crucial to obtain an efficient conversion. Several recent studies have investigated suitable technology and processes for SNG production (Mozaffarian and Zwart, 2003; Duret et al. 2005; Gassner and Maréchal, 2005; Heyne et al., 2008; Luterbacher et al., 2008), the necessary gas upgrading step has however not received much attention. The present paper investigates this issue in more detail and aims to identify the advantages of a tight integration of the reactive steps with a gas separation system by membranes.

2. Problem statement

2.1. Crude SNG production

Representing the biomass as a chemical molecule with the carbon atom as reference, the conceptual design of its conversion into methane is based on Equation (1):

$$CH_{1.35}O_{0.63} + 0.3475\,H_2O \xrightarrow{\Delta\tilde{h}_r^0 = -10.5\,kJ/mol_{wood}} 0.51125\,CH_4 + 0.48875\,CO_2 \qquad (1)$$

Technically, the most envisaged route is to gasify the biomass and convert the producer gas into methane. Prior to gasification, the raw material is dried to below 20-25%wt humidity in order to prevent excessive losses due to water evaporation. From the current state of research and process development (Mozaffarian and Zwart, 2003; Stucki, 2005), it is expected that the first installations will be based on indirectly heated fluidised bed gasification of FICFB-type that has been developed and commercialised by (Hofbauer

et al., 2002). Due to the presence of dust, tars and catalyst poisons like sulphur compounds, the producer gas is cleaned before entering a catalytic fluidised bed reactor, where it is converted at 300-400°C to methane.
The stoechiometric equation (Eq. 1) shows that the overall conversion of wood to methane is exothermic and releases about 450 kJ/kg_{wood} of heat. This net release is distributed over the gasification and methanation reactions. The first one is endothermic and requires heat at high temperature, whereas the second one is exothermic and releases heat at lower temperature. The process thus requires additional energy and the quality of the process integration will define the overall process efficiency. The process is pinched at the gasification temperature and about 200 - 250 kW of high temperature heat at 850 – 900°C are typically required to convert 1 MW of wood to crude SNG.
The expected gas compositions of the producer gas and the crude methanation product computed with a previously developed process model (Duret et al., 2005; Gassner and Maréchal, 2005) are reported for methanation at atmospheric pressure in Table 1.

	C_2H_4	CH_4	H_2	CO	CO_2	N_2	H_2O
Gasification	2.2	10.9	38.8	25.5	18.6	0.5	3.5
Methanation	-	44.8	5.9	0.1	45.1	1.0	3.1
- without H_2O, CO_2	-	86.4	11.3	0.3	-	2.0	-
- without H_2O, CO_2, H_2	-	97.4	-	0.3	-	2.3	-
Grid specifications		> 96	< 4	< 0.2		< 6	-8°C

Table 1: Cold gas compositions and upgrading requirements (in %vol).

2.2. Design problem definition
According to the new Swiss directive for the supply of biogas to the natural gas grid, unlimited amounts of gas can be fed to the grid if its methane content is higher than 96%vol and the CO_2, H_2 and CO content less than 6, 4 and 0.2%vol respectively, while having a dew point at grid pressure (50 bar) lower than -8°C (SVGW, 2007). Assuming that nitrogen can not be easily separated from methane, Table 1 also shows the maximum obtainable purities after complete removal of water, carbon dioxide and hydrogen. Provided that an ideal separation process for removing CO_2 from the SNG is used, the hydrogen concentration is expected to rise to around 11%. The CH_4 purity will be at best around 86%, and at least some of the unconverted hydrogen must be removed.
The identification of the minimum energy requirements of the process furthermore adds a supplementary aspect to the design problem. Gasification has a relatively important heat demand at high temperature, which is usually supplied by burning producer gas and therefore reduces the methanation flow. In the combined heat and power application for which the gasification technology has originally been developed, few other fuel alternatives are present. However, in an SNG plant that necessarily suffers from a non-ideal separation, depleted gas streams from the SNG upgrading section could be used instead of the intermediate product. The condition for this is that its flame temperature is sufficiently higher than the gasification temperature. If the depleted gas is too diluted, it must in any case be treated in a catalytic combustion to eliminate the residual methane due to its high environmental impact as a greenhouse gas.
From these considerations, it is obvious that the design of the separation system is not a trivial problem. It requires the development of an appropriate multicomponent separation system, while also considering possible cost and energy savings originating from the trade-off between using the producer gas or a depleted gas as hot utility. In the framework of the actions aimed to climate change mitigation, rather pure carbon

dioxide (95% minimum) may also represent a valuable by-product. If sequestration instead of venting the separated carbon dioxide is targeted, care must be taken not to dilute this by-product with nitrogen from combustion with air. A possible option is thereby to use oxygen produced by electrolysis in the catalytic combustion, whose by-produced hydrogen could be supplied to the methane synthesis and would increase the SNG output (Gassner and Maréchal, 2008b). A general block flow diagram of these different upgrading options is given on Figure 1.

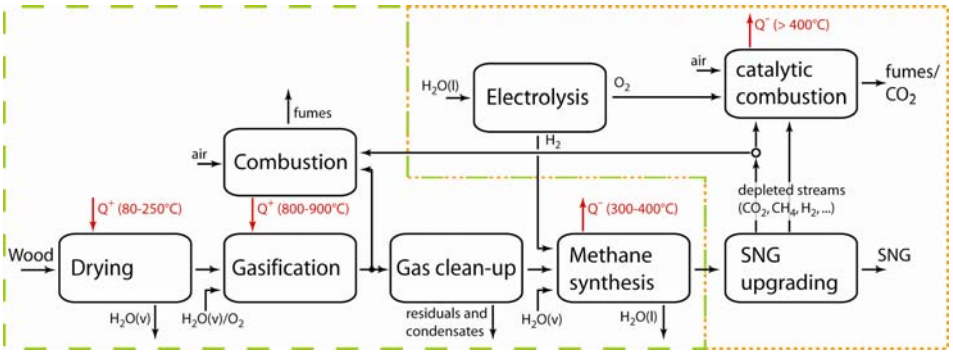

Figure 1: Block flow diagram of the crude SNG production (dashed) and upgrading (dotted) units.

3. Process integration study

3.1. Modelling

According to the applied design methodology (Gassner and Maréchal, 2008a), its thermodynamic part is divided into an energy-flow and an energy-integration model. In the energy-flow model, the thermodynamic conversions occurring in the different process units are modelled with a commercial flowsheeting tool (Belsim SA, 2007). The heat requirement of the process units is transferred to the energy-integration model, where the energy conversion and heat transfer system is determined by a mixed integer linear programming model targeting minimum operating costs with respect to the minimum approach temperature constraints. The thermodynamic conditions are then considered as design targets for the process equipment, which is then rated and costed by design heuristics and data from existing experimental and pilot plant facilities.

In order to investigate the impact of process integration on the optimal design of the separation system and the reactive sections of the plant, multi-stage membrane separation has been chosen among the identified candidate technologies for a detailed modelling. According to the theory of gas separation by membranes, a practical description of the permeation process through a membrane is to consider the difference of partial pressure in the bulk as driving force (Hwang and Kammermeyer, 1975). Using a phenomenological constant termed permeability P_i, the permeation of species i is described as:

$$\frac{d\dot{n}_{i,p}}{dA} = \frac{P_i}{\delta} \cdot \left(p_{i,r} - p_{i,p}\right) \qquad (2)$$

where $\dot{n}_{i,p}$ is the partial molar flow of i that permeates the membrane, A the membrane area, δ its thickness, and $p_{i,r}$ and $p_{i,p}$ the partial pressure on the retentate and permeate side, respectively. The selectivity $\alpha_{i,j}$ of the membrane between two different species i and j is defined by the ratio of their respective permeabilities P_i/P_j.

As the permeation is described by a set of *i* differential equations of the same type as Eq. 2, its resolution depends on the flow pattern of the membrane. Except for the simple case of perfectly mixed permeate and retentate chambers, no analytic solutions have been reported for multicomponent systems, but some simplified analytic or numeric procedures have been suggested. For flowsheet calculations, a simplified algebraic design model for hollow-fiber modules in counter-current operation developed and validated by Pettersen and Lien (1994) proves to be appropriate and has been implemented in the process model.
With the properties of commercially available membranes (Table 2), a single membrane stage is generally not sufficient to reach the required purity and an acceptable recovery of the crude SNG. Several membrane stages must therefore be cascaded, and a multitude of possibilities for the feed location, membrane connections and intermediate product withdrawals to be used as hot utility exist. From a first screening of all the possible cascades schemes, a superstructure of the most promising flowsheets has been defined (Figure 2) and is subjected to the process optimisation.

P_{CO2}	9 barrer	$\alpha_{CO2,H2}$	3.42 -
δ	1000 Å	$\alpha_{CO2,CH4}$, $\alpha_{CO2,CO}$, $\alpha_{CO2,N2}$	21.1 -

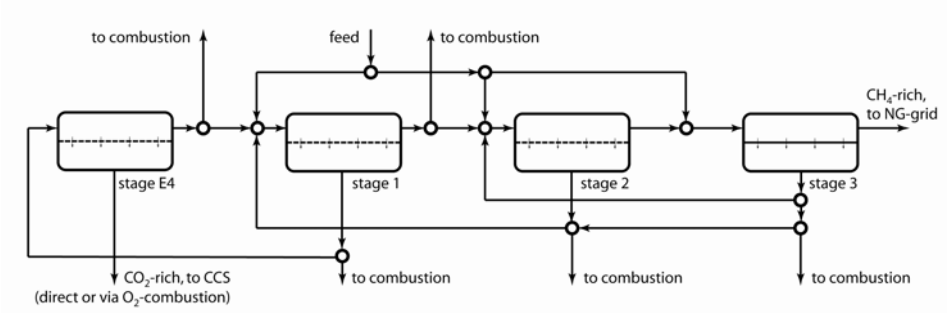

Figure 2: Superstructure of the membrane system.

3.2. Comparison of different levels of process integration

3.2.1. Approach

In order to investigate the influence of the level of integration on the process performance, the separation system is optimised by applying two different strategies. In a first approach, only the isolated performance of the separation system is considered in the optimisation, which represents a sequential design of the production and separation steps without considering the possible synergies resulting from the integration. For this purpose, the thermo-economic indicators are defined to only assess the performance of the separation system. According to its system boundary represented by the dotted line on Figure 1, the performance of the separation is evaluated by its energy efficiency (Eq. 3) and the total cost for the crude SNG separation (Eq. 4):

$$\varepsilon^{sep} = \frac{\Delta h^0_{SNG}\dot{m}^-_{SNG}}{\Delta h^0_{crudeSNG}\dot{m}^+_{crudeSNG} + \dot{E}^{sep,+}} \quad (3); \qquad C^{sep}_p = C^{sep}_{I,d} + C^{sep}_M + C^{sep}_{el} + C^{sep}_{RM} \quad (4)$$

In these equations, Δh^0 terms the heating value of the streams, $\dot{m}$ their mass flows and $\dot{E}$ the electricity consumption. The superscript ^{sep} stands for the separation system, and $^-$ and $^+$ refer to positive output and input terms, respectively. $C_{I,d}$, C_M, C_{el} and C_{RM} represent the depreciated investment, maintenance, electricity and raw material's cost. For the separation system, the latter is calculated by the difference of the energy content between the crude and grid quality SNG. The energy in the depleted streams is therefore considered as lost.
In contrast to this approach targeting only the separation performance, a second set of indicators that represent the whole system performance is defined. The overall system efficiency (Eq. 5) and the production cost for grid-quality SNG (Eq. 6) are used:

$$\varepsilon = \frac{\Delta h^0_{SNG}\dot{m}^-_{SNG} + \dot{E}^-}{\Delta h^0_{wood}\dot{m}^+_{wood} + \dot{E}^+} \qquad (5); \qquad C_p = C_{I,d} + C_M + C_{OL} + C_{el} + C_{RM} \qquad (6)$$

With this formulation, the energy efficiency accounts for the possibility of co-producing electrical power $\dot{E}^-$, and the production cost includes the cost of operating labour C_{OL}. Furthermore, the raw material's cost C_{RM} considers only the expenses for wood, which implies that the depleted gas is treated on-site and might provide useful heat for the system. Since the evaluation of these overall properties in the separation design requires knowledge and data of the whole system, this approach represents a simultaneous design of the crude SNG production and its upgrading. The dotted and dashed parts on Figure 1 are thus considered simultaneously, and advantages due to the process integration with respect to the energy and material streams are accounted.

3.2.2. Optimisation results and discussion

In order to generate a complete set of optimal configurations, a multi-objective optimisation of the product recovery, power consumption and investment cost as objectives is performed, where the membrane system layout, the stage cuts and its operating pressures are used as decision variables. Figure 3 shows the obtained performance indicators for the best system layouts of the superstructure. From these plots, considerable qualitative and quantitative differences in the performance of the isolated membrane cascade and the overall system is observed. The isolated optimisation clearly suggests a 3 stage countercurrent cascade with about 94% of SNG recovery in the separation step. However, from an overall system point of view, it is sufficient to only recover about 84% of the crude SNG in a less costly system with only one recycle loop. For the overall system, a mediocre performance of the separation step is not penalising. With a non-negligible fraction of methane and hydrogen in the depleted stream (20%vol in total), its flame temperature remains sufficiently high to supply heat above the high temperature pinch, and less producer gas must be used for this purpose. Due to the advantageous process integration, considerably less electrical power is consumed in the separation (67 instead of 82 kW_{el}/MW_{SNG}) and a much smaller membrane system (230 instead of 363 $m^2/MW_{crudeSNG}$ in total) is required.

4. Conclusions

By implementing a thermo-economic model for multicomponent membrane gas separation in a process model for SNG production, the process integration of the gas separation with its production has been investigated. It has been shown that a holistic approach provides a qualitatively different and more advantageous process design than separately addressing the crude SNG production and its separation. Using the residual methane and hydrogen in the depleted stream as fuel for the process, it is possible to considerably reduce the size and cost of the gas upgrading system.

The application of a task-based concept for design of innovative industrial crystallizers

Richard Lakerveld[a], Herman J.M. Kramer[a], Peter J. Jansens[a], Johan Grievink[b]

Abstract

A new task based approach is applied to design a solution crystallization process unit. Task-based design involves the conceptual built-up of a process (unit) from functional building blocks called tasks, which represent fundamental physical events. The motivation is to get a better control over the physical events governing crystalline product quality. To deliver a proof of concept, two lines of research are followed. First of all, several small scale experiments are designed to demonstrate practical feasibility of the approach. The new lab-scale equipment allows for isolation and manipulation of individual crystallization tasks. Secondly, a model based on the experimentally tested tasks is developed for a crystallizer design and used for dynamic optimization in batch mode of product quality with minimum energy consumption. The results show that a task based crystallizer is capable of keeping the state variables very closely to ideal values, which is the direct result of the ability to control the rates at which individual crystallization tasks are executed as well as the material flows between those tasks.
Keywords: Crystallization, Process Synthesis, Task Based Design, Optimization.

1. Introduction

Crystallization is one of the oldest and economically most important separation and product formation technologies. The design of crystallization processes still poses many challenges despite its wide application. The selection of crystallization equipment is traditionally done from a limited number of state-of-art crystallizers followed by optimization of that particular type of equipment. Present industrial crystallizers harbor many physical phenomena such as primary nucleation, crystal growth, generation of supersaturation, and attrition. Optimization of each of these individual physical phenomena is not well possible because in present industrial crystallizers these phenomena are strongly entangled. This lack of control over physical phenomena causes crystallizers to exhibit complex process behavior and limits flexibility for both design and operation. The physical phenomena are however of key importance as in the end they determine the properties of the crystalline product and also the efficiency in terms of energy consumption. Therefore there is a need for a design approach which considers the important phenomena as starting point for design rather than the equipment itself. This contribution discusses the application of a task based design (TBD)(Menon, 2007).

In TBD an attempt is made to conceptually construct the crystallization process from fundamental building blocks called physical tasks (comparable to Kondili et al. 1993). In principle the TBD approach for solution crystallization can be embedded in existing generalized frameworks for the representation of superstructures and optimization models in process synthesis such as derived by Yeomans & Grossmann

(1999). For crystallization processes it is however difficult to specify physical devices that will execute a single crystallization task as current crystallizers facilitate many of those tasks simultaneously and the control of individual tasks is not well possible. Therefore, the first part of this paper summarizes the key results of small scale experiments with newly built dedicated equipment showing that it is possible to isolate and optimize single crystallization tasks. The results, of which detailed descriptions are described elsewhere (Lakerveld 2008[a,b,c]), demonstrate the practical feasibility of the approach showing the isolation and optimization of the crystallization tasks supersaturation generation, nucleation and growth. In the second part of this paper a model based on the experimentally tested tasks is developed for a task based crystallizer design and used in dynamic optimization of a batch case study tailored towards optimizing product quality. The results show that simply by changing the operational policy, a tight control over product quality is possible.

2. Experimental isolation of single tasks

The control over a single crystallization task means in practice that the operating conditions in a physical device must be tailored such that the resulting driving forces enable a specific task to be dominant. Figure 1 shows for a number of fundamental crystallization phenomena qualitatively at which driving force the kinetic rate is being maximized (task-impact diagram). It reveals partly why it is inherently difficult to optimize the driving force for each of the tasks in current well mixed crystallizers. To tightly control and possibly enlarge the window of operation for a selected key crystallization task, new equipment and methods are needed.

1. For tight control over the generation of supersaturation, a membrane based crystallization process. It gives more flexibility and better control over solvent removal to optimize the driving force of a selected task, most importantly crystal growth. Membranes can be placed at any location in the design of future crystallizers and can be applied outside boiling conditions.
2. To generate new nuclei, ultrasound as a new method to induce nucleation. Ultrasound uses pressure as driving force and can therefore be applied at global low supersaturation. In this way, it helps to disentangle the task-impact diagram (Figure 1) by adding a new driving force, to the diagram.
3. For separation of the task growth and attrition, a bubble column and airlift crystallizer as new equipment for avoiding regions exhibiting large shear forces. It prevents unwanted operation in the upper part of the task-impact diagram where attrition and growth, two counter effective tasks, interfere.

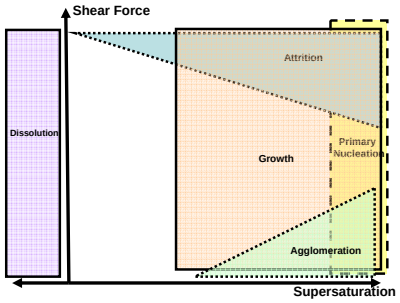

Figure 1: Task- impact diagram qualitatively illustrating for two main driving forces the rate of execution of selected tasks

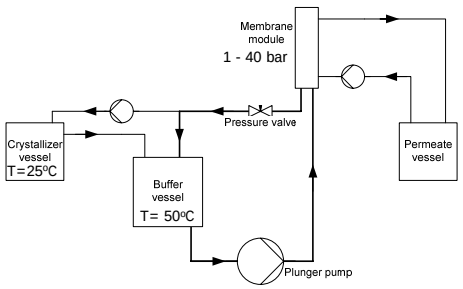

Figure 2: Process flow diagram experimental setup combining crystallization and reverse osmosis

2.1. Tight control over the generation of supersaturation

The first objective of the experimental work is related to tight control of supersaturation at any location in a future crystallizer to prevent spontaneous nucleation bursts and to maximize crystal growth. Membranes can selectively remove the solvent and offer an interesting opportunity to control supersaturation gradients in new crystallizer designs (see for example Tun et al. 2005). Potentially they can also contribute to reduced energy consumption as an expensive vapor liquid equilibrium can be avoided. An experimental setup (Figure 2) was constructed and tested for both an NH_4SO_4 water system and an adipic acid water system to assess the potential application of reverse osmosis (RO) membranes for crystallization processes (Lakerveld et al. 2008[a]). It showed practical feasibility of the concept and typical values for mass flux over the membrane are used in the next section for design.

2.2. Experimental isolation of task Nucleation

Ultrasound is an interesting tool to induce nucleation at low supersaturation in a controlled way (e.g. Virone et al., 2006). The applicability of ultrasound was illustrated in experiments in which an ultrasound generator was placed inside a supersaturated solution of an NH_4SO_4 water system. The supersaturation was kept low to avoid spontaneous nucleation. The objective of the experiments was to relate the power input and insonation time to the number of nuclei produced. It was concluded that nuclei could be generated at low supersaturation. The nucleation rate could be optimized, by changing the power input and insonation time (Lakerveld et al. 2008[b]).

2.3. Experimental isolation of task Crystal Growth in air mixed devices

To isolate the task Crystal Growth a physical environment is needed which can minimize attrition as attrition increases crystal surface area, which competes for growth with the existing crystals. The environment that was selected consisted of a bubble column in which supersaturation was created by simultaneous cooling and evaporation of the solvent by sparging air (Lakerveld et al., 2008[c]). The crystals were kept in suspension by the upward velocity of the bubbles, eliminating the need for a stirrer or a circulation pump. In this way, attrition caused by collisions between crystals and moving mechanical parts was absent. Seeded batch experiments in a 3-l bubble column showed that an initial seed population could grow without an increase in number of crystals. Similar experiments in agitated crystallizers (Hojjati et al. 2005, Lakerveld et al. 2007) showed a clear increase in number of crystals due to attrition. It demonstrated that the concept is very promising to isolate the task nucleation. Further improvements are expected by extending the bubble column to an airlift crystallizer. A dedicated 10-L airlift crystallizer has been designed, constructed and is currently being tested.

3. Dynamic optimization of a task based crystallizer

The starting point of the development of a TBD for solution crystallization, was the development of new process units that could isolate single tasks as described in the previous section. Those new unit operations provide possible building blocks for a task superstructure, which can be optimized resulting in an optimal task structure. In this section, the tasks tested in the experiments, as summarized in the previous section, are combined in a model, which represents a possible outcome of such a task superstructure optimization, and optimized. The aim is to illustrate flexibility for process design resulting in improved product quality with minimum energy demand.

A drawing of the modeled system is given in Figure 3. It contains one compartment with a gas, a liquid and a solid phase (labeled GLS), which behaves as the bubble column. This compartment is used to grow crystals with negligible attrition.

Ultrasound can be applied within the compartment to produce nuclei at low supersaturation with the experimentally determined rate. From this compartment a clear solution is taken to a second compartment (labeled ML) operating at higher temperature, in which the task supersaturation generation is realized. A RO membrane is used here to selectively remove solvent. The system is operated in semi-batch mode.

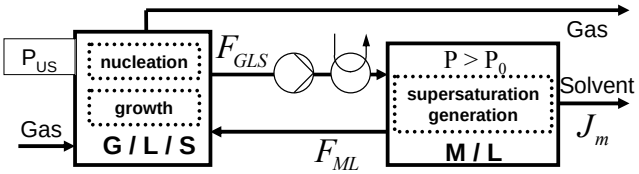

Figure 3: structure of task based crystallizer with 3 tasks

For the development of the model special attention has been paid to proper scaling of the state variables. Furthermore, instead of solving the full population balance describing the dynamic development of the crystal size distribution, which results in a system of PDAE equations, the moment transformation has been used to reduce the system to a set of DAE equations. The growth rate depends linearly on supersaturation

$$G = k_G \cdot \left(w_{GLS} - w_{GLS}^{*} \right) \tag{1}$$

The moment equations are given as follows:

$$\frac{dx_0}{dt} = \eta_U \alpha \tag{2}$$

$$\frac{dx_i}{dt} = i \cdot \left(w_{GLS} - w_{GLS}^{*} \right) \cdot x_{i-1} \quad \text{for i = 1,2,3,4} \tag{3}$$

Where the variable η_U represents the utilization of ultrasound. It can be imagined as the fraction of the total volume that is insonated. Furthermore, $x_0,...,x_4$ represent the scaled moments ($m_0,...,m_4$) and α represents the scaled maximum nucleation rate defined as follows:

$$x_0 = m_0 k_G^3 \;, x_1 = m_1 k_G^2 \;, x_2 = m_2 k_G \;, x_3 = m_3 \;, x_4 = m_4 k_G^{-1} \;, \alpha = B_{max} \cdot k_G^3$$

The component and total mass balance for the GLS compartment are

$$\frac{d\left[V_{GLS} \rho_L w_{GLS} \varepsilon + (1-\varepsilon) V_{GLS} \rho_S \right]}{dt} = F_{ML} w_{ML} \rho_L - F_{GLS} w_{GLS} \rho_L \tag{4}$$

$$-k_V \frac{dx_3}{dt} V_{GLS} \left(\rho_L - \rho_S \right) = \rho_L \left(F_{ML} - F_{GLS} \right) \tag{5}$$

The liquid volumetric flow F_{ML} is flow controlled, the liquid fraction ε is given by

$$\varepsilon = 1 - k_V x_3 \tag{6}$$

The total mass and component balance for the ML compartment complete the model:

$$\frac{dw_{ML} V_{ML}}{dt} = F_{GLS} w_{GLS} - w_{ML} F_{ML} \tag{7}$$

$$\rho_L \frac{dV_{ML}}{dt} = \rho_L F_{GLS} - \rho_L F_{ML} - J_m A_{mem} \tag{8}$$

The energy consumption of the system is defined as

$$E_{tot} = \int_{t=0}^{t=t_f} \left(P_{US} + F_{GLS}(t) \left[\frac{\Delta P(t)}{\eta} + C p_L \rho_L \left(T_{ML} - T_{GLS} \right) \right] \right) \cdot dt \tag{9}$$

The mass flux over the membrane J_m can be manipulated by changing the pressure in the membrane module, which depends linearly on the mass flux. The model was implemented in gPROMS Modelbuilder 3.1.4, (PSE Ltd). The parameter settings corresponded to an NH_4SO_4 water system with initial values in both compartments according to a clear liquid saturated at 25°C. The manipulated variables were the mass flux over the membrane (J_m) and the ultrasound utilization (η_U), which both change the rate at which a specific task is executed. Furthermore, the flow rate F_{ML} between the two

compartments was varied, which manipulated the connection between tasks. The fixed time space was discretized into 100 intervals. The operational policy could be optimized to maximize mean size with minimum energy consumption by introducing two sequential objective functions with (10) having highest priority and constraints

$$\max_{J_M(t),\eta_U,F_{ML}(t),T_{ML}} \frac{m_4\left(t=t_f\right)}{m_3\left(t=t_f\right)} \tag{10}$$

Subject to:

$$\min_{J_M(t),\eta_U,F_{ML}(t),T_{ML}} E_{tot} \tag{11}$$

$$0 < J_M\left(t\right) < 2.5 \tag{12}$$

$$1\cdot 10^{-4} < F_{ML}\left(t\right) < 0.1 \tag{13}$$

$$T_{GLS} < T_{ML} < 373 \tag{14}$$

$$w_{GLS}^{SAT}\left(T_{GLS}\right) < w_{ML}\left(t\right) < w_{ML}^{SAT}\left(T_{ML}\right) \tag{15}$$

$$0.05\% \le \frac{w_{GLS}\left(t\right) - w_{GLS}^{SAT}}{w_{GLS}^{SAT}} \le 1.0\% \tag{16}$$

$$\varepsilon\left(t=t_f\right) < 0.85 \tag{17}$$

for $t \in \left[0, t_f\right]$

The optimal profile for the mass flux over the membrane, which is determined by the pressure difference over the membrane, is depicted in Figure 4 together with the optimal trajectory of the flow rate between both compartments F_{ML}. The trajectory of supersaturation and concentration in ML compartment, which both represent constrained state variables, is shown in Figure 5.

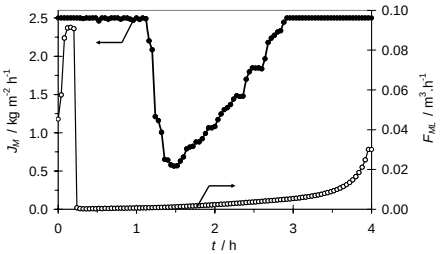

Figure 4: Optimized profile J_M (●) and F_{ML} (○)

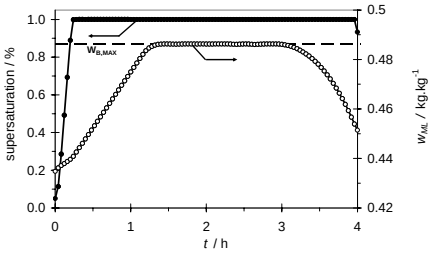

Figure 5: relative supersaturation (●) and solute fraction ML compartment (○)

From Figures 4-5 it can be seen how both the solvent mass flux over the membrane, flow rate between both compartments and utilization of ultrasound work together to maximize the final volume based mean size. Ultrasound is active only for 7% during the first 2 minutes of the batch (not shown) to generate an optimal amount of initial nuclei. The mass flux and flow rate between compartments are high in the beginning (Figure 4) to quickly raise the supersaturation to the constrained value (Figure 5) representing maximum growth (Eq. (1)). The flow rate is reduced as soon as the supersaturation hits the constraint. From this point, the concentration in the ML compartment increases more rapidly (Figure 5) until this concentration becomes saturated (T_{ML} = 81.7 °C). To prevent supersaturation, and therefore scaling on the membrane, the mass flux is reduced quickly at this point to reduce the increase in concentration. As the crystal surface area increases over time more supersaturation can be delivered to the GLS compartment and the mass flux can gradually increase. Note that for minimization of energy the optimizer seeks to minimize the product of T_{ML} and F_{ML} as heating is the most significant contribution to the energy consumption. This is reflected by the profile of W_{ML} (Figure 5), which is at the maximum value, determined by T_{ML}, for a large part of the batch.

It is important to notice that supersaturation is at the maximum value almost throughout the complete batch, showing that the task based crystallizer is very well capable of manipulating supersaturation and therefore product quality (size distribution). Using the same crystallizer design, also a small product with narrow size distribution can be produced (Lakerveld et al., 2008[d]).

4. Conclusions & Outlook

A TBD approach is applied for the design of a crystallization process unit. A two track approach has been followed. First of all, small scale experiments are designed and tested to evaluate technology that is capable of isolating single crystallization tasks. It delivers a proof of principle that dedicated equipment is capable to execute the fundamental crystallization tasks Growth, Nucleation and Supersaturation Generation. Modeling delivers the building blocks for design, which are used in the second part of this paper dealing with dynamic optimization of a task based batch crystallizer for optimization of the final mean size with minimum energy consumption. The results show that a task based crystallizer is flexible and therefore capable of maintaining supersaturation very closely to an optimum value as determined by the designer.

Although the present work is an important step forward in proving the technological viability of TBD for solution crystallization processes, many follow-up questions must be answered. Out of the general engineering abilities reliability and availability have not been discussed. This will be a challenge to the approach since unconventional technology is used. The modeling of individual tasks will also contribute to an improved reliability of the approach and better understanding how to isolate tasks for various systems. Furthermore, the task structure was fixed for the optimization studies performed in this work as it represented the combination of tested experimental setups. However, optimization of the task structure itself could further improve the design of the crystallization process unit. It involves postulation of a task superstructure that is rich enough to incorporate interesting process alternatives on the one hand and removing abundant alternatives on the other hand. Furthermore, optimization of the task superstructure would transform the NLP optimization problem of the current work into an MINLP optimization problem, which is computationally more demanding. Those are challenging questions for future research.

Abstract

Viscoelastic fluids are of great importance in many industrial sectors, such as in food and synthetic polymers industries. The rheological response of viscoelastic fluids is quite complex, including combination of viscous and elastic effects and highly non-linear viscous and elastic phenomena. This work presents a new Computational Fluid Dynamics (CFD) tool for the simulation of viscoelastic fluid flows, which consists of a viscoelastic fluid module to be used with OpenFOAM CFD package. The main reasons for using OpenFOAM in the development of this tool are its characteristics with relation to flexibility to deal with complex geometries, unstructured and non orthogonal meshes, moving meshes, large variety of interpolation schemes and solvers for the linear discretized system, and the possibility of data processing parallelization. Several constitutive equations, such as Maxwell, UCM, Oldroyd-B, Giesekus, Phan-Thien-Tanner (PTT), Finitely Extensible Nonlinear Elastic (FENE-P and FENE-CR) and some derivations of Pom-Pom were implemented, in single and multimode form, and in this work the results are presented with the Giesekus model. The proposed methodology was validated by comparing its predictions with experimental and numerical data from the literature for the analysis of a planar 4:1 contraction flow.

Keywords: Viscoelastic flows, planar contraction, numerical simulation, OpenFOAM.

1. Introduction

Understanding and modeling viscoelastic flows are usually the key step in the definition of the final characteristics and quality of finished products in many industrial sectors, such as in food and synthetic polymers industries.

The rheological response of viscoelastic fluids is quite complex, including combination of viscous and elastic effects and highly non-linear viscous and elastic phenomena, such as strain rate dependent viscosity, presence of normal stress differences in shear flows, relaxation phenomena, and memory effects, including die swell (Bird et al., 1987, Macosko, 1994).

In addition to the basic mathematical and computational difficulties associated with the solution of the system of equations resulting from mass, momentum and energy conservation laws, the analysis of viscoelastic flows requires dealing with an additional set of variables and equations related to the constitutive equation used to describe the rheological behaviour of the viscoelastic fluid.
The first constitutive equation developed to describe viscoelasticity was the Maxwell linear model. To get a better representation of real viscoelastic fluids at higher deformation rates, more sophisticated and complex non-linear viscoelastic models should be used. In this class there are models derived from the kinetic theory (such as Oldroyd-B, Giesekus and FENE-P), from network theory of concentrated solutions and melts (Phan-Thien-Tanner - PTT), and from the reptation theory (Pom-Pom and XPP models). A more complete list of models for viscoelastic fluid and some detailed comparisons among them can be found in Bird et al. (1987), Macosko (1994), and Larson (1988).
In the attempt of solving the 'High Weissenberg Number Problem' (HWNP) or minimizing its effects, many strategies as special interpolations schemes (Alves et al., 2003, Muniz et al., 2005) and specific numerical methodologies for the treatment of nonlinear viscoelastic models have been proposed. As well as the 'viscous formulation', the EVSS (Elastic viscous split-stress), the DEVSS (Discrete Elastic viscous split-stress) and the AVSS (Adaptive Viscosity Stress Splitting Scheme) are among the most known of these numerical methodologies.
Another relevant aspect regarding the analysis of viscoelastic flows is the development of software specifically designed for this purpose. Despite the extensive literature on viscoelastic behaviour modelling and viscoelastic flow simulation, the commercial packages meant to be applied for analysis of polymeric flows and polymer processing operations, such as extrusion and injection molding, are actually limited to the description of purely viscous non-Newtonian phenomena. Software with viscoelastic flow analysis capability are still developed and used only in academic environment, for specific applications.
In this sense the insertion of a viscoelastic fluid flow solver in a widely recognized CFD (Computational Fluid Dynamics) package is a relevant matter, since it would bring to viscoelastic fluid flow analysis field the main features of a good CFD package, which include the ability of dealing with complex geometries, unstructured and non orthogonal meshes, moving meshes, large variety of interpolation schemes and solvers for the linear discretized system, and data processing parallelization among others benefits.
Based on these ideas, the goal of this work is the implementation of constitutive models for viscoelastic fluids in OpenFOAM (Open Source Field Operation and Manipulation). OpenFOAM is a free CFD finite volume method (FVM) package with flexible code that, in addition to the many standards solvers already implemented for more general Newtonian fluids problems, also allows users to build their own codes for specific issues. The whole CFD methodology in OpenFOAM can be found in the work of Jasak (1996).

2. Methodology

In this section, the mathematical formulation and the strategy used to the solution of viscoelastic fluid flow problem is presented.

2.1. Mathematical model

The governing equations of laminar, incompressible, and isothermal flow of viscoelastic fluids are the conservation of mass (continuity):

$$\nabla \cdot (U) = 0 \tag{1}$$

and momentum:

$$\frac{\partial (\rho U)}{\partial t} + \nabla \cdot (\rho U U) = -\nabla p + \nabla \cdot \tau_S + \nabla \cdot \tau_P \tag{2}$$

together with a mechanical constitutive equation that describes the relation between the stress and the deformation rate for a given fluid. In the above equations ρ is the density, U the velocity vector, p the pressure, τ_S the solvent Newtonian contribution, and τ_P the polymeric contribution.

The solvent contribution is given by:

$$\tau_S = 2\eta_S D \tag{4}$$

where η_S is the solvent viscosity and D is the deformation rate tensor given by:

$$D = \frac{1}{2}(\nabla U + [\nabla U]^T) \tag{5}$$

The extra elastic contribution, corresponding to the polymeric part, is obtained from the solution of an appropriate constitutive differential equation. A well known and highly used is the Giesekus constitutive model described as (Giesekus, 1982):

$$\tau_P + \lambda \overset{\nabla}{\tau}_P + \alpha \frac{\lambda}{\eta_p}(\tau_P . \tau_P) = 2\eta_p D \tag{6}$$

where λ and η_P are the relaxation time and polymer viscosity at zero shear rate, respectively, and α is the dimensionless 'mobility factor'.

The upper convected derivative of the elastic stress tensor is (Larson, 1988):

$$\overset{\nabla}{\tau}_P = \frac{D}{Dt}\tau_P - \left[(\nabla U)^T \cdot \tau_P\right] - \left[\tau_P \cdot \nabla U\right] \tag{7}$$

with the material derivative of the extra stress tensor defined as:

$$\frac{D}{Dt}\tau_P = \frac{\partial}{\partial t}\tau_P + U . \nabla \tau_P \tag{8}$$

2.2. DEVSS methodology

DEVSS (Guénette and Fortin, 1995) was the methodology chosen in this work to deal with the HWNP, mainly because of the easiness of its extension to different complex constitutive models. This method is based on the introduction of an additional diffusive term on each side of the momentum equation, which is then rewritten as:

$$\frac{\partial(\rho U)}{\partial t} + \nabla \cdot (\rho U U) - (\eta_S + \phi)\nabla \cdot (\nabla U) = -\nabla p + \nabla \cdot \tau_P - \phi \nabla \cdot (\nabla U) \tag{9}$$

where ϕ is a positive number.

2.3. Solver implementation and solution procedure

The procedure implemented to solve the problem of viscoelastic fluid flow can be summarized in the following four steps:

1. Considering an initial known velocity field U^*, given pressure p^* and stress τ^*, the momentum equation is implicitly solved for each component of the velocity vector resulting in U^{**}. The pressure gradient and the stress divergent are calculated explicitly with values of the previous step.
2. With the new velocity values U^{**}, the new pressure field p^{**} is estimated using an equation for the pressure (obtained from the application of divergent operator on momentum equation) and then is corrected with the velocity to satisfy the continuity equation. Here is chosen the PISO algorithm for transient flows.
3. With the corrected velocity field, the stress tensor field τ^{**} is evaluated using a chosen constitutive equation.

4. For transient flows, steps 1, 2 and 3 can be iterated at each time step to a desired accuracy.

The implementation of this algorithm in OpenFOAM was called viscoelasticFluidFoam solver.

2.4. Test geometry

A planar abrupt contraction with contraction ratio *H/h* of 3.97:1 (upstream thickness of *2H = 0.0254 m* and downstream thickness of *2h = 0.0064 m*) was chosen as test geometry, sketched in Figure 1. Quinzani et al. (1994) presented an extensive experimental study on this geometry using LDV (*Laser-Doppler Velocimetry*) and FIB (*Flow Induced Birefringence*) for stress measurements on a polymer solution of 5% wt. of poly-isobutylene (PIB) in tetradecane (C_{14}). Azaiez et al. (1996) compared these experimental results with the predictions of numerical simulation using the finite element method (FEM) and the Giesekus model.

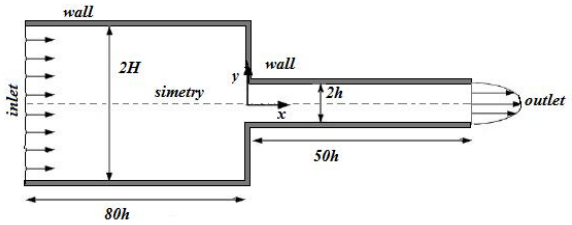

Figure 1: Sketch of geometry and the boundary conditions.

Table 1: Flow conditions.

Q [cm^{3}s^{-1}]	$\langle U \rangle$ [cms^{-1}]	Re_o	De_o
252	15.5	0.56	1.45

The flow conditions are presented in Table 1, where $<U>$ is the average velocity in the downstream section, Q the volumetric flow rate, Re_o and De_o the Reynolds and Deborah number for this case, respectively. The length of the channel before the contraction is *80h* and *50h* for the downstream section.

From the experimental data of Quinzani et al. (1994), the parameters in Table 2 for the Giesekus model were obtained by Azaiez et al. (1996).

Table 2: Parameters of Giesekus model (Azaiez et al., 1996).

Model	α [--]	λ [s]	η_P [Pa.s]	η_S [Pa.s]	ρ [kg m^{-3}]
Giesekus	0.15	0.03	1.422	0.002	*803.87*

The *upwind* and *central differences* approximations were used for the convective terms and the others terms, respectively. *Conjugate gradients* with *AMG* preconditioning were used in the linear system solver for the pressure field and *BiCGstab* with a *Cholesky* preconditioning was used for velocity and stress. The absolute tolerance for pressure was 10^{-7} and the velocity and stress 10^{-6}.

3. Results and Discussion

The obtained results were compared with the simulated data by Azaiez et al. (1996) and experimental data obtained by Quinzani et al. (1994).

Figure 2 illustrates the stress field components τ_{xx}, τ_{xy}, τ_{yy} and the stream lines, showing the effects near the re-entrant corner, where the control volumes are very small. This

region is the most critical region with largest gradients and highest stress values. The stream lines illustrate a vortex appearance in the corner of the geometry.

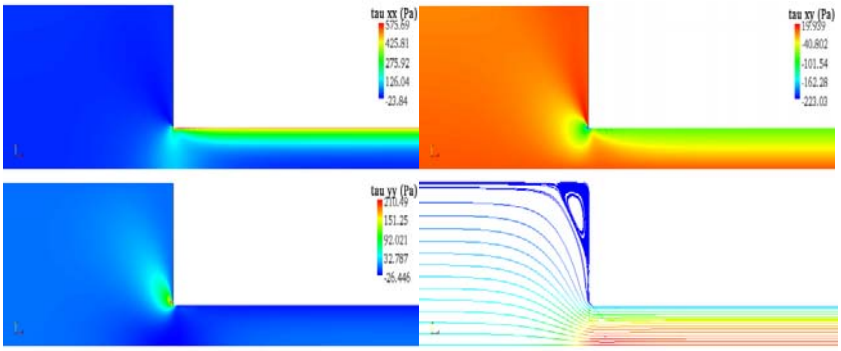

Figure 2: Stress field and stream lines.

In the Figures 3, 4 and 5, a comparison for the velocity profile U, τ_{xy} and the first normal stress difference ($N_1 = \tau_{xx} - \tau_{yy}$), respectively, is made in a lateral and axial scan at the upstream section.

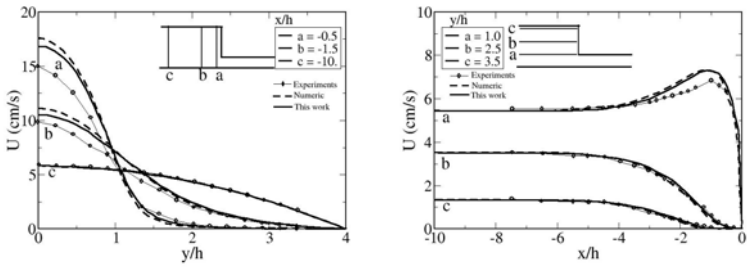

Figure 3: Velocity profile U in the upstream section.

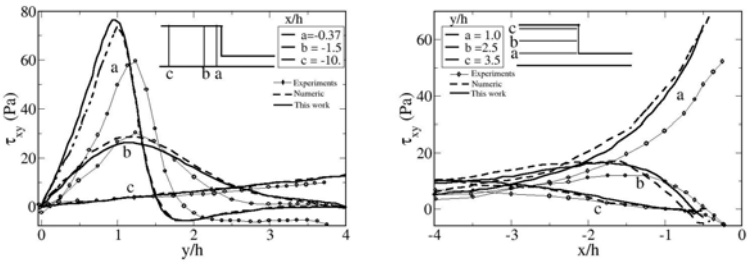

Figure 4: Stress τ_{xy} profile in the upstream section.

It can be observed that the results for the velocity profile are almost identical to those obtained by Azaiez et al. (1996) and both have good agreement with experimental data, mainly in the developed flow region. Higher values of stress were obtained when comparing with the experimental results, but they are in good agreement with the numeric results of the literature. The little difference can be attributed to the different interpolation schemes and meshes used. The difference between the numeric and

experimental data may be attributed to the only one relaxation mode used, and thus, not good enough to completely characterize the stress, mainly in regions where there is a high shear rate and occurs the higher stress values.

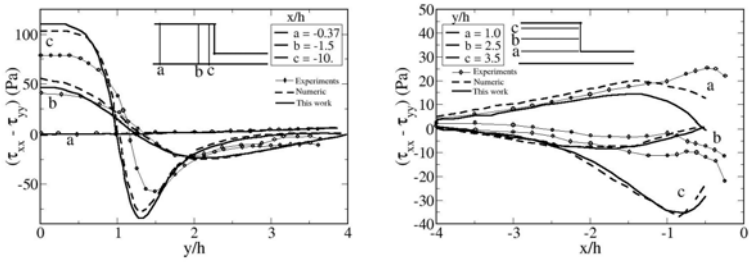

Figure 5: First normal stress difference profile N_1 in upstream section.

The first stress difference (N_1) also show good agreement between the numeric results from literature and the obtained in this work. For the lateral scan, differences between the numeric and experimental data are observed manly at high shear rates. In the developed flow region the numeric and experimental results show good agreement. Analyzing the axial scan, there is a good concordance between the numeric results, but a poor agreement with the experimental data mainly near to the contraction. However, the experimental data may also contain significant errors in that region. Improvements in N_1 prediction may be achieved with the use of multimode models.

4. Conclusion

In this work, a new tool for CFD simulation of viscoelastic fluids was developed. The results showed that the solver leads to consistent results with those found in literature and are in good agreement with experimental data. In order to better represent the values of stress obtained experimentally it would require the use of multimode models. The OpenFOAM is a suitable environment for the development of new solvers for viscoelastic fluid flows, having a great potential for academic and industry researches.

Modeling of Multi-Stream Heat Exchangers with Phase Changes for Cryogenic Applications

Ravindra S. Kamath,[a] Ignacio E. Grossmann,[a] Lorenz T. Biegler[a]

[a]*Department of Chemical Engineering,Carnegie Mellon University, 5000 Forbes Avenue, Pittsburgh PA 15213, USA*

Abstract

A new equation-oriented process model for multi-stream heat exchangers (MHEX) is presented with a special emphasis on phase changes. The model internally uses the pinch concept to ensure the minimum driving force criteria. Streams capable of phase change are split into sub-streams corresponding to each of the phases. A novel disjunctive representation is proposed which identifies the phases traversed by a stream during heat exchange and assigns appropriate heat loads and temperatures for heat integration. Model is suitable for optimization studies particularly when the phases of the streams at the entry and exit of the MHEX are not known *a priori*. The capability of the model is illustrated using a case study on liquefaction of natural gas.

Keywords: multi-stream heat exchangers, heat integration, complementarity

1. Introduction

A multi-stream heat exchanger (MHEX) is a single process unit in which multiple hot and cold streams exchange heat simultaneously. MHEXs are very common in cryogenic applications where heat transfer equipment need to be kept compact and well-insulated while recovering heat from streams at very small temperature driving forces. Use of a MHEX to perform such heat transfer tasks often leads to substantial savings in both energy and capital cost.

Unlike conventional two stream heat exchangers, MHEXs involve many hot and cold streams; it is not clear how to enforce the minimum driving force constraint because the matches between the streams are not known *a priori*. Even performing an energy balance can be non-trivial when some streams involved in the MHEX change phase during heat transfer. This is because the correlations used to calculate enthalpy depend on the phase and since the outlet temperature is not known *a priori*, it implies that the phase is not known *a priori*. This is even more challenging in the case of process optimization because pressure and composition of some or all the streams in the flowsheet are treated as variables, which cause the phase boundaries to move during the optimization. Thus, it is not surprising that there are hardly any process models for MHEX in the open literature. As a result, design and operating conditions of many cryogenic processes like natural gas liquefaction and air separation are often based on rule of thumb or heuristics. Therefore, there is scope to optimize the operating conditions and even the state of the streams at the entry and exit points of the MHEX in order to further improve the process efficiency.

In this work, we propose a general nonlinear equation-oriented model for MHEX that addresses all the issues mentioned above. The model is based on the Duran and Grossmann (1986) model, which relies on pinch analysis for heat integration. The issue

of phase change is dealt with by splitting the physical stream into three sub-streams corresponding to superheated, two-phase and sub-cooled regions. This splitting is performed using a disjunctive representation involving Boolean variables. The disjunctions are reformulated in order to avoid binary variables by solving an inner minimization problem with complementarity constraints. The capability of the model is demonstrated using a case study from the cryogenic industry.

2. Model for MHEX in the absence of phase changes

The model for MHEX is equivalent to the following problem statement:

Given an MHEX that does not consume any heating and cooling utilities, determine feasible temperatures and heat capacity flowrates for the involved streams

Based on the above problem statement, we can modify the Duran and Grossmann (1986) model for simultaneous optimization and heat integration and apply it for MHEXs. The Duran and Grossmann (1986) model uses the heat integration constraints to calculate the utility targets, which are embedded with appropriate cost coefficients in the objective function of the overall nonlinear optimization problem for the flowsheet. Our proposed modification involves setting the hot and cold utility loads in their heat integration constraints to a constant value of zero. This forces the heat integration constraints to treat MHEX as an adiabatic device, i.e. net heat lost by all the hot streams will be matched to the net heat gained by all cold streams. Since the MHEX does not require hot and cold utilities, it does not contribute any utility cost to the objective function of the parent flowsheet. Thus, the final model for MHEX is the modified set of heat integration constraints that only need to be embedded as additional constraints in the nonlinear programming model of the overall flowsheet. This model has the following form:

$$
\begin{aligned}
&\min\ \phi(w,x)\\
&s.t.\ \ h(w,x)=0\\
&g(w,x)\leqslant 0\\
&\Omega(x)=\sum_{i\in H}F_i\left(T_i^{in}-T_i^{out}\right)-\sum_{j\in C}f_j\left(t_j^{out}-t_j^{in}\right)=0\\
&AP_C^p(x)-AP_H^p(x)\leqslant 0 \quad p\in P\\
&AP_H^p(x)=\sum_{i\in H}F_i\left[\max\left\{0,T_i^{in}-T^p\right\}-\max\left\{0,T_i^{out}-T^p\right\}\right] \quad p\in P\\
&AP_C^p(x)=\sum_{j\in C}f_j\left[\max\left\{0,t_j^{out}-(T^p-\Delta T_{min})\right\}-\max\left\{0,T_i^{out}-(T^p-\Delta T_{min})\right\}\right]
\end{aligned}
\tag{1}
$$

where H and C are index sets for the hot and cold streams which are involved with the MHEX and vector x given by $x=\left(F_i,T_i^{in},T_i^{out}:\text{all } i\in H;\ f_j,t_j^{in},t_j^{out}:\text{all } j\in C\right)$ represents the corresponding temperature and flowrate of these streams. $P=H\cup C$ is the index set of all the pinch point candidates i.e. the inlet of the involved streams. The vector w represents all variables in the process flowsheet not associated with heat integration while $\phi(w,x)$, $h(w,x)$ and $g(w,x)$ represent the objective function, mass and energy balances, design equations and other specifications of the process.

3. Dealing with phase changes in the MHEX

Although the concept of pinch and heat integration assumes that the heat capacity-flowrate of the streams is constant during heat transfer, this seems unreasonable when the stream changes phase or traverses through the 2-phase region. Use of a constant heat-capacity flowrate is likely to cut off candidate pinch locations near the dew and bubble points leading to a violation of the minimum driving force criteria.

In this work, we propose a new strategy for handling streams undergoing phase changes where it is not known *a priori* whether a stream changes phase or not. We propose to classify *a priori* the streams involved in heat integration into two mutually exclusive sets of streams which are capable of changing phase and those that do not change phase. Streams belonging to the former set, which are denoted as parent streams, are sub-divided into sub-streams corresponding to superheated (SUP), 2-phase (2P) and the sub-cooled (SUB) regions. From the point of view of heat integration, the parent stream is disregarded and instead, each of its sub-streams is treated as a separate stream with corresponding inlet and outlet temperatures and associated heat loads.

As per our strategy, sub-streams corresponding to all three phases exist in the model irrespective of actual traversal of phases by the parent stream at any feasible solution for the problem. Obviously, when a particular phase does not exist, we need to ensure that the corresponding sub-stream does not contribute to the heat integration calculations. This is done by setting the heat load of the sub-stream to zero and forcing the corresponding outlet and inlet temperature to be equal to a default value. These tasks are performed using a novel disjunctive model which is discussed in the next section.

4. Disjunctive Model for Phase Detection

The phases traversed by the parent stream while exchanging heat can be determined if the state of this stream at the inlet and outlet of the MHEX is known. Our model detects the state of the parent stream by comparing its temperature with dew and bubble point temperatures. The task of phase detection and making appropriate assignments involves combinatorial decision-making and this can be best accomplished using disjunctions and logic propositions (Raman and Grossmann, 1994). The complete model for phase detection consists of three components: disjunctions for phase detection at inlet and outlet, flash calculations for the 2-phase sub-stream that integrate with the disjunctions, and enthalpy calculations and evaluation of heat loads of the sub-streams.

The disjunction for phase detection consists of three terms corresponding to the three possible states. The disjunctions corresponding to the inlet and outlet state of the parent stream involved in the MHEX have the following form:

$$\begin{bmatrix} Y_{IN}^{SUP} \\ T_{IN} \geqslant T_{DP} \\ T_{in}^{sup} = T_{IN} \\ T_{in}^{2p} = T_{DP} \\ T_{in}^{sub} = T_{BP} \end{bmatrix} \bigvee \begin{bmatrix} Y_{IN}^{2P} \\ T_{BP} \leqslant T_{IN} \leqslant T_{DP} \\ T_{in}^{sup} = T_{DP} \\ T_{in}^{2p} = T_{IN} \\ T_{in}^{sub} = T_{BP} \end{bmatrix} \bigvee \begin{bmatrix} Y_{IN}^{SUB} \\ T_{IN} \leqslant T_{BP} \\ T_{in}^{sup} = T_{DP} \\ T_{in}^{2p} = T_{BP} \\ T_{in}^{sub} = T_{IN} \end{bmatrix} \tag{2}$$

$$\begin{bmatrix} Y_{OUT}^{SUP} \\ T_{OUT} \geqslant T_{DP} \\ T_{out}^{sup} = T_{OUT} \\ T_{out}^{2p} = T_{DP} \\ T_{out}^{sub} = T_{BP} \end{bmatrix} \bigvee \begin{bmatrix} Y_{OUT}^{2P} \\ T_{BP} \leqslant T_{OUT} \leqslant T_{DP} \\ T_{out}^{sup} = T_{DP} \\ T_{out}^{2p} = T_{OUT} \\ T_{out}^{sub} = T_{BP} \end{bmatrix} \bigvee \begin{bmatrix} Y_{OUT}^{SUB} \\ T_{OUT} \leqslant T_{BP} \\ T_{out}^{sup} = T_{DP} \\ T_{out}^{2p} = T_{BP} \\ T_{out}^{sub} = T_{OUT} \end{bmatrix} \tag{3}$$

where T_{IN} and T_{OUT} are inlet and outlet temperature of parent stream, T_{DP} and T_{BP} are the dew and bubble point temperature of parent stream and the remaining variables correspond to inlet and outlet temperatures of the proposed sub-streams.

The sub-stream corresponding to the 2-phase region has to be treated separately when the outlet of the parent stream lies in the 2-phase region, because both vapor and

liquid phases exist and flash calculations are required to evaluate the vapor and liquid fractions and their compositions. However, if the parent stream does not traverse the 2-phase region, it is well-known that the VLE equations for flash calculation have no feasible solution when operating in the single region. To handle this issue, we enforce the flash calculations even when the 2-phase region is not traversed, but operate it as a single saturated (vapor or liquid) phase at the boundary of the 2-phase region. Consequently, the VLE equations do not need to be relaxed at all irrespective of state of the parent stream at the inlet and outlet conditions. The inputs to the flash model change depending upon the values of variables supplied by the disjunctions as follows:

$$\begin{aligned} H_{Flash\ inlet} &= H_{IN} - H_V\left(T_{in}^{sup}\right) + H_{DP} + H_{BP} - H_L\left(T_{in}^{Sub}\right) \\ T_{Flash} &= T_{out}^{2p} \end{aligned} \tag{4}$$

Here, H_{IN} is the enthalpy of the parent stream at the inlet of the MHEX and is assumed to be supplied by the upstream process unit. H_{DP} and H_{BP} are the enthalpy of the parent stream at dew and bubble point conditions, respectively. H_V and H_{L} are enthalpy correlations corresponding to the vapor and liquid phases. The flash model operates in (P, T) mode, with the heat duty Q_F being calculated as an output variable.

The advantage of our proposed formulation is that all enthalpy calculations can be performed outside the disjunctions while picking appropriate enthalpy correlations for the vapor and liquid phases. The heat load for the sub-streams is given by following set of equations:

$$\begin{aligned} Q^{sup} &= H_V\left(T_{in}^{sup}\right) - H_V\left(T_{out}^{sup}\right) \\ Q^{sub} &= H_L\left(T_{in}^{sub}\right) - H_L\left(T_{out}^{sub}\right) \\ Q^{2p} &= \ -Q_F \end{aligned} \tag{5}$$

Equation (5) is applicable if the parent stream is a hot stream. For cold streams, we simply reverse the signs of the terms in the RHS of (5).

5. Reformulation of disjunctions

The disjunctions for phase detection can be reformulated as a mixed-integer nonlinear programming (MINLP) problem. However, it is also possible to reformulate it as a nonlinear programming problem and thus avoid the use of binary variables. This reformulation involves solving an inner minimization problem of the following form:

$$\begin{aligned} \text{Min} \quad & -\left[Y_{\text{sup}}\left(T - T_{DP}\right) + Y_{2p}\left(T_{DP} - T\right)\left(T - T_{BP}\right) + Y_{sub}\left(T_{BP} - T\right)\right] \\ \text{s.t.} \quad & Y_{sup} + Y_{2p} + Y_{sub} = 1 \\ & Y_{\text{sup}} \geq 0,\ Y_{2p} \geq 0,\ Y_{sub} \geq 0 \end{aligned} \tag{6}$$

which sets exactly one of Y_{sup}, Y_{2P}, and Y_{sub} to unity. The optimality conditions corresponding to (6) are given by following constraints:

$$\begin{aligned} Y_{sup} + Y_{2p} + Y_{sub} &= 1 \\ -\left(T - T_{DP}\right) - \mu_{\text{sup}} + \lambda &= 0 \\ -\left(T_{DP} - T\right)\left(T - T_{BP}\right) - \mu_{2p} + \lambda &= 0 \\ -\left(T_{BP} - T\right) - \mu_{sub} + \lambda &= 0 \\ 0 \leq Y_{sup} \perp \mu_{sup} &\geq 0 \\ 0 \leq Y_{2p} \perp \mu_{2p} &\geq 0 \\ 0 \leq Y_{sub} \perp \mu_{sub} &\geq 0 \end{aligned} \tag{7}$$

where $\lambda$and μ are multipliers corresponding to equality and non-negativity constraints respectively of (6). The last three equations of (7) are complementarity constraints and are handled using the penalty formulation (Baumrucker et al., 2008).

6. Case Study: Natural Gas Liquefaction

We demonstrate our proposed model for multi-stream heat exchangers using the commercial Poly Refrigerant Integrated Cycle Operations (PRICO) process for natural gas liquefaction (Price and Mortko, 1996). The PRICO process, shown in Figure 1 employs a single-stage mixed refrigerant (MR) system. Natural gas stream enters at 55 bar and 25°C and is liquefied by cooling it to -163°C. This cooling task is accomplished by using a refrigerant of certain composition which circulates in a closed loop. The objective is to determine the operating conditions and composition of the refrigerant that minimizes the compressor work. The posed problem has several challenges which are noted below:

1) Outlet of the cooler (stream S5) can be either superheated or 2-phase.
2) High pressure refrigerant outlet (stream S6) can be either 2-phase or subcooled.
3) Outlet of the throttle valve (stream S7) can be either 2-phase or subcooled.
4) All pressures and temperatures in the flowsheet are free and can be optimized.

The objective of minimizing the compression work in the PRICO process has been studied previously by Del Nogal et al. (2008). Their strategy involves two steps. In the first step, a genetic algorithm proposes a set of candidate solutions over a discretized space which is assessed and refined using an in-house simulator. In the second step, this set of solutions is used as initial guess for determining the optimal solution over the continuous space using standard NLP optimization. On the other hand, our formulation allows the use of an equation-oriented strategy for heat integration, phase detection as well as handling of nonexistent phases. Consequently, we can solve the same problem as a single medium-size equation-oriented NLP problem.

The comparison of our optimization results with that of Del Nogal et al. (2008) is shown in Table 1. As can be seen, our new methodology is able to find a better optimal solution that features more than 10% reduction in power consumption. It is also worth mentioning that our equation-oriented optimization strategy requires only two minutes as compared to 410 minutes by the integrated genetic optimizer-simulator framework of Del Nogal et al. (2008) on similar computer hardware.

n-C_4H_{10}	25.31	34.19	25.62	35.42

7. Conclusions

Developing a process model for MHEXs is not trivial owing to issues like ensuring minimum driving force criteria and accounting for heat load of streams with or without phase changes particularly when the matches between the streams are not known *a priori*. This paper describes a new equation-oriented process model for MHEX which addresses all the previously mentioned issues. The process modeling is based on the fact that a MHEX can be regarded as a special case of a heat exchanger network that does not consume any utilities. Consequently, the model by Duran and Grossmann (1986) for simultaneous optimization and heat integration can be tailored for modeling MHEXs in the absence of phase changes. To handle phase changes, a novel strategy is proposed in which the streams involved in the MHEX are split into three sub-streams corresponding to the super-heated, two-phase and the subcooled regions. This is accomplished by using a disjunctive formulation which automatically detects phases and performs the appropriate flash and enthalpy calculations irrespective of the actual phases traversed by the streams. The model is demonstrated using a small case study involving liquefaction of natural gas. It is shown that this equation-oriented optimization strategy can lead to a significant reduction in computation time and even provide better solutions as compared to strategies used in previous work. It is expected that this model will find useful applications in process simulation and optimization of flowsheets having one or more MHEXs where the state of the streams entering and/or leaving the MHEX are not known *a priori* and can be optimized to achieve a desired objective.

Steady-state optimization of a continuous pharmaceutical process

Dimitrios I. Gerogiorgis and Paul I. Barton

Department of Chemical Engineering, Massachusetts Institute of Technology (M.I.T.)
Landau Building (66-569), 77 Massachusetts Avenue, Cambridge, MA 02139, USA

Abstract

Continuous Pharmaceutical Manufacturing can foster the production of key molecules, because it has a strong potential to improve product quality and suppress operating cost. Novel pharmaceutical production lines are thus ideal for exploring this paradigm shift, by introducing systematic process design, modern analytics and advanced control. Microreactor and microseparator engineering appears particularly advantageous in this high-value and low-capacity context, both at a pilot-plant and a full-production scale, and it can be combined with a plethora of proven continuous downstream technologies, facilitating the reduction of total organic waste emission and environmental footprint. The present paper focuses on flowsheet synthesis and optimization of an upstream process which is targeted at the production of a novel active pharmaceutical ingredient. The process flowsheet comprises four organic synthesis reactions and three separations, considering microsystems (microreactors and microseparators) for the respective steps. Conceptual synthesis allows for efficient separation and solvent integration, and indeed improves process economics, in contrast to wasteful batch pharmaceutical processing. Steady-state mass balances have been determined for the desired throughput and purity.

Keywords: Continuous Pharmaceutical Manufacturing (CPM), modeling, optimization.

1. Introduction and motivation

Continuous Pharmaceutical Manufacturing (CPM) attracts significant attention today, because of the expanding profitability gap experienced by the pharmaceutical industries; this is due to increasing R&D and operating cost and decreasing drug prices (Behr, 2004). Despite the strict licensing requirements for product purity and stability, and the established batch manufacturing processes, the FDA has recognized that CPM has a strong potential to improve product quality and suppress operating cost (Plumb, 2005). Comparative studies have confirmed this potential experimentally (Betz et al., 2003). Corporations must focus on introducing modern process engineering design principles, advances in instrumentation and control, and data management systems (FDA, 2004). The vast majority of *Active Pharmaceutical Ingredients (APIs)* are produced by batch processes, whose reconfiguration implies long, expensive clinical trials and revalidation. Nevertheless, novel APIs provide opportunities to explore a CPM paradigm, addressing systematically the design and operation of continuous pharmaceutical production lines. *Microreactor technology* offers a convenient, efficient, cost-effective way to conduct many organic synthesis reactions (Jensen, 2001); its advantages include miniaturization (thus space and fixed investment cost savings), high heat and mass transfer coefficients, scaleability, quick process condition screening, rapid manufacturing and customization. *Microseparators* are fabricated based on similar principles (Kralj et al., 2007), and can accelerate R&D for CPM processes, from laboratory to pilot-plant and production scale.

Organic synthesis is the cornerstone of CPM process development and flowsheeting, since a robust and efficient chemical reaction pathway is essential for proof of concept. In contrast to standard batch process prerequisites (high purity, conversion and yield), CPM processes can be flexible and viable at a much lower conversion and yield, as long as (a) continuous flow without precipitation and (b) efficient separations are ensured. Batch pharmaceutical manufacturing often relies on recipe-oriented R&D, conducted via many campaigns of arduous, expensive and time-consuming laboratory experiments.

Advances in unit operations engineering can also positively impact CPM processes, by improving efficiency as well as reducing solvent emissions and environmental footprint. Nanofiltration (Lin & Livingston, 2007), steady-state recycle (Kennedy et al., 2004) and continuous granulation (Vervaet et al., 2005) are examples of proven technologies which enhance the upstream (API production) and downstream (drug formulation) part of many pharmaceutical production lines, accelerating the transition to CPM processes. Concurrently, breakthroughs in Process Analytical Technology (PAT) (Munson et al., 2006), novel sensors and actuators provide in-depth understanding of chemical kinetics, thus enabling first-principles modeling and more efficient multivariate process control.

The present paper focuses on plantwide synthesis and optimization of an upstream process targeted at the production of a novel Active Pharmaceutical Ingredient (API). The conceptual flowsheet comprises 4 organic synthesis reactions and 3 separations, considering microsystems (microreactors and microseparators) for the respective steps. Conceptual synthesis allows for solvent integration (Ahmad & Barton, 1999) which can improve process economics, in contrast to wasteful and expensive batch processing. Steady-state upstream process optimization allows the determination of optimal stream flows and liquid-liquid extraction solvent flow, for specified API throughput and purity.

2. Pharmaceutical synthesis chemistry

The present paper considers a chemical reaction pathway for the continuous production of an API whose batch manufacturing has been successfully demonstrated and relies on 12 reaction steps and 11 intermediate separation steps, with the use of several solvents. The continuous version of the process comprises only 4 reaction steps, which occur in a polar solvent (acetonitrile, CH_3CN), under atmospheric pressure and room temperature. An aqueous API stream is significantly more preferable for downstream processing, due to the appreciable toxicity and strict limits for CH_3CN, a Class 2 solvent (EMEA, 2001). The use of relatively unstable diazomethane (epoxidation agent in the second reaction) dictates the installation of a sizeable adjacent continuous plant (Proctor & Warr, 2002). The first (addition) reaction combines 2 organic molecules to the solid intermediate C3:

$$C1 + C2 \xrightarrow[CH_3CN]{Pd,\ H_2O} C3 + HCl \quad (1)$$

The second (epoxidation) reaction activates the C3 polar end towards intermediate C4:

$$C3 + CH_2N_2 \xrightarrow[CH_3CN]{Et_2O} C4 + N_2 \quad (2)$$

The third (conversion) reaction nitrifies the same C4 polar end towards intermediate C5:

$$C4 + CH_3CN \xrightarrow{HCl} C5 \quad (3)$$

The fourth (hydrolysis) reaction occurs in acidic environment towards the final product:

$$C5 + 2H_2O + HCl \longrightarrow API + CH_3COOH \quad (4)$$

Evidently, API synthesis reactions are fostered by the acidic polar solvent environment and CH_3CN has a vital role (solvent as well as reagent) in the first 3 synthesis reactions.

3. Process synthesis and flowsheeting

The conceptual process flowsheet that has been synthesized for the production of API considers that organic synthesis can proceed continuously within a minimal number of unit operations (*4 reactors*, *3 separators*) and comprises a total of *20 streams* (Figure 1). *Microreactors* (R-001, R-002 R-003 and R-004) produce the first, second and third organic solid intermediates (C3, C4 and C5) and the final product (API), respectively. *Separator 1* (S-001) is the initial separator, removing the H_2O (used as proton acceptor) or the precipitating salt (if an organic base is used) during the first synthesis reaction. *Separator 2* (S-002,003) is the intermediate system separating the gas (N_2) from R-002, and subsequently removes (via microdistillation) the CH_2N_2 stream carrier (ether, Et_2O). *Separator 3* (S-004) is the final separator, removing CH_3CN to yield a pure API stream.

A detailed description of all streams encountered in the flowsheet (Figure 1) follows.

- *Flow 1* (F-001) contains the reagent (C1) solution in CH_3CN which is introduced into R-001.
- *Flow 2* (F-002) contains the reagent (C2) solution in CH_3CN which is also fed into R-001.
- *Flow 3* (F-003) contains the base (H_2O) that is necessary for HCl removal in the first reaction.
- *Flow 4* (F-004) contains all first reaction (R-001) compounds towards separation (S-001).
- *Flow 5* (F-005) contains the entrainer used for efficient separation of the base used in R-001.
- *Flow 6* (F-006) contains the bottoms which is drawn from S-001 with reaction by-products.
- *Flow 7* (F-007) contains the purified product stream which is introduced into R-002.
- *Flow 8* (F-008) contains the CH_2N_2 solution in ether (Et_2O) which is fed to R-002 from a line.
- *Flow 9* (F-009) contains all second reaction (R-002) compounds towards separation (S-002).
- *Flow 10* (F-010) contains nitrogen (N_2), which leaves the product using a degasser (S-002).
- *Flow 11* (F-011) contains a gas-free stream which is fed to S-003 for solvent (Et_2O) removal.
- *Flow 12* (F-012) contains the ether (Et_2O) which is separated out of the R-002 product stream.
- *Flow 13* (F-013) contains the purified stream which is fed to R-003 for the third reaction.
- *Flow 14* (F-014) contains the HCl which is introduced to R-003 to catalyze the third reaction.
- *Flow 15* (F-015) contains all third reaction compounds (from R-003) that are fed to R-004.
- *Flow 16* (F-016) contains the water that is fed to R-004 for the final hydrolysis reaction.
- *Flow 17* (F-017) contains all fourth reaction (R-004) compounds towards separation (S-004).
- *Flow 18* (F-018) contains the entrainer used for efficient organic solvent (CH_3CN) recovery.
- *Flow 19* (F-019) contains the bottoms drawn from S-004 (extraction solvent + most CH_3CN).
- *Flow 20* (F-020) contains the aqueous API solution, which is the upstream flowsheet target.

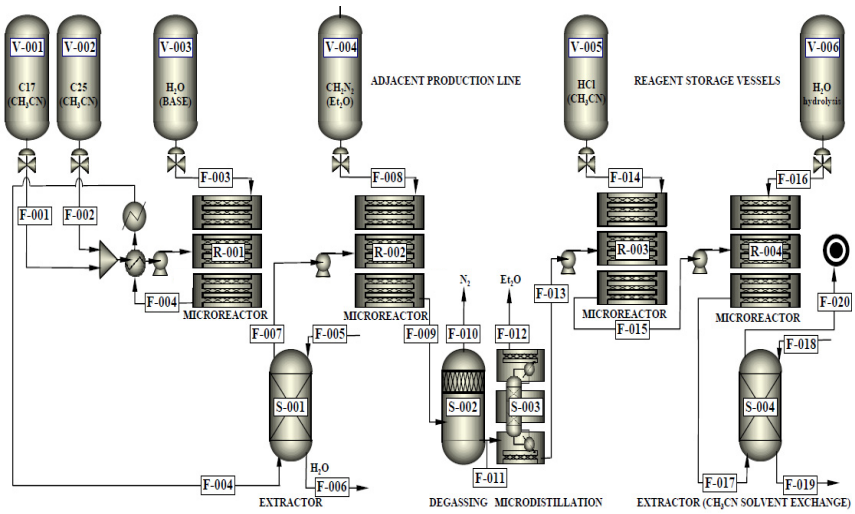

Figure 1: A conceptual upstream process flowsheet developed for the production of a novel API.

4. Mass balances for the upstream process

4.1. Mass balances: Necessary assumptions

A series of assumptions are necessary in order to determine the upstream mass balances:

4.1.1. Reactors – Kinetics

Organic synthesis reactions are irreversible without by-products, and a stoichiometric feed ratio is assumed for reaction 1 (R-001), to avoid carry-over of excess feedstocks. Both C1 and C2 solutions in acetonitrile are fed at a concentration of **3.75 M** (1:5 mol). Diazomethane (CH_2N_2) is fed at 100% excess to R-002 (**3.15 M**), to ensure a high yield. Hydrochloric acid (HCl) captured in S-001 is fed to R-003 at a concentration of **2 M**. Literature values of reaction yields are: $\mathbf{r_1}$**=0.53**, $\mathbf{r_2}$**=0.74**, $\mathbf{r_3}$**=0.90**, $\mathbf{r_4}$**=0.90**, respectively. The use of other CPM auxiliary solvents is not necessary, in contrast to batch schemes; reagent excess use is avoided, thus effectively reducing separator duties and total waste.

4.1.2. Thermodynamics – Separators

Nitrogen (N_2) is insoluble in ether and escapes the degasser (S-002) almost completely. *Water (H_2O)* is the inorganic basis used (R-001), and undergoes very efficient removal. For both, we assume that **95%$_{mol}$** escapes (only **5%** of material remains in the stream). Separator efficiencies are assumed as: $\mathbf{s_1}$ **= 0.70**, $\mathbf{s_3}$ **= 0.90** and $\mathbf{s_4}$ **= 0.90**, respectively. Thus, at separator **i**, $\mathbf{s_i}$% of undesired and (**1-**$\mathbf{s_i}$)% of valuable compounds are removed. Portions of solvents and carry-over chemicals remain inert in all subsequent reactions. *Solvent and reagent recycling* is not considered due to low (pilot plant) stream volumes. All unit operations (microreactors, separators) operate at atmospheric pressure, and all thermophysical properties for reagents and solvents are calculated at room temperature. The target API flowrate and purity in the final stream are given (**48 g.h^{-1}** and **> 40%$_{wt.}$**).

4.2. Mass balances: Results

The upstream process mass balances for the main streams are illustrated in Figure 2:

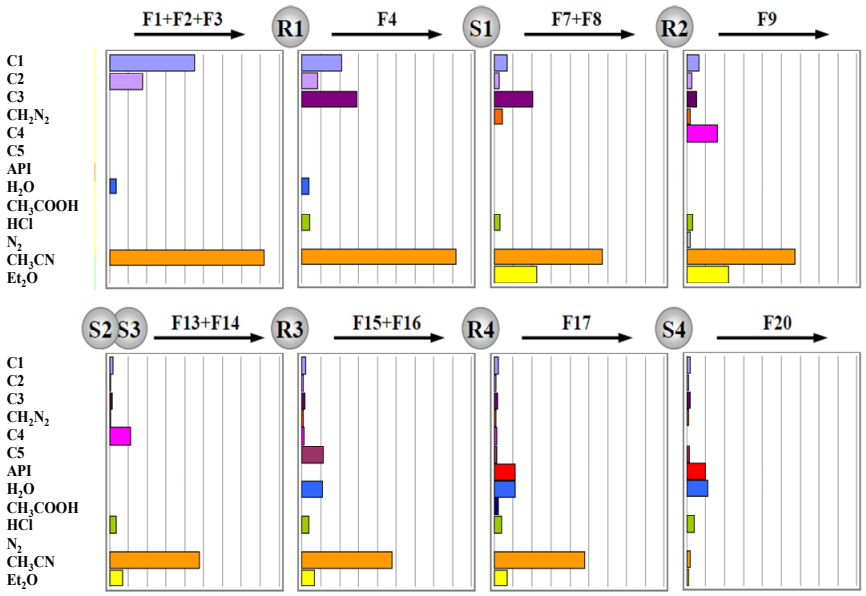

Figure 2: Schematic illustration of mass balances for the principal process streams (unit: 50 g.h^{-1}).

5. Liquid-liquid extraction (LLE)

The final separator (S-004) is the most challenging separation step of the novel process: the inlet stream contains the API (whose solution stability must be ensured, maximizing its outlet stream retention) dissolved with impurities in an acidic CH_3CN-H_2O mixture. This flow (F-017) contains traces of unreacted intermediates and reaction by-products. High API solubility is assumed therein, despite a known low solubility in pure CH_3CN, as it is very soluble in CH_3CN-H_2O-$HClO_4$ mixtures, so low pH is probably a stabilizer. A dense effluent (F-020) reduces operating cost and facilitates downstream processing.

5.1. LLE solvent selection

The ideal LLE solvent has flow and heat stability (low melting and high boiling point), acceptably low viscosity (for flow), high density (for mixing and reduced fixed cost) and most importantly, a high distribution factor (m) for acetonitrile (CH_3CN) extraction. Furthermore, a low aqueous saturation concentration and a low toxicity are desirable. Industrial CH_3CN-H_2O separations rely on butyl acetate, which is prohibitively toxic. Evaluating the respective properties of several organic solvents leads to the selection of *toluene* (C_7H_8), which has an acceptable toxicity and an outstanding distribution factor, determined by linear approximation from literature data (Di Cave & Mazzarotta, 1991). A compilation of important physicochemical properties of candidate solvents and the ternary CH_3CN-C_7H_8-H_2O phase diagram by Rao et al. (1979) are presented in Figure 3.

CANDIDATE SOLVENT	MW (g/mol)	MP (°C)	BP (°C)	ρ (g/cm³)	μ (cP)	$C_{sat}^{H_2O}$ (g/l)	m_{ACN} (i / H_2O)	CLASS	TOXIC (< ppm)

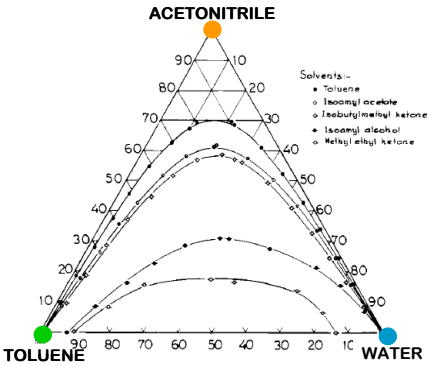

Figure 3: Liquid-liquid extraction: solvent selection and the CH_3CN–C_7H_8–H_2O ternary system.

5.2. Determination of LLE solvent duty

The liquid-liquid extractor (S-004) can operate in crosscurrent or countercurrent mode. The first offers higher flexibility, faster dynamics and is thus suitable for a pilot plant; the second balances mass transfer, economizes on solvent and is suitable for production. Considering a pure solvent feed (S), solvent equidistribution (crosscurrent), no solvent blowdown (countercurrent) and solvent-feed immiscibility, the reduction ratio X_F/X_R is:

$$\frac{X_F}{X_R}=\left(1+\frac{mS}{nF}\right)^n \quad \textit{(crosscurrent LLE)} \quad (5) \qquad \frac{X_F}{X_R}=\frac{\left(\frac{mS}{F}\right)^{n+1}-1}{\left(\frac{mS}{F}\right)-1} \quad \textit{(countercurrent LLE)} \quad (6)$$

The pure solvent duty (S) can be determined as a function of feed (F) and stages (n) for a high reduction ratio ($5\cdot10^4$), due to the stringent residual solvent limits (EMEA, 2001). For $\{2,3,4\}$ stages, the crosscurrent solvent duty is $\mathbf{S=\{200.5,48.4,25.1\}\,g\,C_7H_8/g\ feed}$, while the countercurrent solvent duty is much lower: $\mathbf{S=\{100.5,16.4,6.6\}\,g\,C_7H_8/g\ feed}$. Hence, S-004 requires several stages in both pilot-plant and production scale operation.

6. Conclusions

A conceptual upstream CPM process and its mass balances clearly indicate that the API of interest can be continuously manufactured at the prescribed flow rate and purity, and that the use of acetonitrile and toluene as reaction and separation solvent, respectively, have a clear impact on minimizing the number of process steps, reducing flowsheet size (fixed investment cost), and suppressing feedstock and solvent duties (operating cost). The proposed continuous flow chemistry is based on a concise reaction pathway, and *toluene* is the most efficient extraction agent among all 9 candidate solvents considered. A CPM flowsheet is presented here, and detailed mass balances have been calculated. The API capacity considered is **48 g** per hour of operation **(F-020: $\mathbf{m_{API} = 48\ g.h^{-1}}$)**, and *the product stream* (F-020) contains **48.19 g $\mathbf{h^{-1}}$** of API in a total flow of **109.02 g $\mathbf{h^{-1}}$**, with several compound traces (unreacted raw materials, intermediates, acids, solvents) which can be removed in the next downstream processing steps (crystallization, drying). The *total effluent waste* is: **$\mathbf{F_W = 15.58\ mol.h^{-1}}$ ($\mathbf{830.13\ g.h^{-1}}$) ($\mathbf{76\%_{mol}}$=$\mathbf{64\%_{wt}}$** solvents), thus *an order of magnitude lower* than that generated by a batch manufacturing process. The waste is almost 8 times the product stream in a flowsheet without solvent recycling (1.46 mol=**$\mathbf{107.6\ g.h^{-1}}$ $\mathbf{Et_2O}$**, 10.36 mol=**$\mathbf{424.6\ g.h^{-1}}$ $\mathbf{CH_3CN}$**); the latter is not pursued, because installing additional unit operations can adversely affect pilot-plant economics. The cost savings shown here will be augmented in the case of a production-scale plant.

"Smelly" Pinch

Toshko Zhelev[a], Natasha Vaklieva-Bancheva[b], Jaime Rojas-Hernandes[a], Tony Pembroke[a]

[a]*University of Limerick, Ireland*
[b]*IChE, Bulgarian Academy of Sciences*

Abstract

This paper attempts to make one further step in energy efficiency improvement of wastewater treatment plants connecting it with environmental considerations, namely the suppression of unpleasant aromas. Solution of the optimum heat integration when the off-gas from reactors is considered as heat source together with the effluent heat, is presented. Further, the thermal management is linked to absorption efficiency through the classical concept of simultaneous heat and mass transfer. The conceptual approach of heat integration applied through Pinch analysis is extended to consider the mass exchange through a combined operating composite and equilibrium curve plot allowing for adjustment of uncertain variables, such as streams target temperatures and stripping water flowrate. An case study from an autothermal anaerobic digesting plant (ATAD) in Ireland is presented and the future plans of this ongoing project are discussed.

Keywords: ATAD, Pinch, efficiency, heat integration, aroma.

1. Introduction

The new addition to the bio-energy utilisation problem for ATAD treatment, discussed earlier by Rojas-Hernandes et al., 2008 is the source of heat associated with the gas, drawn from all reactors and from the sludge storage, which is supplied for ammonia absorption.

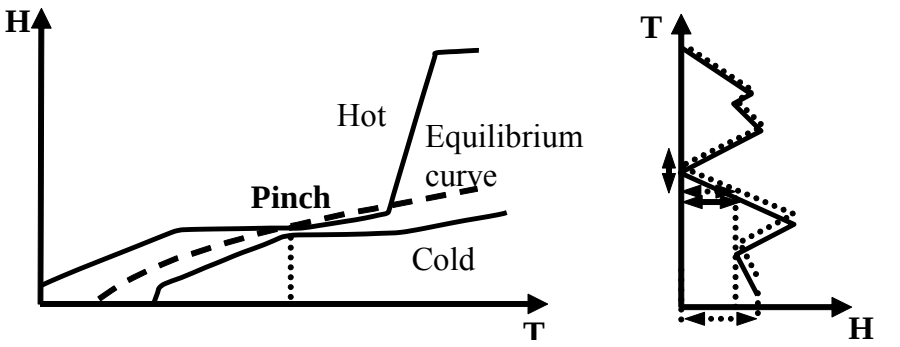
The specifics of the problem of bio-energy recovery justify certain uncertainties in the estimation of the final temperatures of majority of streams participating in the heat integration task. The cooling level of the effluent stream can be specified as "as low as possible". The heating of the fresh sludge stream – as "as high as possible". The same is the case with the air for aeration and the desired temperature of the exhaust gas.

Naturally the thermodynamic feasibility restricts the extreme level of these temperatures. The cold sludge temperature can not be higher than the heating effluent as the effluent target temperature can not be lower than the cold sludge supply temperature. The exhaust gas temperature can not be lower than the wastewater ambient conditions justified temperature or the temperature of the aeration air can not get higher than the gas stream extraction temperature.

2. Simultaneous Heat and Mass Transfer

2.1. Background

Apart from the obvious grass-root optimisation solution to the energy integration problem we propose to apply in parallel an attractive graphical approach, which was proposed by Zhelev & Semkov, 2004 for the purpose of efficiency management of an economiser system for flue gas energy recovery.



(a) Reversed Composite curve (b) Grand Composite Curve

Figure 1: Composite curves for simultaneous heat and mass integration

Combined heat-mass transfer targeting: - maximum energy recovery; - maximum potential of recovered heat

According to the concept of the H/T composite curve, streams' temperatures have to be adjusted to ensure the equilibrium curve does not cross any of the hot or cold composites. The Grand composite curve, constructed as suggested by Pinch analysis (Smith, 2001) based on "shifted composites" can be extended and used to target the maximum energy interchange and the level at which the cold sludge can be preheated. It will correspond to the highest level of the Pinch (actual level – highest temperature of "cold utility"), restricted by the beginning of the opening of the rand composite at the top.

3. Smell

Now, what about the smell?
The function representing the change of the absorbability of ammonia in water with temperature is presented below. The ideal gas method can predict well the mass absorption rate.

$$P_v(t)V = m_v(t)RT_i \Rightarrow m_v(t) = \frac{P_v(t)V}{RT_i} \quad (1)$$

Where the total vapor volume, $V = 1.55\text{x}10^{-3}$ m^3.
If we substitute the existing temperatures of the gas stream with the temperatures corresponding to the environmental standards constrained ammonia concentration (less than 1 ppm as mentioned by Taghirpour, 2008), the solution of the heat integration problem in general will change and then the recovery of heat will be aroma-driven.

4. Heat Integration

Two options were analysed:

(a) heat integration utilising the sensible heat of the exhaust gas;
(b) heat integration utilising the sensible and the latent heat of the exhaust gas.

The second option envisages the inclusion of the absorber in the integration scheme. Because of the simultaneous heat and mass transfer this increases the complexity of the formulated problem.
This will allow us to consider the efficiency of the aroma absorption in parallel to the heat recovery.

4.1. Sensible heat utilization

The proposed heat integration scheme is presented in Figure 2.

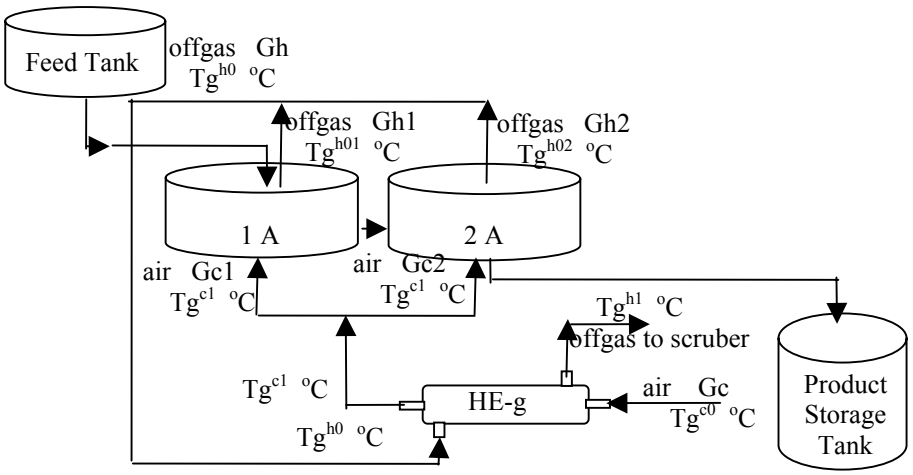


Figure 2: Heat integration scheme including the gas and the aeration air streams

The gas exiting reactors 1-A and 2-A contains air, water vapour, ammonia and hydrogen sulphide. Next it enters a scrubber for absorption of aromas. The gas leaves the reactors at the operational temperature of the sludge there, i.e. around 55°C, which represents a promising source of energy. We propose the following recovery scheme: Continuous stream $Gh1$ [m^3/day] of a warm gas at temperature $Th1$ [^oC], leaving 1-A is merging the warm gas extracted from reactor 2-A at $Gh2$ [m^3/day], $Th2$ [^oC]. The joined stream has a flow of Gh and temperature of $Th0$ and is used to preheat the joined stream of cold air (Gc [m^3/day], $Tc0$ [^oC]), used for aeration of both reactors. The data for the streams involved in the heat integration are given in the table below.

Stream	Total flow G [m^3/day]	Integrated G [m^3/day]	Process duration	Duration of integration τ	T^{o}C
Offgas 1-A	6210	5807,75 (Gh1)	24 h	22h 31 min	50
Offgas 2-A	6390	5982,62 (Gh2)	24 h	22h 31 min	60
Air to 1-A	6210	6110,57 (Gc1)	22h 54 min	22h 31 min	12
Air to 2-A	6390	6364,02 (Gc2)	23h 16 min	22h 31 min	12

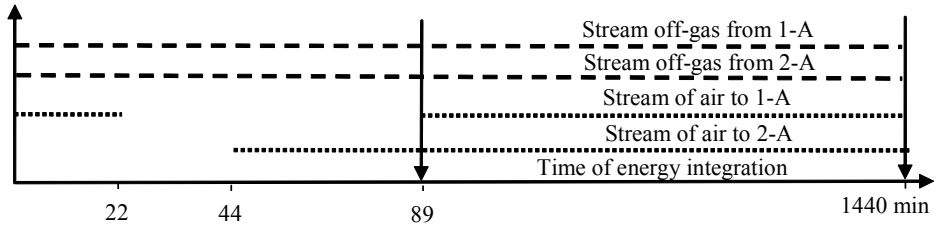

Figure 3: Gantt chart of the process

The specific heat capacity and the density of the two gas streams are ($Cph = Cpc = 1012$ [J/kg.°C]; $\rho h = \rho c = 1{,}225$ [kg/m^3]. The relative humidity of the warm stream is $\varphi = 100\%$, when that of the cold air is assumed as $\varphi = 80\%$.

Determined are: (1) The lowest achievable temperature of cooling the reactors' exhaust gas; (2) Energy saving as result of the heat recovery from the exhaust gas.

4.1.1. The lowest achievable temperature of cooling the reactors' exhaust gas

4.1.1.1. Mathematical model of the heat recovery

As the inlet streams temperatures are known, the target temperatures are determined as a function of the heat exchange surface area as follows:

$$\mathrm{Th1} = \mathrm{Th0} - (\mathrm{Th0} - \mathrm{Tc0}).\frac{1 - e^{-mUA}}{1 - \frac{Wh}{Wc}e^{-mUA}}, \quad (2)$$

and that of the preheated cold air is:

$$\mathrm{Tc1} = \mathrm{Tc0} - \frac{Wh}{Wc}(\mathrm{Tc0} - \mathrm{Th0}).\frac{1 - e^{-mUA}}{1 - \frac{Wh}{Wc}e^{-mUA}}, \quad (3)$$

where:

$$Wh = \frac{Gh1 + Gh2}{\tau}.Cph\,,\ Wc = \frac{Gc1 + Gc2}{\tau}.Cpc\,,\ \text{and}\ m = \frac{1}{Wh} + \frac{1}{Wc}.$$

4.1.1.2. Constraints

The heat exchange has to be physically feasible:

$$\Delta Th = Th0 - Tc1;\ \Delta Tc = Th1 - Tc0;\ \Delta T\_Eg = \min\{\Delta Th,\ \Delta Tc\},$$
$$\Delta T\_Eg = \Delta Tmin\,. \quad (4)$$

The heat exchange surface area is fixed within preliminary given upper and lower bounds (restricted by manufacturing/engineering feasibility):

$$A^{min} \le A \le A^{max}. \quad (5)$$

4.1.1.4. Objective function

The goal is to cool the reactors' exhaust stream to the lowest possible temperature. Thus, equation (2) of the model will be used as objective (efficiency) function.

$$\underset{A}{F} = \min\ Th1. \quad (6)$$

4.1.1.5.Results

To study the influence of $\Delta Tmin$ the optimisation problem was solved at three different values for the economically justifiable $\Delta Tmin$ equal to 5, 7 и 10 degrees. The interval of acceptable changes of the heat exchange surface area is assumed to be between 0 and 50 [m^2]. The results are given in table below.

$\Delta Tmin$	Th1 [°C]	Tc1 [°C]	A [m^2]
5	17	48	5.245
7	19	46.1	3.741
10	22	43.3	2.505

It is clear that a substantial decrease of the temperature of the exhaust supplied to the scrubber is achievable (from 55.1 to 17.2 or 22.0°C). Achieved lower temperature will improve the conditions of the scrubber. If assumed that the water temperature in the scrubber is in the range of 10-20°C, then the solubility of the ammonia will be between

59.7 and 52.6 g in 100 g water, which compared to the solubility at 40.3-30.7 at temperature 30-40°C will demonstrate the true ecological benefit of proposed heat integration. For the hydrogen sulphide the situation is similar: at a temperature of 10-20°C the volume of the gas resolved in a unit of pure water would be between 2.9-2.6, when at 30-40°C, it would be between 2.0-1.7.

4.1.2. Energy savings resulting from the heat recovery from the exhaust gas

The target (final) temperatures of the preheated cold aeration air are the base for calculation of the energy saving in the reactors resulting from heat integration. Assuming the relative humidity at 80% (average for Ireland) and using Ramsin's diagrams of most air we read the humidity x=0.007 [kg water/kg of dry air] at the temperature $Tc0$ of the cold air. Next, the enthalpy of the moist air will be:

$$Ic0 = \left(1000 + 1.97 * 10^3 * x\right) Tc0 + 2493 * 10^3 * x \text{ [J/kg of dry air].} \quad (7)$$

Analogically the enthalpy of preheated in the heat exchanger air will be:

$$Ic1 = \left(1000 + 1.97 * 10^3 * x\right) Tc1 + 2493 * 10^3 * x \text{ [J/kg of dry air].} \quad (8)$$

	$Tc0$=12	$Tc1$= 48 at $\Delta Tmin$ =5	$Tc1$=46.1 at $\Delta Tmin$ =7	$Tc1$ = 43.3 at $\Delta Tmin$ =10
$Ic0$	$2.962x10^4$			
$Ic1$		$6.611x10^4$	$6.419x10^4$	$6.135x10^4$

The difference between $Ic1$ (eq. (8)) and $Ic0$ (eq.(7)) multiplied by the flow of the supplied for aeration air will give the amount of the saved heat for the period of integration in [J].

	$Tc1$ at $\Delta Tmin$ =5	$Tc1$ at $\Delta Tmin$ =7	$Tc1$ at $\Delta Tmin$ =10
Energy-saved [J]	$5.577x10^8$	$5.283x10^8$	$4.849x10^8$

Knowing that, 1 kWh = $3.6x10^6$ J, the energy, saved in each of the three cases of assumed $\Delta Tmin$ will be:

	$Tc1$ at $\Delta Tmin$ =5	$Tc1$ at $\Delta Tmin$ =7	$Tc1$ at $\Delta Tmin$ =10
E-saved [kWh]	154.921	146.745	134.695

It is known that the compensation of the temperature shock in the reactors due to the cold feed load for the winter period requires extra energy associated with prolonged agitation equivalent to some 1000 kWh for the two reactors. Therefore the additional investment for heat exchange equipment can be compensated by achieved daily electrical saving of 13-15%.

4.2. Sensible and Latent heat utilization (Conceptual approach)

As mentioned by (Zhelev, 2008), the Enthalpy-Temperature plot can help to reasonably manage the mass and energy targeting escaping from complex rigorous optimisation. The lack of precision in finding optimum solution in this case is compensated by better control of solutions using engineering inside.

Note, the scrubber/absorber may play the role of humidifier or dehumidifier, which depends on the internal conditions. At present it may very well be a dehumidifier, because the temperature of the gas is higher than the water temperature and in winter conditions the water temperature can very well reach temperatures below the dew point of the water vapour. If the temperature of the gas is lowered by utilisation of its energy through heat integration, then this will represent a humidification scenario.

In the gas-heat integration case the pre-heated air for aeration will be supplied to the hotter reactor sludge, which will cause condensation of moisture contained in the air, accompanied by release of extra heat (compensated by the sensible air heating by sludge). In any case this process has to be carefully monitored because of the danger of foam formation – another not very well-understood phenomenon.
The composite curves constructed for the case study demonstrate the specifics of the heat integration task. It appears to be a typical threshold Pinch problem from both sides (absence of hot or cold utility requirements). This is expected because the wastewater treatment plant naturally does not use external heating, and at the same time no cooling would be expected.
Proposed graphical methodology allows manipulation of control variables. The complete set of "free" variables is: Target temperature of the effluent; Cold air (for sludge aeration) target temperature; Cold sludge target temperature; Stripping water target temperature; Stripping water flowrate.
Proposed manipulations are related to the amount of energy recovery and the efficiency of absorption, which would depend on the stripping water flowrate maintaining the exit ammonia concentration at 1 ppm as per environmental standards. The operating conditions will be influenced by the ambient conditions and this can be taken care of by the control system. Our manual evaluation system is based on the reversed composite curves plotted together with the equilibrium curve. The starting point of this plot needs fixed supply temperatures, target temperatures and flowrates.
These are fixed as follows: Target temperature of the effluent = 19°C (max cold sludge temp + ΔT_{min} (5°C)); Cold air (for sludge aeration) target temperature (50°C); Cold sludge target temperature (57°C); Stripping water target temperature (16°C); Stripping water flowrate (from the energy balance at all fixed temperatures).
"Dragging" the kinks of the composite curve one can try escape from crossing or touching and to achieve as much as possible favourable distribution of driving forces along the stripper. An important part of this temperature/flow re-adjustment procedure would be not to affect the earlier assigned minimum level of ammonia concentration. Here we have to stress that the Enthalpy/Temperature drawing would demonstrate in more details of gas/water mixture condition, then the gas concentration changes.

5. Conclusion and Future Work

Presented work combines rigorous mathematical optimisation with conceptual targeting in energy efficiency improvement accounting for the unpleasant aromas associated with wastewater treatment. Our future work is related to the discrete character of the reactor feeding at present. The feeding pattern, i.e. the frequency and the volume of feeding portions are mixed with the continuous character of aeration/gas extraction and absorption.

Supporting Chemical Process Design under Uncertainty

Achim Wechsung[a,b], Jan Oldenburg[a], Joanna Yu[a], Axel Polt[a]

[a]*BASF SE, 67056 Ludwigshafen, Germany*
[b]*currently: MIT, Dept. of Chem. Eng., 77 Mass. Ave, Cambridge, MA 02139, USA*

Abstract

A major challenge in chemical process design is to make design decisions based on partly incomplete or imperfect design input data. Still, process engineers are expected to design these processes safe, dependable and cost-efficient. The complexity of typical process models limits intuitive engineering estimates to judge the impact of uncertain parameters on the proposed design. In this work, we present an approach to quantify the effect of uncertainty on a process design in order to enhance comparisons among different designs. To facilitate automation, a heuristic to differentiate between numerical and physical infeasibility when simulations do not converge is introduced. It is shown how this methodology yields more details about limitations of a studied process design.

Keywords: Chemical process design, Modeling and simulation, Uncertainty, Process performance measures.

1. Introduction

Process engineers are expected to design safe, dependable and cost-efficient processes. During the stage of conceptual process design, most design decisions are yet to be made, as the design will become more detailed. As each decision at this early stage will limit future choices and also reduce scope of future decisions, one still has a comparable large leverage on overall cost at this moment, but also lacks detailed information. On top, chemical processes are typically complex networks where effects of modifications at one unit operation on the overall process performance are not intuitive. If uncertainty of a subset of model determining parameters is incorporated in the modeled process, complexity increases further. In the end, impact of changes to underlying assumptions of the process model is even less intuitive—even to an experienced process engineer. Hence, providing engineers with a systematic method to foster understanding of implications of uncertain parameters on their current design will facilitate better decision-making in process design.

Uncertainties are introduced in process design in many ways, e.g. by insufficient knowledge about chemical reactions, by limited thermodynamic models, by varying raw material purities or by inadequate cost estimates for raw materials. At the same time, the designed process is nowadays expected to be less accommodating to unforeseen risks or deviations from design conditions using costly means of equipment overdesign.

Commonly, commercial deterministic process simulation and/or optimizing software (e.g. Aspen Plus) is used to design processes beginning at very early stages of the design process. As these simulators require exact values, customarily, engineers first approximate uncertainties using likeliest values to set up the process models. In a possible second step, they can estimate the impact of their limited knowledge about several model parameters by manually perturbing these and studying the effect on their design in a

very laborious and time-consuming matter, esp. since one is generally interested in more than a single uncertain parameter. As early as in the 1970's, first publications aimed at moving beyond simple perturbation schemes. These were mainly motivated by better justifying—and possibly reducing—overdesign factors used in the design of chemical processes (Freeman and Gaddy, 1975; Grossmann and Sargent, 1978; Grossmann *et al.*, 1983).

Building upon Freeman and Gaddy's approach, we employ a Monte Carlo scheme to study the impact of uncertain parameters on the design of a process plant. Utilizing i-TCM (Wiesel and Polt, 2006), processing equipment and its limitations is modeled in Aspen Plus using short-cut sizing methods. The simulation runs are controlled via an Excel interface. One of the greatest obstacles of automated process simulations is the difficulty to differentiate between physical infeasibility and numerical difficulties within the solver. We propose a heuristic priority scheme that supports the user in significantly increasing the number of converged runs by augmenting the optimization with a tailored relaxation scheme. With this procedure, the process engineer gains insight into the limitations of the process without the need of interpreting the results of failed simulation runs–in itself a difficult and sometimes even hopeless task in times of equation-oriented simulation.

The present contribution is organized as follows: First, the dependability analysis is presented in Section 2. Then, a case study will illustrate the application of the method in Section 3. Our work is summarized in Section 4 and possible extensions are discussed.

2. Dependability Analysis

When all parameters to a process are known exactly, the optimal design for this process can be obtained performing a single optimization. In case of uncertain parameters with a known probability distribution, computing the optimal design is more involved as design of a chemical process turns into a two-stage problem (Malik and Hughes, 1979). Expected values will have to be computed numerically, e.g. using stochastic techniques, leading to the repeated requirement to solve the inner optimization problem that selects for the operating conditions. Hence, determining an optimal design using rigorous optimization methods becomes computationally prohibitive when studying complex processes. One usually abandons the requirement to solve both optimization problems rigorously. It is common industry practice to perform the outer optimization, which selects the best flowsheet and sizes the equipment, manually based on engineering insight while using commercial process simulation and/or optimization tools, e.g. Aspen Plus, to solve the inner optimization problem.

When several uncertain parameters are involved, it becomes increasingly difficult to compare designs manually. Especially the need to compute expected values as a basis of comparison is cumbersome when performing this task manually. Also, resorting to perturbation analysis will only yield a qualitative understanding of differences between competing designs. Hence, being able to use a quantitative measure as a result of automatically performed calculations is advantageous in designing an optimal process.

Freeman and Gaddy (1975) propose such a measure that they named dependability, defined as the probability that the process meets its specification,

$$D(x_d, s) = \int_{x_0} P(x_0)\, \delta(x_0, x_d, s)\, dx_0 \ , \qquad (1)$$

where x_d notes the design variables, s the process specifications, x_0 the uncertain parameters, $P(x_0)$ the probability density function for x_0 and $\delta(x_0, x_d, s)$ states if the design meets the specifications under the assumed uncertain parameters $(\delta = 1)$, or if does not ($\delta = 0$). $P(x_0)$ will be known in advance, whereas $\delta(x_0, x_d, s)$ is the result of solving the inner optimization problem for one sample of the uncertain parameters and one particular design; it is not trivially accessible a priori.

D can also be interpreted as the percentage of time when the plant is operating in specification (Freeman and Gaddy, 1975). In many cases, $D < 1$ does not necessitate that the process will not be able to meet its specification on average. On the contrary, a plant with a smaller additional design margin may still be able to make up for times of reduced production when the varying parameters are in its advantage at a later time. Also, $D < 1$ does not entail that the plant is not down at some instances throughout the year, though product quality or quantity may be reduced. In contrast, methods requiring the process to stay within its specifications at all times (e.g. Grossmann *et al.*, 1983) lead to greater equipment overdesign to fulfill these conditions.

2.1. Determining Dependability using a quasi Monte Carlo Method

In order to obtain an estimate for the dependability, the integral in Eq. 1 has to be solved. When examining the integrand, one notes that δ is a complicated function and it is in most cases not known upfront. On the other hand, the probability density function for the uncertain parameters is specified when the problem is set up. Though the integral is too complex to be solved analytically, it can be solved by numerical means. Monte Carlo (MC) methods are widely used to solve such—possibly multi-dimensional—integrals in supplementing decision-making (Sprow, 1967).

In contrast to random MC sampling which use randomly selected samples in parameter space according to the probability distribution function, quasi-Monte Carlo (QMC) methods uses a deterministic number sequence that is chosen explicitly to increase rate of convergence. Latin hypercube sampling, an example for a QMC method, divides parameter space in each dimension in equally probable sections and samples only once from each section. It has been shown that QMC methods are capable of outperforming MC methods in terms of obtaining more accurate results with the same number of evaluations (Morokoff and Caflisch, 1994). For this contribution, a Hammersley sequence was used to obtain the number sequence for the QMC method. Diwekar and Kalagnanam (1997) proposed this sequence as it can easily be expanded to higher dimensions. The authors also presented evidence for favorable convergence properties of their proposed sequencing method.

2.2. Implementation of dependability analysis

Dependability is accessible to determination with the tools available to process engineers. In contrast to rigorous methods that depend on specialized optimization software, the stochastic approach can be carried out using process simulation tools in combination with standard office software. The above outlined method can be implemented in commercial process optimization tools, in our case Aspen Plus, in connection with an external controller for the MC simulations, here Microsoft Excel. Simulations and their data in Aspen Plus are accessible from Excel using an ActiveX automation server interface. Additionally, routines to determine the Hammersley sequence, to transform this uniform sequence to the specified probability distribution of the uncertain parameter, and to control runs in Aspen Plus are implemented in Visual Basic for Applications (VBA) in Excel. Furthermore, post-processing and visualizing of accumulated data is also included in the Excel workbook. In detail, for each individual Aspen Plus run, information on the

values of the sampled parameters, selected computed variables, and status of the run are reported to the user as a reference. These data are aggregated and reported for each variable as mean and standard deviation. Furthermore, dependability and fraction of converged simulations are provided.

2.3. Aid in Differentiating between Numerical and Physical Infeasibility

One of the major drawbacks in early attempts was the lack of robustness when solving the optimization problem for the process flowsheet. Since only converged results—regardless of their success—provide insight into physical constraints of the problem, it is essential to reduce infeasibility due to numerical reasons. Otherwise, when not converged runs are excluded, the statistic can be severely biased and report too optimistic values as simulations are more likely to converge for perturbation towards physically "easier" parameter values.

Non-convergence of a flowsheet can be either due to numerical issues when solving the flowsheet or physical infeasibility of the designed process subject to the assumed conditions. While latter provides the engineer with useful information about the design, former is unfavorable as numerical problems conceal the question of physical feasibility. In general, it is a very time-consuming, manual task to converge a process flowsheet. In this case, this path is infeasible as there will be of the order of hundreds or thousands simulations for one specific process design. To boost convergence—key to providing reliable information about the process—we introduce a heuristic to prioritize competing restrictions using insights from daily operations. According to this ranking the most important priority is to produce substances of desired purity, the second priority is to achieve the desired quantity of product, and lastly, the process is to remain cost-effective. Hence, the optimization problem is set up to maximize product subject to purity constraints and includes an upper limit on the produced amounts.

Furthermore, bounds of the optimization problem can be selectively relaxed when the original problem does not converge. If the problem converges in a second attempt with the relaxed bounds, this solution is used as the starting point for a homotopy method. After each successful convergence of the optimization problem, the relaxed bounds will be consecutively retightened until the original constraints are reached. If convergence is lost as the bounds are retightened, this is noted in the detailed output to the user. Apparently, one is attempting to operate the process just beyond its physical limit, which is useful information when studying the feasibility limits of a proposed process design.

Dependability can be viewed as a condensed measure of the ability of the process design to cope with varying conditions. In combination with heuristics to improve convergence of the flowsheet, it can be determined automatically. Certainly, more converged runs increase the statistical foundation for the measure of dependability. Furthermore, more detailed information about feasibility limits also gives the process engineer a better understanding where physical limitations of the process are.

3. Case study on uncertainty in process design for ethylene oxide synthesis

To illustrate the above-described method, we study a process to synthesize ethylene oxide that was set up based on available information in the literature (Onken and Behr, 1996; Rebsdat and Mayer, 2005). The process is modeled and solved in Aspen Plus using the equation-oriented (EO) simulation mode.

3.1. Setting up simulation for dependability analysis

First, an optimal process design—in terms of minimized overall cost—is found using short-cut equipment sizing and costing methods to provide the baseline for the analysis

of effects of uncertain parameters (Wiesel and Polt, 2006). The dimensions resulting from this optimization are subsequently adjusted to account for empirical overdesign factors. Then, physical limitations of used equipment are included in the model using simplified physical measures, such as F-factors for distillation columns, similar to those used in the sizing procedures. The optimization problem to solve for the dependability analysis is to maximize product quantity subject to unbounded feed streams, product purity restrictions and the above designed plant with its modeled physical limitations.
In this case study, uncertainty in conversion rates used to model the reaction kinetics as well as fluctuating raw material purities are regarded. It is assumed that all parameters follow a triangular distribution with specified lower and upper limits as well as a mode. In order to obtain trustworthy results, 1000 simulations are performed sampling the uncertain parameters according to the above-described QMC technique. Overall, the simulations require computation time of the order of several hours.

3.2. Results of dependability analysis

In the studied case, more than 95% of all simulations converged; 18% required lower product quantity to converge whereas more than 77% complied with the process specifications. Therefore, the dependability of the design is 0.77. Figure 1 shows that these different result areas are rather cleanly separated from each other except for few numerical artifacts.

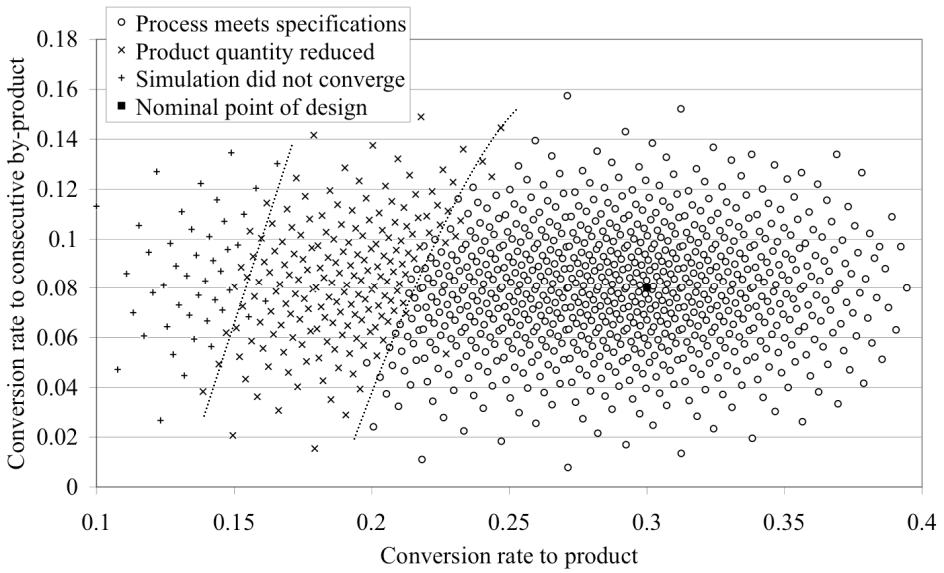

Figure 1: Plot of simulation results show the influence of two uncertain parameters on process dependability. Bounds of the dependable range are approximated and included for illustration.

In the reported case, the plant is capable of producing on average close to 98% of nameplate product quantity when neglecting samples for which no information is available due to not converged simulation runs.

3.3. Discussion

As fig.1 shows, the process is well behaved in proximity to its nominal point of design. However, as conversion rates deviate in unfavorable directions, the limits of the process are tested and exceeded as denoted by decrease of product. When the studied parameters vary even more, numerical issues inhibit further studies, as convergence is lost.

Although the dependability of the designed process appears to be fairly low, the design is capable of nearly achieving nameplate product quantity. The discrepancy between low dependability and high actual product quantity can be explained by the only gradual decline of product output as the process is operated at points beyond its name plate production bound. Here, the importance of as many as possible converged simulations becomes obvious since conclusions can only be drawn from results of converged results. Therefore, if one were to not account for and not to include this region between fulfilling specifications and no convergence in numerical results for averaged process state variables, the actual performance of the plant would be greatly underestimated resulting in the seemingly need for greater equipment overdesign.

4. Conclusion

An approach to support process design when some parameters are not known exactly has been proposed in this work. Important aspects of the methodology are interconnection of process simulator and simple user interface to encapsulate and automate repeated Aspen Plus runs. Equally important are the proposed heuristic means to differentiate between numerical problems and physical limitations. These lead to an increase in converged runs which allow this approach to generate non-trivial insight into complex chemical processes and to provide a quantitative measure of sensitivity of the designed process to uncertain parameters. Hence, the proposed method can provide help to process engineers when designing processes to meet uncertain process conditions on one hand while on the other hand limiting unnecessary process overdesign.
The method of dependability analysis can be applied to study effects of manifold uncertain influences to a process. Though in the presented case study, uncertainties have been restricted to process parameters, the method can be easily extended to incorporate uncertain cost coefficients, e.g. to study the impact of fluctuating raw material costs. Likewise, the proposed priority ranking need not be applicable for all processes; it can be adjusted to meet different priorities without further implications to the methodology.

Cutting Edge Biodiesel Production by Catalytic Reactive Absorption

Anton A. Kiss

AkzoNobel Research, Development & Innovation, Process & Product Technology, Arnhem, The Netherlands, tony.kiss@akzonobel.com

Abstract

This study takes previous work on separative reactors for biodiesel production to a new level by proposing a novel technology based on reactive absorption. This is a significant step forward as reactive absorption offers important advantages in addition to typical benefits of reactive distillation: reduced capital investment and operating costs due to the absence of the reboiler and condenser, and lower temperature profile in the column to avoid thermal degradation of the products. Computer aided process engineering tools such as AspenTech Aspen Plus are used for the process design and simulation of a plant producing 10 ktpy biodiesel from waste oil with high free fatty acids content.

Keywords: reactive absorption, green catalysts, sustainable fuels

1. Introduction

Biodiesel is an alternative fuel with similar propersties as petroleum diesel. Therefore, it can be used alone, or blended with conventional petrodiesel, in unmodified diesel-engine vehicles. Tipically, biodiesel is produced from green sources such as vegetable oils, animal fat or even waste cooking-oil from the food industry.[1,2] Therefore, biodiesel is a *green fuel* that has many advantages over conventional petrodiesel: it is safe, renewable, non-toxic and biodegradable, it contains insignificant amounts of sulfur and its increased lubricity extends the life of diesel engines. In addition, it has a high cetane number (above 60 compared to 40 for petrodiesel), a high flash point (>130°C) and it emits ~70% fewer hydrocarbons, ~80% less CO_2, and ~50% less particles.[1-3]

As a non-petroleum-based diesel fuel, biodiesel consists of short chain alkyl esters of fatty acids, currently produced by acid/base-catalyzed (trans-)esterification, followed by several neutralization and purification steps. Nevertheless, all the conventional methods suffer from problems associated with the use of homogeneous acid or base catalysts, leading to serious economical and environmental consequences, especially considering the recent growth of the overall biodiesel production scale. The increasing worldwide interest in biodiesel is illustrated by the exponential increase of the production, mostly in Western Europe, USA, and Asia (Figure 1).

This study presents a novel biodiesel technology based on reactive absorption that offers significant advantages compared to conventional methods: simple and robust process, high conversion and selectivity, elimination of conventional catalyst-related operations, no thermal degradation of products, no waste streams, as well as reduced capital investment and operating costs. The process design proposed in this work is based on experimental results and rigorous simulations performed using AspenTech AspenONE Engineering Suite as computer aided process engineering tool.

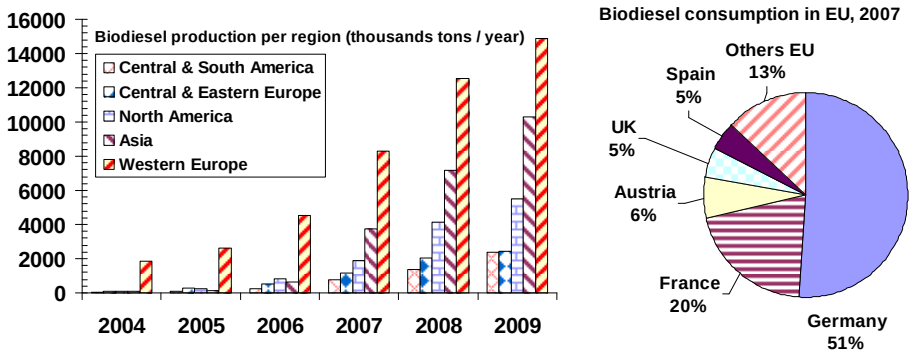

Figure 1. Biodiesel production per region (left), and biodiesel consumption in EU (right).

2. Problem statement

There are three basic methods to produce fatty esters from oils/fats: 1) base catalyzed trans-esterification, 2) acid catalyzed esterification, and 3) enzymatic catalysis.[1-3] The first method is the most frequently used. However, due to the escalating costs of fatty raw materials, the current trend is to use less expensive alternatives such as animal fat, waste cooking oil from catering premises, or waste vegetable oil (wvo).

The problem with waste oils is the very high content of free fatty acids (FFA) that lead to soap formation in a conventional base catalyzed process. Therefore, in order to avoid production loss and soap associated problems, the FFA's must be completely converted first to fatty esters by esterification. Moreover, the conventional biodiesel processes employ liquid catalysts, such as H_2SO_4, NaOH or methoxides.[3] The problem is that homogeneous catalysts require neutralization, washing, separation, recovery, and waste disposal operations with severe economical and environmental penalties.

To solve this problem we propose a novel fatty esterification process based on reactive absorption (RA) using solid acids as catalysts[4,5] and therefore eliminating the additional separation steps and the salt waste streams, thus simplifying the downstream processing. Table 1 presents an overview of the available solid acid catalysts for biodiesel production.[4-6] In this work we selected the metal oxides as acid catalysts, but the ion-exchange resins are also suitable due to the moderate temperatures used in the process.

Note that previous literature studies on separative reactors for biodiesel production are solely based on reactive distillation (RD).[6-9] The novel RA technology proposed in this work offers additional advantages compared to RD, as for example lower temperature profile in the reactive separation column to avoid the thermal degradation of the fatty esters products. As a consequence the process becomes much simpler and more robust, meaning reduced capital investment and operating costs due to the absence of a reboiler (no product vapors return to the column) and condenser (no reflux of water by-product). Moreover, the integrated RA unit is able to shift the chemical equilibrium to completion by continuous removal of products instead of using an excess of reactant. This novel approach based on RA is particularly suitable for treating waste oil or animal fat, including tri-glycerides with up to 100% free fatty acids (FFA) – this is in fact the worst case scenario considered in the work described here.

Table 1. Advantages and disadvantages of the acid catalysts tested for fatty acids esterification.

Catalyst type	Benefits	Drawbacks
Ion-exchange resins (Nafion, Amberlyst)	Very high activity Easy regeneration	Low thermal stability Possible leeching
TPA ($H_3PW_{12}O_{40}$)	Very high activity	Soluble in water
TPA-Cs ($Cs_{2.5}H_{0.5}PW_{12}O_{40}$)	Super acid sites	Low activity per weight
Zeolites (H-ZSM-5, Y and Beta)	Controlable acidity and hydrophobicity	Small pore size Low activity
Sulfated metal oxides (zirconia, titania, tin oxide)	High activity Thermally stable	Deactivates in water, but not in organic phase
Niobic oxide (Nb_2O_5)	Water tolerant	Average activity

3. Simulation methods

Based on the mixture of any particular starting oil/fat used in the biodiesel production process, there will be an associated blend of fatty acid esters in the final biodiesel product. Therefore, the simulation can be performed using one of the available simulation methods illustrated in Table 2: rigorous, shortcut or hybrid method. Note that each method has its key benefits but also specific drawbacks and the requirements can differ considerably. Although favored, the rigorous method is virtually not feasible in practice due to the amount of input data required. On the other hand, the shortcut method provides merely low-fidelity models with very limited practical applications. Therefore, for practical reasons, the hybrid approach gives the best results. Note that in the following simulations the experimentally determined kinetic parameters[5,6] were used but the fatty components were lumped into one fatty acid/ester compound, according to the following chemical reaction:

$$R\text{-}COOH + CH_3OH \leftrightarrow R\text{-}COO\text{-}CH_3 + H_2O$$

Table 2. Simulation methods for biodiesel production: requirements, benefits and drawbacks.

	Rigorous method	Shortcut method	Hybrid method
Requirements	Properties for all species. VLL data and BIP's for all pairs of components. Kinetic parameters for all reactions possible.	Properties for single fatty acid/ester/tri-glyceride. VLL data for the system ester/glycerol/alcohol. Asumed conversion (no kinetic parameters).	Single or reduced list of fatty acid/ester/TG. Short list of VLL data and BIP's for components. Reduced list of kinetic parameters, few reactions.
Benefits	Easy optimization of reaction and separation. High fidelity model. Usable for many plants. Easy comparison for various feedstocks.	Simple model. Fast simulations. Easy-to-build mass and energy balance. No data needed for all species present.	Optimization possible for reaction and separation. Certain ability to compare various feedstocks. Better model fidelity. Fast simulations for RTO.
Drawbacks	Slow simulations and convergence problems. Expensive measurements. Limited RTO and model based control usage.	No comparison possible for various feedstocks. Low-fidelity model. Less ability to use RTO.	More effort to build component list and get kinetic parameters. More work to find VLL data and regress BIP's.

4. Results and discussion

The physical properties of the components present in this process were determined experimentally,[5-7] or estimated using state-of-the-art contribution methods such as UNIFAC – Dortmund modified. Vapor pressure is one of the most important properties with a critical effect in modeling reactive separations. At ambient pressure the boiling points of fatty esters are relatively high (over 300 °C). High purity products are possible in a RD setup, but the high temperature in the reboiler – caused by the high boiling points, is in conflict with the thermo-stability of the biodiesel product. This problem can be avoided by working at lower pressure or allowing methanol in the bottom product.[5-7]

By using reactive adsorption, the drawbacks of reactive distillation can be completely avoided and biodiesel can be produced at moderate temperatures and ambient pressure. Moreover, the water by-product is not refluxed in the RA column hence the detrimental effect of water on the equilibrium reaction and the catalyst is completely avoided.

Figure 2 presents the flowsheet of a biodiesel production process based on a reactive absorption column (RAC) as the key unit. The process was rigorously simulated and optimized using AspenTech AspenONE. The production rate considered for the biodiesel plant designed in this work is 10 ktpy fatty esters. Note that the kinetic parameters used in the simulations were previosly reported in the open literature.[5,6]

The RAC is operated in the temperature range of 135–160 °C, at ambient pressure. Out of the 15 stages of the integrated unit, the reactive zone is located in the middle of the column (10 stages). The fatty acid is pre-heated then fed as hot liquid in the top of the column while a stoichiometric amount of alcohol is injected as vapor into the bottom of the column, thus creating a counter-current flow regime over the middle reactive zone.

Water by-product is removed as top vapor, then condensed and separated in a decanter from which only the fatty acids are recycled back to the column while water can be re-used. The fatty esters are delivered as high-purity bottom product of the RAC. The hot product is flashed first to remove the remaining methanol, then it is cooled down and stored. Further heat-integration is possible but this is beyond the scope of this study.

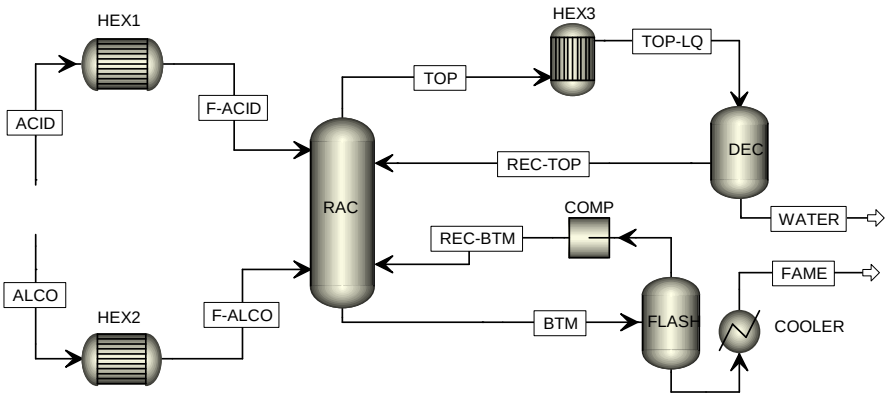

Figure 2. Flowsheet of biodiesel production by catalytic reactive absorption.

Table 3. Mass balance of a 10 ktpa biodiesel production process based on reactive-absorption.

	F-ACID	F-ALCO	BTM	REC-BTM	REC-TOP	TOP	WATER	FAME
Temperature C	160	65.4	136.2	246.2	51.8	162.1	51.8	30
Pressure bar	1.05	1.05	1.03	1.216	1	1	1	0.203
Vapor Frac	0	1	0	1	0	1	0	0
Mass Flow kg/hr	1166.755	188.306	1261.295	11.295	9.369	114.43	105.061	1250
Volume Flow cum/hr	1.492	157.565	1.417	8.949	0.011	213.042	0.109	1.259
Enthalpy Gcal/hr	-0.94	-0.279	-0.904	-0.013	-0.009	-0.337	-0.395	-0.957
Mass Flow kg/hr								
METHANOL	0	188.306	9.083	7.51	0.002	0.129	0.127	1.573
ACID	1166.755	0	0.112	0	9.13	9.147	0.017	0.112
WATER	0	0	0	0	0.237	105.154	104.917	0
ESTER-M	0	0	1252.1	3.785	0	0	0	1248.315
Mass Frac								
METHANOL	0	1	0.007	0.665	0	0.001	0.001	0.001
ACID	1	0	0	0	0.974	0.08	0	0
WATER	0	0	0	0	0.025	0.919	0.999	0
ESTER-M	0	0	0.993	0.335	0	0	0	0.999

The mass and energy balance is given in Table 3. High purity products are possible, the purity specifications exceeding 99.9%wt for the final biodiesel product (FAME stream). Water by-product is also recovered at high purity, hence this stream could be reused as industrial water on the same site. The energy usage is less than 135 kW/ton biodiesel. Note also that the total amount of the recycle streams (REC-TOP and REC-BTM) is not significant, representing only ~1.5% of the total biodiesel production rate.

Figure 3 shows the molar composition profiles in both liquid and vapor phase. The concentration of fatty acid and water increases from the bottom to the top of the column, while the concentration of fatty ester and methanol increases from the top to bottom. Therefore, in the top of the reactive absorption column there are vapors of water and liquid fatty acids, while in the bottom there are vapors of the methanol feed and liquid fatty esters product (biodiesel).

Figure 4 shows the temperature and reaction rate profiles in RAC, as well as the mass flowrates along the column. The temperature difference between the top section and the bottom part of the RA column is relatively low (~30 °C) compared to a RD column. However, the reaction rate profile is similar to the one in a RD column, exhibiting a maximum in the middle and thus keeping the best of both reactive-separation designs.

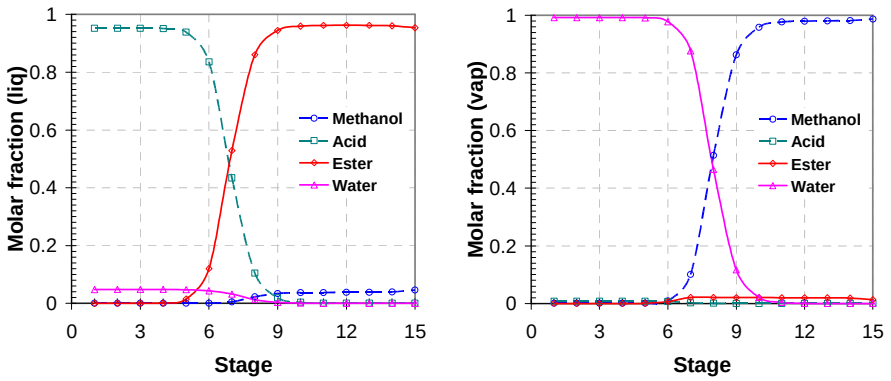

Figure 3. Profiles in RAC: liquid composition (left), vapor composition (right).

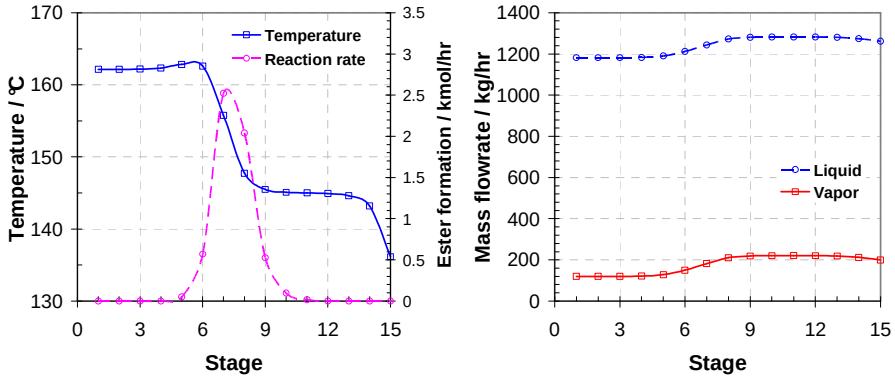

Figure 4. Temperature and reaction rate profiles (left), mass flowrates profiles in RAC (right).

5. Conclusions

This study uses computer aided engineering tools such as AspenTech Aspen Plus for the development of an innovative biodiesel process based on reactive absorption. This novel process radically improves the biodiesel production and dramatically reduces the number of downstream processing steps. The key benefits of this unique process are:

1. Simple and robust process with no catalyst-related waste salt streams, no soap formation, and sulfur-free biodiesel as solid catalysts do not leach into the product.
2. Elimination of conventional catalyst-related operations such as: handling of toxic chemicals and corrosive solutions, catalyst neutralization, separation and disposal of waste salts, waste water treatment, recovery and recycling of excess alcohol.
3. Reduced equipment costs, with up to ~60% savings on the total capital investment.
4. Low operating costs due to the integrated design with no reboiler or condenser.
5. Effective use of the reactor volume leading to significantly high unit productivity.
6. Efficient use of raw materials: no thermal degradation, down to stoichiometric reactants ratio, high conversion as equilibrium is shifted towards completion.
7. Multifunctional plant suitable for a large range of alcohols and fatty raw materials with very high FFA content, such as frying oils, animal tallow, waste vegetable oil.

Study of silver and oxide hybrids of catalysts formaldehyde production by using NLP model

Anita Kovac Kralj

Faculty of Chemistry and Chemical Engineering, University of Maribor, Slovenia, EU

Abstract

Hybrid catalysts are engineered to contain elements of two or more catalysts. Hybrid catalysts are becoming increasingly important advantages for obtaining novel and desirable catalyst activities and properties. The nature of a hybrid catalyst can be changed with additional characters. The disadvantages can be divided and the advantages multiplied.

This study describes a novel technology for the synthesis of formaldehyde production by using hybrid catalysts and the optimization of them. The nature of the hybrid catalyst can be changed by the addition of positive properties. Both, 100 % oxide and 100 % silver formaldehyde production processes can be optimized during hybrid processes. The application of a nonlinear programming, (NLP) mathematical method can be used for optimizing the hybrids of catalysts consisting of percentages of oxide and silver catalysts. The NLP model contains equations for parametric optimization.

The optimized silver process modification was based on 80 % silver catalyst material and the addition of 20 % oxide catalyst. A 20 % change of catalyst can enhance the available heat and product production by 3.8 %.

Keywords: hybrid catalysts, formaldehyde, NLP model

1. Introduction

Formaldehyde is a chemical compound with the formula H_2CO. It is the simplest aldehyde - an organic compound containing a terminal carbonyl group: it consists of exactly one carbonyl. It was first synthesized by the Russian chemist Aleksander Butlerov, but was conclusively identified by August Wilhelm von Hofmann (Reuss et al., 2001). Formaldehyde exists in several forms aside from H_2CO: the cyclic trimer trioxane and the polymer paraformaldehyde. It exists in water as the hydrate $H_2C(OH)_2$.

Two important routes are prominent during industrial formaldehyde production (Fischer, 1992 and Twigg, 1996). The first synthesis route is performed over an electrolytic silver catalyst under lean-air conditions, and was been commercialized at the beginning of the 20^{th} century. The second route, industrialized since the late 1959's, is by oxidation in excess air over a ferric molybdate catalyst. Other routes have not as yet been commercialized, e. g. the sodium catalyzed dehydrogenation of methanol to anhydrous formaldehyde and the partial oxidation of methane over silica catalysts. In 2000, about 55% of the industrial production capacity in Western Europe was based on the silver-catalyzed route (Burridge, 1983), thus it plays an important role. Its advantages are the relatively low investment cost and stable production.

Formaldehyde production can be used in either of the two different kinds of process plants: silver process and oxide process.

This study presents a novel technology for the synthesis of formaldehyde production by using hybrid catalysts.

2. Hybrid catalyst processes

Hybrid catalyst processes can change the characteristic of basic process. It can enlarge the available heat or/and amount of product production.

The silver and oxide processes were analysed one by one, by using an Aspen Plus simulator (Aspen Plus User, 2004) and then compared graphically because of the simple comparisons between the processes (with the same feed flow-rate). The catalyst effect can be analysed by using Aspen Plus and the results are presented with linear equations (1-4). It is a very simple method for an effective approach when using different catalysts. The parameter X_{oxid} can denote the value of oxide catalyst amount. The pure silver process is presented as a 0 % oxide process amount with $X_{oxid} = 0$. The oxide process is presented as a 100 % oxide process amount with $X_{oxid} = 100$. There were different hybrid processes using different catalysts amount between the silver and oxide processes. The parameter X_{oxid} was calculated in fraction (not in percent) in all equations.

The right thermodynamic properties for oxygen and hydrocarbon mixtures during process simulation and optimisation can be estimated by the Wilson property model. In the case-studied formaldehyde plant, the flow rates of oxygen (O_2) and hydrocarbon mixtures can be simulated using an Aspen Plus simulator, but accurate estimates regarding the thermodynamic properties of oxygen and hydrocarbon mixtures need to be made. In this case study, the model is in relatively good agreement with experimental measurements in the existing formaldehyde production plant. So we can use these results for a possible theoretically - identifiable topic area, as key to hybrid catalyst themes. The most important parameters such as: inlet oxygen's mass flows, inlet methanol mass flows, conversion in the reactor, temperature in reactor and available heat, can be defined between the oxide and silver processes.

The processes used different mass flows of oxygen as raw materials. The silver process is using 1130 kg/h of oxygen. The oxide process uses 4189 kg/h of oxygen. Hybrid processes use different catalytic amounts and use different inlet oxygen mass flows between 1130 to 4189 kg/h. The mathematical approximation equation (1) of oxygen's mass flows (q_{ox}) for hybrid was:

$$q_{ox} = 3059\, X_{oxide} + 1130 \quad (1)$$

Conversion in the reactor was different; the oxide process had higher conversion. The oxide process had 99 % conversion and the silver process 80 % conversion. The hybrid processes, using different catalytic amounts, had different conversions between 80 % and 99 %. The mathematical approximation equation (2) of the conversion in reactor (C_{on}) for hybrid was:

$$C_{on} = 19\, X_{oxide} + 80 \quad (2)$$

The temperature in reactor was higher during the silver process. The silver process had an approximate temperature of about 600 ^{o}C. The oxide process had an approximate temperature of about 300 ^{o}C. The mathematical approximation equation (3) of temperature in the reactor (T_r) for hybrid was:

$$T_r = -\,300\, X_{oxide} + 600 \quad (3)$$

The oxide process had the higher available heat. The available heat can be estimated approximately by using linear equation (4). Almost exact estimation can be established by using the Aspen Plus simulator. The mathematical approximation equation (4) of total available heat (Φ_{av}) for hybrid was:

$$\Phi_{av} = 7238\, X_{oxide} + 2149 \quad (4)$$

We have to choose the best one from among the hybrid processes as the criteria energy analysis was used and for maximal additional product production. The energy criteria used was the thermodynamic method better known as "pinch analysis". Pinch analysis helps us to better analyse heat integration, available heat during a process using graphical representation as a grand composite curve (see Figures 1 and 2). It is a powerful technique for the synthesis of a utility system and the results from this method can be used to postulate a superstructure (Zhu et al., 1995). Pinch analysis is guiding heat and power integration using an extended grand-composite curve (Tjoe et al, 1986). Thermodynamic analysis does not guarantee a global optimum solution because it cannot be used simultaneously with the material balance, but it quickly proposes good ideas for the heat and power integration of complex processes (Yee et al., 1990).

The hybrid simulations were simulated by using an Aspen Plus simulator. The different hybrid processes were tested. Both the 100 % oxide and 100 % silver formaldehyde production processes can be modified during different hybrid processes. Comparisons between the grand composite curves of the oxide and silver hybrid processes were decisive for choosing the kind of hybrid. Figure 1 presents comparisons between the pure oxide process and hybrids with 80 % oxide and 20 % silver catalysts, and 60 % oxide and 40 % silver catalysts. The energy efficiency of oxide hybrid can be analysed using the grand composite curve (Fig. 1). The highest available heat areas have 80 %, then 100 %, and the last 60 % oxide catalyst.

Figure 2 presents comparisons between the pure silver process and hybrids with 80 % silver and 20 % oxide catalysts, and 90 % silver and 10 % oxide catalysts. The energy efficiency of silver hybrids can be analysed using the grand composite curve (Fig. 2), too. The highest available heat areas have 80 %, then 90 %, and the last 100 % oxide catalyst.

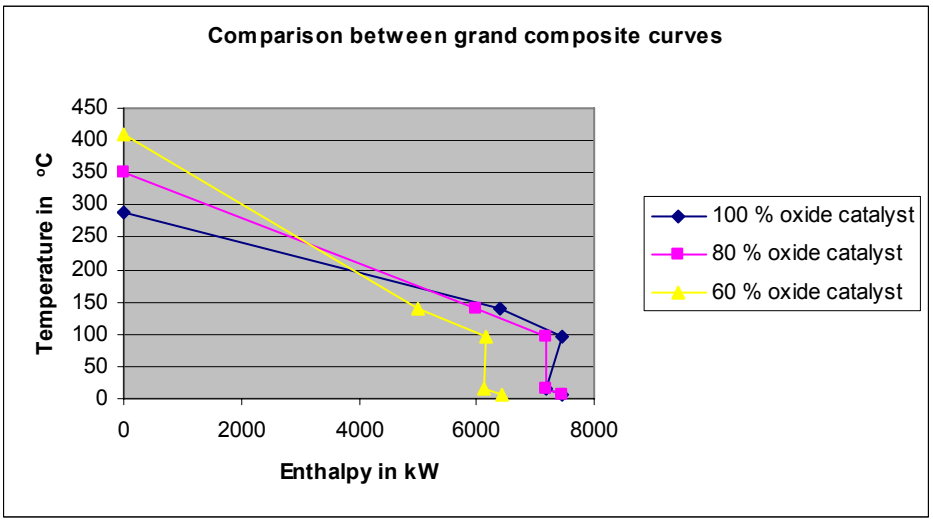

Figure 1: Comparison of grand composite curve of oxide hybrids processes.

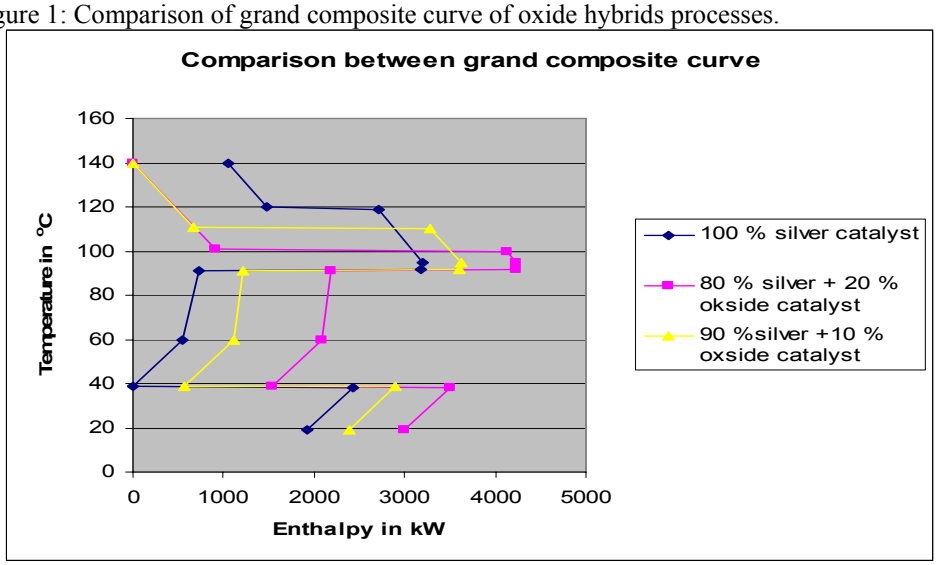

Figure 2: Comparison of grand composite curve of silver hybrids processes.

Energy efficiency (E_{ff}) as a fraction for both hybrids can be denoted by using mathematical polynomial of the 4th order (Eqs. 5−6):

$$E_{ff} = a\, X_{oxid}^{**4} + b\, X_{oxid}^{**3} + c\, X_{oxid}^{**2} + d\, X_{oxid} + e \quad (5)$$

$$E_{ff} = -33.405\, X_{oxid}^{**4} + 67.694\, X_{oxid}^{**3} - 42.015 X_{oxid}^{**2} + 8.0105\, X_{oxid} + 0.5137 \quad (6)$$

The mathematical approximation equation (4) of total available heat (Φ_{av}) for hybrid was not linearly constant; it was multiplied by Energy efficiency (E_{ff}) in the objective function (Eq. 7).

3. The NLP model

The hybrid process parameters are optimized using a nonlinear programming (NLP) model (Brooke et. al, 1992). Optimization could increase annual profit.

The parameters in the hybrid model were simultaneously optimized using the GAMS/MINOS software. This NLP can be solved using a large-scale reduced gradient method (e. g. MINOS). This model is non-convex, it does not guarantee a global optimization solution, but it quickly gives good results for non-trivial, complex processes. This NLP model used the simple linear equations from 1 to 4 and polynomial of the 4th order. The parameter X_{oxid} can denote the value of oxide catalyst mass. The pure silver process is presented as a 0 % oxide mass (X_{oxid} = 0). The pure oxide process is presented as a 100 % oxide mass (X_{oxid} = 1). The parameter X_{oxid} can variable between 0 and 1; it can be presented by the composition of a hybrid catalyst.

The objective function (Eq. 7) of the NLP model is to maximize the annual profit in EUR/a, V; it includes the income from formalin production ($C_f\, C_{on}\, q_M$), income from available heat ($C_{heat}\, \Phi_{av}\, E_{ff}$), and annual cost of raw material for oxygen ($C_{ox}\ q_{ox}$) and cost of oxide catalyst ($C_{ox\text{-}cat}\ X_{oxid}$; Table 1). The silver catalyst is cheaper than the oxide. The cost for average equipment in both process, C_{eq} was 4 MEUR/a.

Maximal additional annual profit is defined by eq. 7 :

$$V_{max} = C_f\, C_{on}/100\; q_M\, t_{op} + C_{heat}\; \Phi_{av}\, E_{ff} - C_{ox}\; q_{ox}\, t_{op} - C_{ox\text{-}cat}\, X_{oxid} - C_{eq} \quad (7)$$

Where q_M is the mass flow rate of methanol, C_{on} is the conversion of methanol in formaldehyde. Time of operation (t_{op}) is 8000 h/a.

Table 1: Cost items for the example processes.

Price of formaldehyde, C_f/(EUR/t): 150
Price of heat, C_{heat}**/(EUR/kW · a): 60
Cost of oxygen and including the equipment, C_{ox}/(EUR/t): 50
Additional cost of oxide catalyst, $C_{ox\text{-}cat}$/(EUR/a): 200 000
Cost of average equipment in both process C_{eq}/(MEUR/a): 4

** Swaney, 1992

The objective function of the optimized hybrid process was 0.85 MEUR/a. The parameter X_{oxid} was 0.2, which was denoted by 20 % composition of oxide and 80 % silver catalysts. Conversion was 83.8 % (0.838 in fraction). The available heat including efficiency was 2050 kW. It needed 1.74 t/h of oxygen.

The optimised silver process modification with 80 % silver and 20 % oxide catalysts - the silver hybrid process (Fig. 3) was very close to the silver process, having little difference and was simulated by using an Aspen Plus simulator. The inlet stream of air increased from 1130 kg/h of oxygen to 1742 (Eq. 1). The temperature in the reactor was lower by about 60 °C (Eq. 3) but with an additional reactor heat enthalpy of 1983 kW. This heat can be used for heating the column reboiler, so during this process steam is not needed for heating. The constant need for heat can be covered in the process. The silver hybrid process had the lower catalytic costs (McKetta, 1985). The production of formaldehyde was higher by 3.8 % for the static inlet value of methanol.

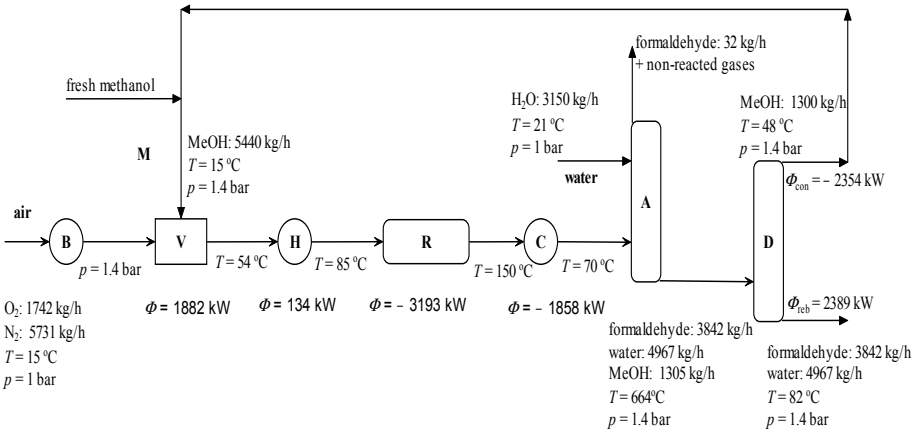

Figure 3: Optimized silver process modification.

4. Conclusion

Hybrid catalysts are used more frequently in enzyme catalysis than in chemical catalysis. The nature of a hybrid catalyst can be changed with additional positive

characteristics. Opportunities for positively increasing these characteristics depend very much on the hybrid catalysts used. An important characteristic of a hybrid catalyst is its effect on process efficiency. The basic characteristic of the silver and oxide formaldehyde processes can be maintained. The hybrid silver and oxide processes can be affected on the quality and/or quantity of available heat and product production. The criteria as to which hybrid can be used, depends on the quality and/or quantity of available heat and maximal product production. Pinch analysis is used for better energy analysis, which helps us to choose the better hybrid by using a graphical representation of the grand composite curve.

The results and methodology for possible theoretically identifiable hybrid catalytic themes can be analysed by using Aspen Plus and presented by linear equations. The most important parameters: such as inlet oxygen's mass flows, inlet methanol mass flows, conversion in the reactor, temperature in the reactor, and available heat, can be defined between hybrid, and the oxide and silver processes.

We can keep the basic characteristics of silver and oxide formaldehyde processes. The hybrid process has an affect on the quality and/or quantity of available heat and product.

Hybrid catalysts were optimized using the NLP algorithm. The NLP model contains equations of parametric optimization. In the optimization model a number of possible alternatives for hybrid catalysts can be included and computer based tools can find the best new catalyst composition. This procedure does not guarantee a global cost optimum, but it does lead to good, perhaps near-optimum, retrofit.

The optimized silver process modification was based on 80 % silver catalyst material and the addition 20 % oxide catalyst. The 20 % changing catalyst can enlarge the available heat and product production by 3.8 %.

Abstract

An important problem in the bioethanol production process is the purification of ethanol from a dilute solution, i.e., approximately 10% ethanol in water. The key factor in the purification process is the formation of the ethanol-water binary homogeneous azeotrope, and an additional process is required to obtain high purity ethanol that can be used in motor vehicles. This study examines the design and optimization of three extractive distillation options (two with thermal coupling) for the purification of a representative mixture of ethanol and water. These extractive arrangements can produce ethanol as distillate with the required purity and energy savings, reduction in CO_2 emissions, high thermodynamic efficiencies and good control properties.

Keywords: extractive distillation, thermal coupling, energy savings.

1. Introduction

A large portion of the world economy has been based on processes highly dependent on petroleum; as a consequence, two major problems have arisen: draining of oil reserves, and increasing gas emissions, associated with global warming. Researchers in many areas are working on solutions to mitigate these problems. One option that offers a partial solution is to intensify production and use of biofuels, including biodiesel, bioethanol, biomass, etc. Of these, bioethanol is currently being used in unmodified combustion engines in a mixture of up to 20%. The use of this mixture is important because it enables improved oxidation of hydrocarbons and, as a result, reduction in both hydrocarbon and carbon dioxide emissions (Quintero et al., 2008).

Currently, most bioethanol is produced from sugar cane, with corn in second place. However, a great deal of current research is focused on industrial production from lignocellulosic material such as agricultural and forest residues. In the production process, four main steps can be identified: Treatment of raw material to obtain the cellulosic mass, saccharification to obtain sugars from the cellulosic mass, fermentation of the sugars, and recovery of ethanol. Independently from the raw material and/or the

process used, the product obtained from the fermentation step is a dilute solution of ethanol in water, from which ethanol is separated and purified to the desired concentration. In addition to research efforts in the saccharification and fermentation process, the separation step should also be viewed as a challenge, and studied accordingly, because of the energy it requires. Assuming that the fermentation process produces a dilute solution of ethanol in water (10% in moles of ethanol) requiring treatment in order to obtain high-purity ethanol for mixing with gasoline (Cardona and Sanchez, 2007; Wingren et al., 2008), the production of high-purity ethanol using distillation requires significant quantities of energy and mass separation agents such as ethylene glycol, NaCl, KI or $CaCl_2$.

The key factor in the purification process is the formation of the ethanol-water binary homogeneous azeotrope. This azeotrope is formed with 96 mass percent of ethanol in water, and an additional process is required to obtain high-purity ethanol to be used in motor vehicles. Several methods can be used: the first is dehydration using a salt, e.g., NaCl, KI, CaCl2, while a second method involves the use of ethylene glycol as an entrainer. Other option is the use of membranes for dehydration by pervaporation (Jiang et al., 2008). This study examines the design and optimization of three extractive distillation options for the purification of a representative mixture of ethanol and water using ethylene glycol (Figure 1), where two of the options use thermally coupled extractive distillation sequences (thermally coupled extractive distillation sequence, Figure 1b; and extractive Petlyuk column, Figure 1c). The study is complemented by a thermodynamic efficiency analysis, CO_2 emissions calculations and determination of control properties at zero frequency.

As previously mentioned, bioethanol can be used in a mixture with gasoline in current combustion engines (Goldemberg, 2007; Goldemberg and Guardabassi, 2009), and it is the most important biofuel produced at present, with worldwide output of about 32 million tons in 2006, of which 90% was from only two countries, Brazil and the USA (Dimian and Bildea, 2008). If bioethanol were to replace gasoline, emissions of greenhouse gases would be reduced by more than 85%, taking the complete fuel cycle into consideration (Bergeron, 1996).

2. Design of Purification Options

Figure 1 shows the three alternatives for the purification of the mixture. A dilute feed of 100 lb-mol/h ethanol in water (10% in moles of ethanol in water) as saturated liquid at 1 atm is introduced into a conventional distillation column that removes the binary homogeneous azeotrope as distillate. This study focuses on the separation stage for ethanol with a high mass fraction (0.995). The bottoms product of the first distillation column is almost pure water. This conventional distillation column is needed in all three distillation options. The first alternative (Figura 1a) uses an extractive conventional distillation column with ethylene glycol as entrainer; the distillate of the column is ethanol with a mass fraction of 0.995. The bottoms product of the extractive distillation column is a ternary mixture of ethanol, water and ethylene glycol. This mixture is fed to a third distillation column in order to recover the entrainer as bottoms product, where the distillate is a mixture of ethanol and water that can be returned to the first distillation column, where the azeotrope is formed. The second and third options (figures 1b and 1c), in the extractive stage of the separation, use a distillation column coupled to a side rectifier and a Petlyuk column, respectively.

Design and optimization methods for thermally coupled extractive distillation are reported in Gutiérrez-Guerra et al., 2009, and briefly described below: To overcome the complexity of the simultaneous solution of the tray arrangement and energy consumption in a formal optimization algorithm, we decoupled the design problem into two stages: (i) tray configuration; (ii) optimal energy consumption. The first stage of the approach begins with the development of preliminary designs for the complex systems, starting from the design aspects of conventional distillation columns. After the tray arrangement for the complex extractive sequence has been obtained, an optimization procedure is used to minimize the heat duty supplied to the reboilers of the arrangement, taking into account the constraints imposed by the required purity of the product streams. Next, the degrees of freedom that remain after design specifications and tray arrangement are used to determine operating conditions that provide minimum energy consumption. The optimization strategy can be summarized as follows: (a) A base design for the complex scheme is obtained. (b) Values for the extractant stream stage and interconnecting flows are assumed. (c) A rigorous model for the simulation of the complex scheme with the proposed tray arrangement is solved (in this study, Aspen Plus™ was used for this purpose). If product compositions are obtained, then the design is kept; otherwise, appropriate adjustments must be made. (d) One value of interconnecting flow is changed, returning to step (c) until a local minimum in energy consumption for the assumed value of the extractant stream stage is identified. (e) The value of the extractant stream stage is modified, returning to step (c) until the energy consumption is minimum (optimization criterion). This result implies that an optimum value has been identified for the design of the complex scheme.

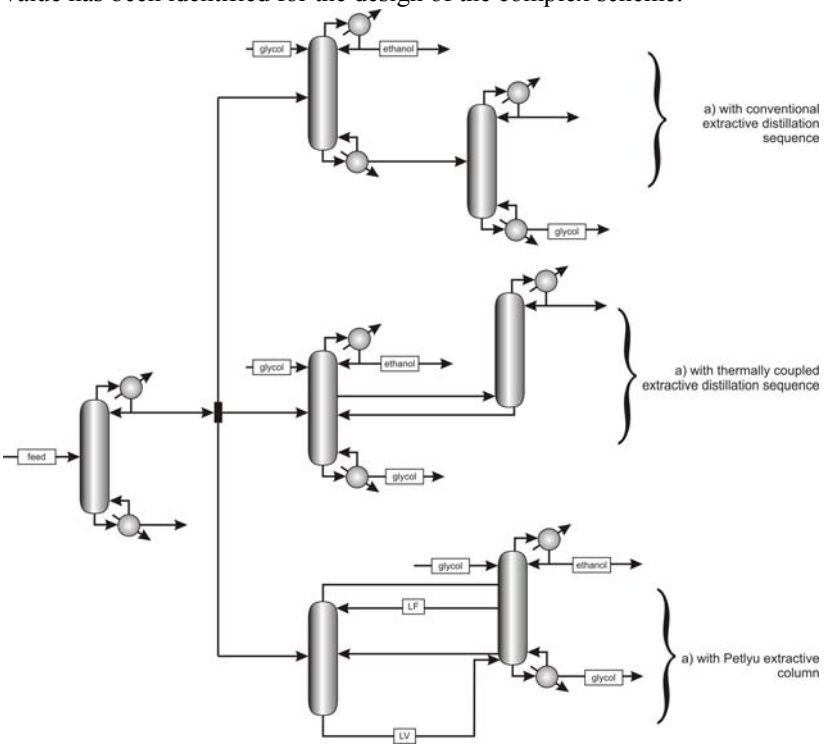

Figure 1. Purification options studied.

Thermodynamic properties of the liquid and vapor phases were calculated using the NRTL model and the Redlich-Kwong equation, respectively. Proper modeling of thermodynamic properties is very important since, in the first stage of the separation procedure, a binary distillation column is required to obtain the binary ethanol-water azeotrope. In this regard, the NRTL model can predict the formation of the binary azeotrope. In all distillation columns, the design pressure for each separation was chosen to ensure the use of cooling water in the condensers. A pressure drop of 10 psi was assumed for each distillation column of the separation sequences.

3. Results

The resulting designs and their performance with respect to optimum solvent to feed ratio (E/F), optimum energy consumption (Q), CO_2 emissions (Gadalla et al., 2005), thermodynamic efficiency (η) and control properties [minimum singular value (σ_*) and condition number (γ) at zero frequency] are discussed. As mentioned previously, the first option (Figure 1a) uses an extractive conventional distillation column with ethylene glycol as entrainer. This option has total energy consumption (including three columns) of 487.63 kW (Table 1) and it is considered a basis for the analysis.

Table 1. Results for the cases of study.

Option	E/F Optimum	Total Energy Consumption (kW)	CO_2 Emissions (Ton/h)	η (%)	σ_*	γ
With conventional extractive sequence	1.5	487.63	0.105	8.13	0.0296	852
With thermally coupled extractive distillation sequence	1.4	497.32	0.111	7.97	0.125	57.5
With extractive Petlyuk column	1.5	362.30	0.0798	12.5	0.987	45.8

Typical optimization curves for the thermally coupled extractive distillation sequence are shown in Figure 2, where the optimal value for the extractant stage and interconnecting flowrate can be identified in order to guarantee minimum energy consumption. The optimization curves show an interesting effect of the search variables on energy consumption. The design is sensitive, in terms of its energy consumption, to changes in interconnecting flowrates and extractant stage. An implication of this observation has to do with operational considerations (the presence of recycle streams can contribute to good dynamic behavior). For all alternatives, the results can be summarized as follows: (i) the energy savings achieved by the option using a Petlyuk

extractive column are 25.7% over the option using a conventional extractive arrangement; (ii) the least favorable option is the sequence using a thermally coupled extractive distillation sequence, as it shows the highest energy consumption and lowest thermodynamic efficiency; (iii) the second law efficiency (η) of the option using a Petlyuk extractive column is higher than that of the corresponding conventional extractive distillation option; (iv) the reduction in global CO_2 emissions, in the arrangement with the Petlyuk structure, is considerable: 24% over the option using the conventional extractive sequence. The inefficiency of conventional sequences (associated with increased CO_2 emissions) has been reported as a consequence of remixing (Hernández, et al., 2006).

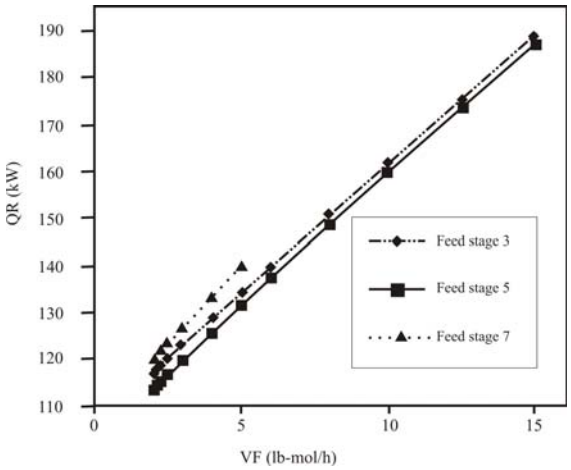

Figure 2. Search for minimum energy consumption in the thermally coupled extractive distillation sequence design.

Therefore, proper optimization of the Petlyuk extractive sequence avoids such a remixing problem. The methodology used generates designs where the effect of the remixing is eliminated. In addition, it is important to analyze the composition profiles in the extractive distillation systems. The option using the conventional extractive column can produce ethanol with a high mass fraction (0.995), with the bottoms product composed of ethylene glycol, water and ethanol. The options using complex extractive columns produce ethanol with the same mass fraction, but it is important to highlight that these complex columns separate the entrainer as the bottoms product and the side rectifier or side stream removes a mixture of ethanol and water.

A final test was carried out on the control properties of the options studied, using the singular value decomposition (SVD) technique at zero frequency. The singular values of the transfer function matrix of a process at zero frequency are the squared roots of the eigenvalues of the product of the transfer function matrix by its transpose and conjugated. Two parameters of interest are the minimum singular value and the ratio of maximum to minimum singular values, or condition number. The systems with higher σ_* values and lower γ values are expected to show the best dynamic performance under feedback control. Table 1 shows the SVD results for the three options analyzed. The arrangement using an extractive Petlyuk column presents the highest minimum singular value; therefore, it can be expected that this complex system will exhibit better closed-loop dynamic behavior than the option using an extractive conventional sequence. Condition number results show that the sequence with the Petlyuk structure offers the

best value. As a result, it can be expected that the complex distillation system is better conditioned to the effect of disturbances than the conventional arrangement.
According to the results, the Petlyuk extractive arrangement is the best scheme option for separation of the binary homogeneous azeotrope of ethanol and water as regards energy consumption, CO_2 emissions, thermodynamic efficiency and control properties. In addition, this complex distillation sequence can reduce capital costs since it can be implemented in a single distillation column using a dividing wall.

4. Conclusions

In this work, the separation of a typical mixture of ethanol and water from a fermentation process was studied, considering an extractive conventional distillation column and two thermally coupled extractive distillation sequences using ethylene glycol as entrainer. The results show that the option using an extractive Petlyuk column can produce energy savings of 25.7% over the option with an extractive conventional distillation arrangement. Moreover, the structure with the Petlyuk scheme shows the best results with regard to CO_2 emissions (associated with energy consumption), thermodynamic efficiency and control properties. In general, the results are important because they indicate that the use of complex extractive distillation systems in the bioethanol purification process is feasible as regards economic, thermodynamic and control aspects.

The Influence of Tangent Pinch Points on the Performance of Batch Rectifications: Development of a Conceptual Model for Ternary Mixtures

Karina A.Torres,[a] José Espinosa,[b]
[a,b] *INGAR – CONICET - UNL, Avellaneda 3657, S3002 GJC Santa Fe, Argentina*

Abstract

This contribution explores the influence of tangent pinch points on the performance of batch distillations of highly non ideal ternary mixtures and its incorporation into a conceptual modeling framework under the assumption of a batch rectifier with infinite number of stages.
Two algorithms are developed to determine the maximum feasible distillate composition on the line of preferred separation and its corresponding limiting reflux ratio. The first one is based on a region elimination method (REM) and relates the occurrence of a saddle-node bifurcation to the appearance of a maximum in the curve reflux vs. molar liquid fraction of any of the components of the mixture. This method takes into account the bifurcation analysis of reversible distillation profiles. The second method is analytical and consists in solving an equation system that represents two facts: the liquid compositions of the bifurcation point, together with its vapor in equilibrium and its distillate must be aligned, and a turning point occurs. The resolution of the system is simplified because of the fact that in batch distillation of ternary mixtures operating at reflux below or equal to the limiting one, the bifurcation point coincides with the instantaneous still composition in the reboiler. Then, the dependence of feasible distillate mole fractions on reflux ratios above the limiting one is calculated by solving a non linear equation system, which incorporates the tangency condition and provides the unknown compositions of tangent pinches. A numerical method, based on the improved memory method, is implemented here to solve this non linear system. The conceptual model replaces the one based on the assumption of the invariance of a controlling saddle pinch, only valid for ideal systems and non ideal mixtures without tangent pinch points, and emphasizes the variation of the composition of the tangential pinch points for reflux above the limiting one. Results obtained from the conceptual model for instantaneous column performance are in excellent agreement with rigorous simulation in Hysys and highlight the effectiveness of the proposed algorithm. Two highly non ideal ternary mixtures are studied along the contribution: the systems methanol/2-propanol/water and acetone/chloroform/benzene.

Keywords: batch distillation, saddle-node bifurcation, reversible profiles, tangent pinches.

1. Quantitative determination of the trajectory of feasible distillate compositions in nonideal ternary mixtures

1.1. Quantitative determination of the maximum feasible distillate composition on the line of preferred separation

Calculation of the maximum feasible distillate composition on the equilibrium vector or preferred separation line for a given instantaneous still composition is the key ingredient

of a conceptual model which attempts to incorporate the influence of tangent pinches on the performance of batch distillations. Duessel[1] was the first to introduce the idea of solving the eigenvalue problem of the Jacobian of the equilibrium function in the instantaneous still composition x_B to obtain a linearization of the adiabatic profile in the neighborhood of the still composition and hence, an estimation of the instantaneous minimum reflux ratio. Note that for an instantaneous still composition x_B, the feed to the column is a vapor stream whose composition $y^*_{x_B}$ is in phase equilibrium with the composition of the liquid in the still and the liquid leaving the lower column end x_N is located on the linear approximation of the adiabatic profile departing from x_B. The mass balance envelope used in the conceptual model is shown in Figure 1(a).

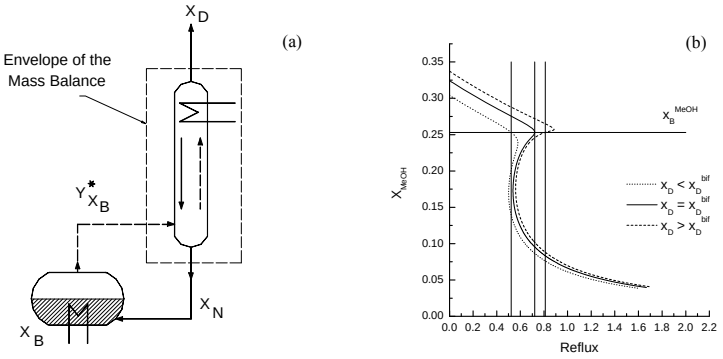

Figure 1. (a) Envelope of the mass balance used in the conceptual modeling of batch distillations; (b) System methanol/2-propanol/water. Pinch point curve x_{MeOH} *vs.* r for three distillate compositions on the preferred line with direction $\left(y^*_{x_B} - x_B\right)$.

On the other hand, Espinosa and Salomone[2] adapted Duessel's approach to handle the operation at constant reflux ratio and they identified three different situations: i) for reflux ratios between zero and $R^* = \left(x^*_D - y^*_{x_B}\right) \Big/ \left(y^*_{x_B} - x_B\right)$, the distillate compositions are aligned with the equilibrium vector, starting from $y^*_{x_B}$ ($r = 0$) up to the point x^*_D (where the composition of the heaviest component becomes zero). A pinch at the rectifier lower end, with identical composition to that of the mixture in the still, controls the separation; ii) for reflux ratios between R^* and $R^{**} = \left(x^{**}_D - y^*_{x_B}\right) \Big/ \left(y^*_{x_B} - x_{N,\max}\right)$, the distillate compositions are located in the binary edge corresponding to the lighter components between x^*_D and x^{**}_D. $x_{N,\max}$ is the intersection of vectors $\left(x^{**}_D - y^*_{x_B}\right)$ and the linearization of the adiabatic profile $x_N = x_B + \lambda v$. There is now a binary saddle pinch x^{II}_P, with invariant composition; iii) for $r \geq R^{**}$ the distillate composition equals x^{**}_D, the composition of the more volatile species with a pinch at the top of the column controlling the separation.

In this contribution, we will focus on the incorporation of tangent pinches into the conceptual modeling of batch distillations, which affects the maximum distillate composition achievable on the preferred line. Similarly to ideal mixtures, the lower pinch controls the separation for values of the reflux ratio within an interval with

bounds $\left[0; r^{bif}\right]$. At $r = r^{bif}$, the lever arm rule determines the maximum feasible distillate composition x_D^{bif} for which the corresponding pinch point curve shows a saddle-node bifurcation at the instantaneous still composition x_B. The operation at reflux ratios above the bifurcation value is controlled by tangent pinches of unknown compositions.

1.1.2. Quantitative determination of profiles of reversible distillation

In order to calculate the reversible profiles or pinch point curves, the following system of linear equations must be solved:

$$\frac{d\vec{f}_c(T,\vec{x})}{dT} = \vec{0} = \frac{\partial \vec{f}_c}{\partial T} + \left(\frac{\partial f_{c,i}}{\partial x_j}\right)^{\Sigma}\left(\frac{d\vec{x}}{dT}\right)^{\Sigma} \qquad (1)$$

where both $\frac{\partial \vec{f}_c}{\partial T}$ y $\left(\frac{\partial f_{c,i}}{\partial x_j}\right)^{\Sigma}$ can be analytically calculated. The supraindex Σ in Eq. (1) indicates that the mole fraction summation over all components is accounted for. The numerical integration of $\left(dx/dT\right)^{\Sigma}$ in Eq. (1), (beginning from an initial point such as a pure component or azeotrope) allows the calculation of the entire reversible profile for a given distillate $\mathbf{p}$.

1.1.3. Region Elimination Method (REM)

As it was mentioned before, the maximum feasible distillate mole fraction on the line of preferred separation is characterized by a saddle-node bifurcation of the corresponding reversible profile at the instantaneous still composition, and it is related to the appearance of a maximum in the curve r vs. the composition of any of the components of the mixture. This fact can be appreciated in Figure 1(b) and it is used to determine the limiting distillate composition x_D^* and its corresponding reflux ratio $r^* = r^{bif}$. Given a distillate $\mathbf{p}$ belonging to the line of preferred separation, the main idea of this method is to first calculate two points x_B^+ and x_B^- of the reversible profile around x_B by numerically integrating the equation system (1) for given values of the temperature increments ΔT_1 and $\Delta T_2 = -\Delta T_1$. Then, reflux ratios are obtained from the lever arm rule for the three compositions and finally, values of the derivatives $\Delta r_1 / \Delta x_k^1 = \left(r_{x_B} - r_{x_B}^-\right) / \left(x_{B,1} - x_{B,1}^-\right)$ and $\Delta r_2 / \Delta x_k^2 = \left(r_{x_B} - r_{x_B}^+\right) / \left(x_{B,1} - x_{B,1}^+\right)$ on both sides of the still composition are estimated. If the signs of the derivatives differ each other, a saddle-node bifurcation at instantaneous still composition is found with the corresponding distillate mole fraction as the maximum feasible one. Otherwise, another distillate composition must be picked up (according to the bisection method) until convergence. The initial search interval is $\left[y_{x_B}^*, z_D\right]$, where z_D is the intersection of the equilibrium vector with either the binary axis corresponding to the more volatile components (zeotropic systems) or the pinch distillation boundary, PDB (azeotropic mixtures with unstable distillation boundaries).

1.1.4. Analytical Method

The following equation system, adapted from the work of Fidkowski et al.[3], represents the tangent pinch situation in a given column section (e.g., for the rectifying section):

$$\begin{cases} -y(x_k) + \dfrac{r}{r+1} x_k + \dfrac{1}{r+1} p_k = 0 & (2) \\ \det\left(Y - \dfrac{r}{r+1} I \right)\Big|_{x_k} = 0 & (3) \end{cases}$$

where $Y = \left[\dfrac{\partial y_i}{\partial x_j} \right]^{\Sigma}_{\hat{x}_{i \neq j}}$ is the Jacobian matrix of the equilibrium function and x_k, $y(x_k)$ and p_k are the *k -th* components of the bifurcation point, its vapor in equilibrium and the distillate, respectively. This method uses the fact that in batch distillation of ternary mixtures operating at a reflux ratio $r \leq r^{bif}$, the bifurcation point coincides with the instantaneous still composition x_B. Therefore, a simple way to obtain the maximum feasible composition in the line of preferred separation consists of the following steps: i) calculate the elements of the Jacobian matrix of the equilibrium function from their analytical expressions[4,5], ii) solve the eigenvalue problem given by equation (3) at x_B to obtain the bifurcation value of the reflux ratio $r = r^{bif} = r^*$, iii) calculate the maximum feasible distillate composition $p = x_D^* = x_D^{bif}$ through the lever arm rule, equation (2). It is interesting to note that two values of the reflux ratio are obtained from solving equation (3). For systems where the reversible profile either resembles a pinch point curve without a tangent pinch point or a reversible profile showing a non-controlling tangent pinch, the reflux ratio values will take either negatives values or positive ones, giving rise in the last case to distillate compositions outside the composition simplex.

1.2. Quantitative determination of the curve of feasible distillate compositions for reflux ratios greater than r^{bif}

For reflux ratios above r^{bif}, the instantaneous operation is controlled by unknown values of tangent pinches x_p, lower end liquid compositions $x_N \neq x_B$, and distillate mole fractions x_D, that can be calculated by solving the equation system 4-8:

$$-y^*_{x_B} + \frac{r}{r+1} x_N + \frac{x_D}{r+1} = 0 \qquad (4)$$

$$-y^*_{x_p} + \frac{r}{r+1} x_p + \frac{x_D}{r+1} = 0 \qquad (5)$$

$$y^*_{x_p} = \frac{\gamma_i(x_p, T) p_i^0(T)}{p} x_p \qquad (6)$$

$$x_N = x_B + \lambda v, \qquad x_N \in [x_B, x_{N,\max}] \qquad (7)$$

$$\det\left(Y - \frac{r}{r+1} I \right)\Big|_{x_p} = 0 \qquad (8)$$

It's easy to check that consistency and solution unicity of this system are guaranteed. The numerical resolution of 4-8 is based on the improved memory method developed by Shacham[6] for the solution of a non-linear equation and is presented below:

Step 1. Given a value for the reflux ratio r, select values for $x_{N,1}$ and $x_{N,2}$, belonging

to the eigenvector within the interval $\left[x_B, x_{N,\max}\right]$. Therefore, equation (7) is obeyed.

Step 2. Solve equation (4) for $x_{D,1}$ and $x_{D,2}$ from the estimated values $x_{N,1}$ and $x_{N,2}$.

Step 3. For each distillate composition from Step 2 calculate, by integrating equation (1), the pinch point curve and Δr (the difference between the reflux ratio corresponding to the first i-th point of the pinch curve for which $r(i+1)-r(i)<0$, and the operating reflux ratio r). The selected point corresponds to a saddle-node bifurcation of the reversible profile (see Figure 1(b)) and equations (5) and (6) are satisfied (the error function Δr replaces the tangency condition, equation (8)). However, the bifurcation reflux differs in general from the operation reflux r.

Step 4. If $\Delta r(x_{N,1}).\Delta r(x_{N,2})<0$, initialize the improved memory method by taking $\left[x_{N,1}, x_{N,2}\right]$ as the initial search interval until determining the composition at the lower end column x_N for which the error function $\Delta r \cong 0$. Otherwise, go to step 1, select a new value for x_N and repeat steps 2 and 3 until an appropriate search interval is found.

From the analysis of the algorithm above it is clear that the method searches for a distillate composition whose corresponding pinch point at the saddle-node bifurcation [x_p , $y^*_{x_p}$, r^{bif} and T_p] has a reflux ratio r^{bif} such that $r^{bif}=r$ (Figure 2(a)). In other words, it searches for the root of the error function $\Delta r=\Delta r(x_N)$.

The results from the conceptual model were compared to rigorous simulations from Hysys for different values of $r \geq r^{bif}$ and all of them were in excellent agreement.

1.3. Conclusions

Figure 2(b) shows the curve of feasible distillate mole fractions corresponding to an instantaneous still composition x_B for the mixture acetone/chloroform/benzene at some reflux ratios $0 \leq r \leq r^{**}$. The products are situated on the "preferred line" for reflux ratios $r \leq r^{bif}$ and along a curved trajectory if $r > r^{bif}$. The system 4-8 replaces the model based on the assumption of the invariance of a controlling saddle pinch, valid for ideal systems and nonideal mixtures without tangent pinch points. Figure 2(c) emphasizes the variation of the composition of the tangential pinch points for $r \geq r^{bif}$.

2. Two ternary mixtures as examples of application

Two non ideal ternary mixtures are studied: the systems MeOH/IPA/W (unstable distillation boundary) and A/C/B (stable distillation boundary). The Wilson-Ideal model is used to calculate the liquid-vapor equilibrium. All the necessary parameters (also the analytical derivatives) are obtained from codes implemented in Matlab.

Abstract

A new method for applying Quantitative Structure Property Relationship type methods for prediction of properties needed for phase equilibrium calculation is presented. The use of the new method is demonstrated by predicting vapor pressure for members of the 1-alkene homologous series. It is shown that the new method enables the prediction of vapor pressure within experimental uncertainty, depending on the level of similarity between the predictive compounds and the target compound.

Keywords: Property prediction, Phase equilibria, Molecular structure, QSPR.

1. Introduction

Phase equilibria calculations are of key importance for process and product design. In many cases the required data for these calculations are not available and have to be estimated. Up-to now, most published methods that relate molecular structure and properties have been devoted to constant properties of pure compounds, which are necessary but not sufficient for phase equilibria calculations of mixtures at different compositions, temperatures and pressures (Poling et al, 2001).

We have investigated the use of a new method, which is a combination of the Short-Cut Quantitative Structure-Structure-Property Relationship (SC-QS2PR, Cholakov et al, 2007) and the Targeted Quantitative Structure Relationship (TQSPR, Brauner et al. 2006) for prediction of the phase equilibrium related properties.

In the next section the properties needed for phase equilibrium computation are reviewed and categorized. In the 3rd section the proposed combination of the SC-QS2PR and TQSPR methods is described. The use of this new method is demonstrated by predicting vapor pressure (saturation temperature) for members of the 1-alkene homologous series.

2. Properties Needed for Phase Equilibrium Calculations

Vapor – liquid equilibrium ratio K (K-value) is commonly used for phase equilibrium computations. At low and moderate pressures the $\gamma - \Phi$ model is typically used. Using this model the K – value for the i-th component is given by:

$$K_i = \frac{\gamma_{iL} f^{0}{}_{iL}}{\phi_{i_V}} \tag{1}$$

where γ_{iL} and f^{o}_{iL} denote the activity coefficient and the standard-state fugacity of the i -th component in the liquid phase and ϕ_{iV} is the fugacity coefficients of the i -th component in the vapor phase. The pure component saturation pressure P_i^s is essential for calculating the standard-state fugacity of a pure liquid at a specified temperature and pressure. For ideal systems at low pressures Eq. (1) is reduced to:

$$K_i = P_i^s / P\,, \tag{2}$$

where P is the total pressure. Thus, for ideal systems the prediction of P_i^s is sufficient for phase equilibrium calculations. At high pressures the gas and liquid fugacity coefficients are usually modeled by equations of states. The equation of state form of the phase equilibrium ratio is usually written as:

$$K_i = \phi_{iL} / \phi_{iV}\,. \tag{3}$$

where ϕ_{iL} is the partial fugacity coefficient of a species in the liquid mixture and ϕ_{iV} is the partial fugacity coefficient of a species in the vapor mixture.

To calculate the fugacity coefficients, either the Soave-Redlich-Kwong or Peng-Robinson EoS are usually employed. In the EoS, the properties of the pure compounds required are the critical temperature (T_c) and pressure (P_c), and the acentric factor (ω). The application of EoS to mixtures requires the use of mixing rules for the mixture energy parameter a_{mix}, which accounts for interactions between the species in the mixture, and for the co-volume parameter b_{mix}, which accounts for the excluded volume of the species of the mixture:

$$a_{\text{mix}} = \sum_i \sum_j x_i x_j a_{ij}\,; \qquad b_{\text{mix}} = \sum_i x_i b_{ii} \tag{4}$$

The cross coefficient a_{ij} is related to the corresponding pure-component parameters by the following combining rule:

$$a_{ij} = \left(a_{ii} a_{jj}\right)^{0.5} \left(1 - k_{ij}\right) \tag{5}$$

Thus, for phase-equilibrium calculations some of the following properties are usually needed:

1. Pure component constant properties: T_c, P_c, and the ω.
2. Binary interaction parameters for the calculation of ϕ_{iL} and ϕ_{iV} (using equation of state), and the activity coefficients (e.g., using the UNIFAC model).
3. Pure component saturation pressures at various temperatures.

3. The Combination of the SC-QS2PR and TQSPR methods

The SC-QS2PR and TQSPR methods are described in detail by Cholakov et al., 2007 and Brauner et al., 2006. A brief description of the new combined method follows. It is assumed that an unknown *target property* of *a target compound* (y_t) can be represented

as linear combination of known property values of two *predictive* compounds y_{p1} and y_{p2}, provided that the predictive compounds are *similar* to the target compound:

$$y_t = \beta_1 y_{p1} + \beta_2 y_{p2}. \quad (6)$$

The coefficients β_1 and β_2 are calculated by solving the structure-structure relationship:

$$\begin{aligned} \beta_1 + \beta_2 &= 1 \\ \beta_1 \rho_{p1} + \beta_2 \rho_{p2} &= \rho_t \end{aligned} \quad (7)$$

where ρ_{p1} and ρ_{p2} are molecular descriptor values of the predictive compounds and ρ_t is the (known) molecular descriptor value of the target compound. Solving Eq. (7) for β_1 and β_2 and introducing these values into Eq. (6) yields:

$$y_t = \frac{\rho_{p2} - \rho_t}{\rho_{p2} - \rho_{p1}} y_{p1} + \frac{\rho_t - \rho_{p1}}{\rho_{p2} - \rho_{p1}} y_{p2}. \quad (8)$$

For obtaining reliable prediction via the property-property correlation (Eq. 8), the predictive compounds must belong to a *similarity group* of the target compound and the molecular descriptor ρ must be collinear with the property y for the members of the similarity group.

If the target compound belongs to a homologous series, the natural similarity group comprises members of the same homologous series for which experimental values of the target property are available. In other cases the identification of the similarity group can be carried out using methods described by Brauner et al. (2006). To identify a descriptor which is collinear with the property y for the members of the similarity group, a stepwise regression program is employed on a dataset which contains the property y as the dependent variable and various descriptors (associated with the members of the similarity group) as independent variable.

The prediction of pure component constant properties by applying the proposed method is straightforward (Cholakov et al, 2007). The prediction of binary interaction parameters is discussed elsewhere. Following is an example of application of the proposed method for prediction of vapor pressure of 1-alkenes.

4. Predicting the Vapor-Pressure (Saturation Temperature) of 1-alkenes Using the Proposed method

4.1. Databases and Programs Used in the Study

A database containing 1280 descriptors for 324 compounds was used for this study. The descriptors were calculated with the Dragon, version 5.4. software (DRAGON is copyrighted by TALETE srl, http://www.talete.mi.it) using minimized molecular models. The SROV (Shacham and Brauner, 2003) stepwise regression program was used for the selection of descriptors collinear with a property. Experimental normal boiling temperature data and Antoine equation constants were taken from the NIST (2005) database.

4.2. Deriving the Saturation Temperature (T_s) Prediction Equation

All the correlations which represent the vapor pressure variation as function of temperature (such as the Antoine, Riedel and Wagner) can be used for prediction of vapor pressure for the target compound. We will be using the Antoine equation for this demonstration. The Antoine equation is:

$$\log(P_i^s) = A_{pi} - \frac{B_{pi}}{C_{pi} + T}. \qquad (9)$$

where A_{pi}, B_{pi} and C_{pi} are the Antoine equation coefficients for the i^{th} predictive compound, and P_i^s (bar) is the saturation pressure at temperature T (K). Introducing the $\log(P_i^s)$ values from Eq. (9) into Eq. (8) yields $\log(P_t^s)$, where P_t^s is the saturation pressure (bar) of the target compound at temperature T (K). This method can be viewed as an enhancement of the "two reference fluid" estimation method (described, for example, by Poling et al., 2001) where the same two predictive compounds often used for all the target compounds and the acentric factor is employed, instead of the molecular descriptor in Eq. 8. Using predictive compounds which are similar to the target is, of course, preferable to the use of the same predictive compounds for all targets, also the use of molecular descriptors is preferable to the use of acentric factor (which requires experimental data of T_c and P_i^s value at $T = 0.7\ T_c$).

An alternative form of the Antoine equation, which is explicit in the saturation temperature, T_i^s, at pressure P is the following:

$$T_i^s = \frac{B_{pi}}{A_{pi} + \log(P)} - C_{pi}. \qquad (10)$$

Introducing the T_i^s values from Eq (10) into Eq. (8) yields the value of the saturation temperature of the target compound at pressure P. Recalling that the normal boiling temperature (T_b) is the saturation temperature at atmospheric pressure suggests the use of a descriptor collinear with T_b in the structure-structure correlation (Eq. 7). It is assumed that for all the members of the similarity group (and the target compound) the values of a descriptor collinear with T_b are available. For few (at least two) members of the similarity group experimental data and/or models for vapor pressure need also to be available.

4.3. Prediction of T_t^s for the 1-alkene Series

In Table 1 seventeen members of the 1-alkene series are shown with the vapor pressure data and equations that are available in the NIST (2005), and values of the descriptor Vev1 (a 2D eigenvalue-based descriptor: eigenvector coefficient sum from van der Waals weighted distance matrix , calculated by the Dragon program). The data shown includes the number of carbon atoms (n_C), T_b, the recommended temperature range of applicability of the Antoine equation for vapor pressure calculation the Antoine equation coefficients: A, B and C. Up to 1-hexadecene experimental T_b values are available as well as Antoine equations parameters. For higher n_C, only few T_b values and no Antoine-equation parameters are available. However, values of the VEv1 descriptor can be calculated, irrespective of n_C.

In Figure 1 a plot of T_b versus the values of the descriptor VEv1 for the 1-alkene series is shown. Observe that the T_b data can be represented by a straight line, T_b = 1103.7 Vev1-12.647, with a linear correlation coefficient R^2 = 0.9981. This equation can be used for predicting T_b for the compounds for which no experimental values are available.

Let us select 1-decene and 1-undecene as predictive compounds and 1 – dodecene as target compound. Reliable prediction of P_t^s or T_t^s can be obtained only if the predictions are carried out in the common temperature applicability range of the Antoine equations for the predictive compounds (for the case of P_t^s), or the common pressure applicability range of the same equations (for the case of T_t^s). In Figure 2 the vapor pressure vs. temperature of the predictive and target compounds (obtained by the Antoine-equation parameters of Table 1) are shown. Looking at the temperature range of validity of the high and low pressure-range parameters of the predictive compounds shows a rather limited overlap between those ranges. However, there is a complete overlap between the pressure ranges of validity. This provides an additional justification for preferring the prediction of $T_t^s(P)$ over the prediction of $P_t^s(T)$.

Introducing ρ_{p1} = 0.4093; ρ_{p2} = 0.4663; and ρ_t = 0. 0.448 into the structure-structure correlation (Eq. 7) yields the parameter values: β_1 = 0.48814 and β_2 = 0.51186. T_t^s was predicted using the SC-QS2PR method with these parameter values and compared to values obtained by the Antoine equation (the parameters are given in Table 1). The difference between the SC-QS2PR prediction and the Antoine equation calculation is the prediction error. The highest absolute prediction error obtained was 0.2 K (0.04 %) at P = 0.9 bar. Considering that the uncertainty in the reported T_b value of 1-dodecene is 0.6 K, the prediction uncertainty is below the experimental uncertainty in this case.

The use of the two immediate neighbors of 1-dodecene in the homologous series as predictive compounds can explain the very low prediction error in this case. For a longer range interpolation we have selected 1-octene (n_C = 8) and 1-tridecene (n_C = 13) as predictive compounds, keeping 1-undecene (n_C = 11) as target compound. This yielded an SC-QS2PR with β_1 = 0.37188 and β_2 = 0.62812. The highest prediction error in this case is 1.33 K (0.3%) at P = 0.9 bar. Thus, although there is some deterioration in the prediction accuracy when using a longer range interpolation, the precision is still very good.

For testing the extrapolation capabilities of the SC-QS2PR method, we have selected 1-octene (n_C = 8) and 1-undecene (n_C = 11) as predictive compounds, and 1-tetradecene (n_C = 14) as target compound. This yielded an SC-QS2PR with β_1 = -0.87029 and β_2 = 1.8703. The highest prediction uncertainty in this case was -3.63 K (0.7%) at P = 0.9 bar. Thus, extrapolation yields mixed-sign parameter values and higher prediction uncertainty than interpolation.

Dearden (2003) provides prediction uncertainty values for current state of the art QSPRs for predicting T_b. For the Alkenes group a QSPR which includes 5 topological descriptors is mentioned. The average prediction uncertainty using this QSPR reported us 2.3 %. Thus the prediction uncertainties with the proposed method are lower than those of state of the art QSPRs even for the case of extrapolation.

5. Conclusions

It has been demonstrated that the new combined SC-QS2PR and TQSPR methods enables the prediction of vapour pressure within experimental uncertainty, depending on the level of similarity between the predictive compounds and the target compound. In cases of longer range interpolation or extrapolation there is some degradation of the precision of the prediction, but in the cases tested (for n-Alkane, 1-alkene, alkanoic

acid, n-alcohol and alkyl-benzene homologous series) the prediction uncertainty did not exceed 1%.

The new method has been applied successfully for prediction of pure component properties and binary interaction parameters. The results of these studies are reported elsewhere.

Simultaneous synthesis of the downstream process and the reactor concept for the Oxidative Coupling of Methane (OCM)

Steffen Stuenkel, Hamid R. Godini, Jens-Uwe Repke, Guenter Wozny

Berlin Institute of Technology, Department of Process Engineering, Chair of Process Operation and Dynamics, Straße des 17. Juni 135, 10623 Berlin, Germany
E-mail: Steffen.Stuenkel@tu-berlin.de

Abstract

The Oxidative Coupling of Methane (OCM) is a promising alternative for the oil based production of olefins. The aim is the catalytically conversion of methane containing natural gas to ethylene, which builds up a base for olefins and further synthesis. The overall yield is still limited to 30%. Beside new catalysts and reactors, new concepts for integrated downstream processes are necessary to overcome the exist limitations [3]. To meet this target as fast as possible, the downstream process, the reactor and the catalyst are designed simultaneously. This novel strategy causes particular interactions between the downstream process, the reactor and the catalyst design. Design specifications for each part of the plant are established as targets such as carbon dioxide concentration.
In order to modify and investigate the different approaches in our mini plant easily, the whole process is designed and built up modular. The entire process is divided into three units: reaction, purification and separation unit. On each unit interfaces of each unit the targets and the process specification are defined by laboratory screenings. Due to the novel process design strategies, the downstream impose specification to the reaction unit and the catalyst too e.g. maximum carbon dioxide concentration for the reaction product. For this purpose different reactor concepts like membrane reactors, fluidized bed and fixed bed reactors have to be investigated along with different integrated downstream concepts. The most promising reactor concepts are discussed in this article regarding their implementation and their influence on the separation process.
The downstream concept should also be design appropriately for the OCM Process. Therefore a novel hybrid purification process, a combination of a membrane and an amine unit for the carbon dioxide removal could be implemented and is presented in this article. The modification results of this novel hybrid process are presented along with the simulation results for the hybrid process and they are discussed regarding the whole OCM Process. Thus the results have to be validated in our mini plant.

Keywords: Downstream OCM, membrane, hybrid process, miniplant.

1. Introduction

Oxidative coupling of methane (OCM) is a novel technology for the conversion of natural gas to ethylene, reaching widespread attraction among various research groups in the last two decades. OCM is a set of catalyzed surface induced gas phase reactions and the overall yield of the desired products is still limited to reach 30%. New and efficient downstream processes are needed for sustainable exploitation of resources. The novel strategy of simultaneous design for each part of the whole OCM process causes particular interactions between the downstream process, the reactor and the catalyst.

Various processes for the OCM with integrated downstream concepts have been proposed 0. The generalized sequence of sections in the OCM process is shown in Figure 1. All processes emphasize on the importance of the product separation under high pressure and recycling the methane, which have major impact on the process economics. Evaluating the alternatives in process synthesis regarding to separation efficiency, energy consumption, operating and investment cost are essential for industrial application of the OCM Process, but rarely have been reported.

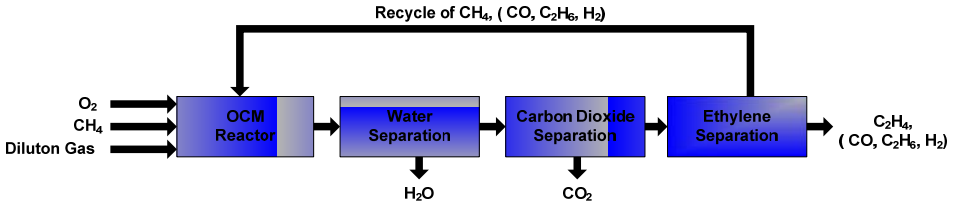

Figure 1: Process Flow Diagram of the OCM Process

2. Process synthesis

The OCM Process has not been industrially applied yet. Apart from general information on the reaction kinetics, the heat and mass transfer efficiency, fundamental studies of the process possibility, catalyst life time, effects of recycles and efficiencies of each unit are crucial for process implementation. These can only be achieved by investigation of the real process. The mini plant technique is a well known technique for the process synthesis, to obtain the required fundamental information experimentally. According to the simultaneous process design and due to economical reasons, the downstream imposes some requirements to the reaction unit and the catalyst, especially to the yield, the C_2 and CO_2 selectivity, and the methane conversation rate and dilution concentration.

2.1.1. Novel design Strategy - Simultaneous design and construction

For the process synthesis, the whole OCM Process is divided into three general unit operations: the reaction unit, the purification unit and the separation unit. All of them are linked and investigated simultaneously. Therefore a design case for each unit has been defined according to the composition, which is presented in table 1.

Table 1: Defined feed gas concentration in [vol%] for the process units

Unit	CH_4	O_2	C_2H_4	C_2H_6	CO_2	H_2O	Inert gas
Reaction	60 – 70	20	-	-	-	-	20 – 10
Purification	45	-	10	10	25	-	20 -10
Separation	60	-	13	13	-	-	14

Table 2: Process conditions for each unit

Unit	Pressure range	Temperature range
Reaction	1 to 30 bar	30 to 900 °C
Purification	1 to 35 bar	30 to 100 °C
Separation	Up to 35 bar	Down to -100 °C

The range of the process and operating conditions for the units is presented in table 2. At this step, those conditions are defined by literature study, since they have to be determined and evaluated carefully.

3. The reactor concept

The operating parameters in the reactor along with the reactor concept affect not only the performance of this unit but also sequentially affect the efficiency and economy of the separation process and subsequently the whole OCM Process.

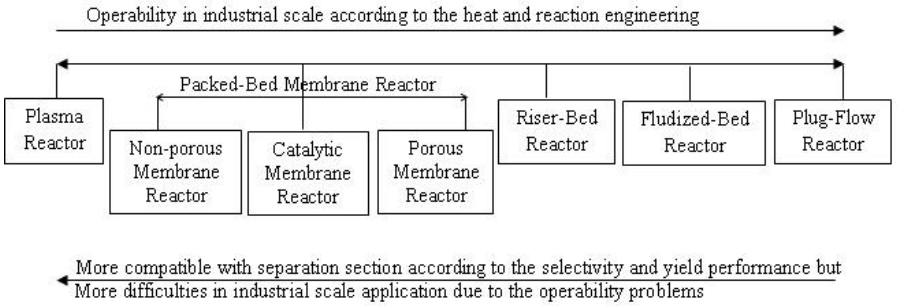

Figure 2: Comparison of different reactor concepts

Figure 2 addresses the major reactor concepts which have been reported for the OCM Process [4]. Some of these structures are very efficient in points of selectivity and yield but they have some difficulties in operation and their performance is not stable which is very crucial for an industrial-scale reactor. The more practical reactor concepts sever from low yield or selectivity and consequently affect the process economy. Therefore most of these alternatives can not be simply applied in an industrial scale yet. The potential of operability is also pointed out in Figure 2. In conventional reactors, like the plug flow or the fluidized bed reactor, either the yield is to low or the selectivity is not acceptable, and this reduces the process performance drastically. On the other side, the application of advanced reactor concepts such as membrane reactors reduce the separation effort and increase the process economy, but they have practical implementation difficulties. The dense membrane reactor uses an oxygen-permeable dense membrane. This membrane is non-permeable for other components and shows a very high selectivity. Due to the low permeation rate, the scale-up performance for this kind of reactor is not validated yet. The plasma reactor is even harder to be implemented as an industrial scale reactor regarding the energy consumption and providing a sustainable plasma media. The riser-bed reactor struggles with mass transfer limitations, back-mixing effects and low selectivity due to the undesired gas phase reactions. It has to be noticed that membrane reactors are preferred regarding the yield and selectivity, but the operability in general has to be improved in advanced reactor concepts. Whereas the fluidized bed reactor are preferred regard to the operability due to the better heat transfer performance, but the selectivity for this reactor concept should be improved. In case of operating condition, especially the composition of reactor product stream should be considered as an important factor. For example the type and quantity of the inert gas for diluting the reaction media, strongly affect the separation section. This becomes more important when the hybrid separation system such as the proposed one in this research, are used to remove the undesired components and purify the products. Furthermore the reactor can be operated under pressure up to 30 bar, which lowers the energy demand for the product separation.

4. The downstream concept for the OCM Process

The downstream section of the OCM Process consists of a phase separation unit, a carbon dioxide removal unit and a product separation unit, as addressed by diffrent researchers 0. Concerning the simultaneous design and improvement in the miniplant, the state of the art separation processes are taken as a base case for the downstream units. The purification unit consists of an amine based absorption process for the carbon dioxide separation. The separation unit consists in a cryogenic distillation for the product separation. Due to the high energy consumption of the cryogenic distillation, the pressure is increased up to 35 bar to increase the boiling point of the hydrocarbons. Regarding the idea of using carbon dioxide as an inert gas for the dilution in the OCM reactor, the carbon dioxide removal step becomes even more important in the downstream process. Therefore, the purification section as the first downstream unit is picked out and the carbon dioxide removal is investigated particularly.

4.1. The purification unit

The specification of this unit is to remove the whole carbon dioxide from the product stream as given in table 1. Such a requirement is not unusual in the process industry, but attracts wide interest nowadays. Different approaches are known for those separation units like: absorption processes, adsorption processes, cryogenic distillation or membrane processes. These processes are based on different physical and chemical principles:

- Absorption: physical or chemical absorption in liquids, caused by the gas solubility in the liquid or in combination with a superimposed chemical reaction.
- Adsorption: physical or chemical adsorption on a particle surface of the sorbent.
- Cryogenic separation: caused by the different condensation points of the gas species
- Membranes: selective solubility and diffusion or molecular sieve effects caused by different molecule dimensions and Knudsen diffusion.

Here again, there is a trade off between the operability and efficiency of the separation process. A well developed and industrial applied technique is the absorption process with chemical or physical absorption liquids. A modern technique is the membrane separation, which has low selectivity for carbon dioxide yet and is mainly implemented as stand alone units for biogas or natural gas cleaning. The adsorption is available only for small gas streams and is hard to handle, concerning the sorbent regeneration. The range of the operation conditions for the cryogenic distillation are up to 60 bar for the pressure and from -20 °C to 20 °C for the temperature, which is economically applicable only in combination with liquefaction and storage of the carbon dioxide. The membrane and the absorption techniques can be an alternative for the purification unit of the OCM miniplant.

4.1.1. Absorption processes

The absorption technique for the carbon dioxide separation is well developed and it is available in industrial scale. As physical absorption processes the UOP Selexol® or the Lurgi Rectisol® Process are known, which using dimethyl ether and methanol as sorbent respectively. Those physical absorption processes causes high product losses of more than 30 vol%, due to a nearly similar solubility of the product and the carbon dioxide in the absorbent. Therefore chemical solvents like Monoethanolamine (MEA), Diethanolamine (DEA) and Methyldiethanolamine (MDEA) or a mixture of them are more applicable for the purpose in the OCM miniplant. Those chemicals are used in amine sweetening processes like the aMDEA® Process in different concentration ranges 0.

Rigorous simulations for the absorption process of the miniplant were carried out in Aspen Plus® 0. As sorbent 15 wt% MEA and 30 wt% MDEA solution were compared. Table 3 summarizes the basic engineering details for the column design.

Table 3: Technical and hydrodynamic operation conditions of the absorption process

Packing height [m]	Column diameter [m]	F-factor [$Pa^{0,5}$]	Gas feed kg/h]	Packing section [-]	Packing capacity [m^2/m^3]	Maximum liquid load [m^3/m^2h]	Liquid stream [kg/h]	Top pressure [bar]
5	0.04	0.8	21	50	450	55	70	35

The carbon dioxide concentration can be reduced to 15 vol% with 25 kW energy demand using MEA solution, whereas with MDEA the carbon dioxide concentration can be reduced down to 7 vol% with only 5 kW energy input for regeneration. This separation efficiency obviously is caused by the different solvent concentration, but they are corrosion limited 0. Neither MEA nor MDEA as solvent can remove the carbon dioxide totally in a standalone absorption process under the given conditions.

4.1.2. The one stage Membrane unit

The advantages of a membrane unit are the easy operation and having a short start up and shut down time due to their small size 0. Those units are very flexible in operation, regard to their modular design. Furthermore no additives are necessary for the operation. Therefore no regeneration is required, which is the most energy consuming part of absorption processes. For vapor/gas membrane separation different kinds of materials are available:

- Polymeric membranes: rubbery or glassy polymers, with different solubility and diffusion properties for carbon dioxide and hydrocarbons.
- Molecular sieves: different pore size, separation by the different molecule diameters.

Glassy and rubbery polymeric membrane preferred for the carbon dioxide separation and hydrocarbon recovery 0. In the investigated membrane unit a carbon dioxide selective membrane is applied 0. The membrane unit is calculated using geometry and permeability data for a GKSS flat sheet membrane module 0.
The carbon dioxide concentration could reduce with a one stage membrane unit of an area of 0.5 m² down to 14 vol %. The product losses in this unit are in the range of 30 vol%, similar to those of the physical absorption and for the purpose in the OCM miniplant not applicable.

4.1.3. The two stage membrane process

By the application of a two stage membrane unit the product losses could reduced drastically, whereas the carbon dioxide reduction is of the same range as for one stage membrane system: down to 14 vol%.

Table 4: Technical requirements of the two stage membrane process

Membrane surface for the 1st Stage	Membrane surface for the 2nd stage	Pressure second stage	Product losses
1 m²	0.5 m²	6 bar	10 vol%

Table 5: Energy balance of the hybrid process

Compressor power	Cooling power	Heating power	Pumping power
1.5 kW	3.5 kW	5 kW	1 kW

The dimension and process conditions of the two stage process are shown in Table 4. Neither with the one stage membrane unit nor with the two stage membrane unit the carbon dioxide can be removed totally. Furthermore membrane units can easily extended and therefore the downstream process can be adjusted easier to changed process and operation conditions.

5. Conclusion – The hybrid separation process

Concerning the mentioned facts for the reactor concepts, the main remaining alternatives for the OCM reactor are the membrane and the fluidized bed reactor. The limitations for those concepts must be improved and have to overcome for industrial application. Regarding the required purity of the product stream and the high energy demand of energy for the absorption, the use of a membrane section for the pre - separation of carbon dioxide could apply successfully. This hybrid membrane amine process, figure 3, can remove the carbon dioxide in the product stream totally. With membrane units the downstream is more flexible regarding the process and operation conditions. A two stage membrane system shows the lowest hydrocarbon losses and was combined with an absorption column to form a hybrid process. The overall energy consumption is listed in table 5. The ethylene loss could reduced to 10 vol% with an over all energy consumption of 11 kW. In a next step the whole process has to be economically optimized and the simulation results have to be validated in the miniplant by experiments.

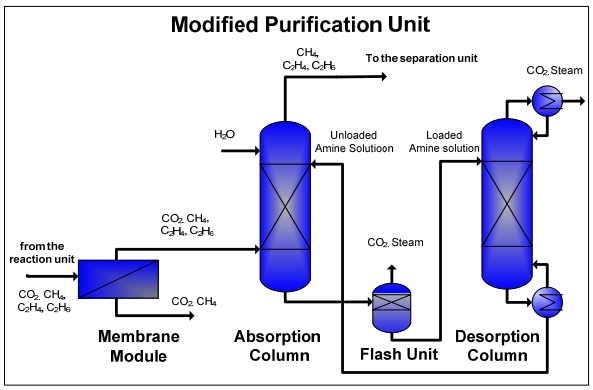

Figure 3: Hybrid separation process for the purification

Rigorous Design of Complex Liquid-Liquid Multi-Staged Extractors Combining Mathematical Programming and Process Simulators

José A. Caballero[b], Ignacio E. Grossmann[b]

a Department of Chemical Engineering, Universidad de Alicante, Apartado de Correos 99, 03080 Alicante, Spain
b Department of Chemical Engineering, Carnegie Mellon University, Pittsburgh, PA. 15213 USA.

Abstract

This work addresses the design of liquid-liquid multistage extractors using a mixed approach that combines mathematical programming with explicit equations, and the rigorous models that are available in commercial Chemical Process Simulators. A superstructure that has embedded all the potential configurations and interconnections is proposed. Based on this superstructure representation the problem is formulated as an optimization problem using generalized disjunctive programming (GDP) to minimize the total cost of the process, subject to design specifications. The method determines the optimal number of equilibrium stages and flow rates needed to obtain the specified product separation and recovery, and accounts for the possibility of side feed streams and product extractions.
A commercial chemical process simulator (HYSYSTM or UnisimDesingTM) that is dynamically connected with the external optimizer that also deals with explicit equations performs the complex liquid-liquid equilibrium calculations. A case study involving a quaternary mixture is presented in order to illustrate the robustness and efficiency of the model.

Keywords: Liquid-Liquid extraction, MINLP, Process Simulators, Process Synthesis, Disjunctive Programming

1. Introduction

Liquid-liquid extraction is a competitive separation technology mainly used when distillation is difficult or impossible to apply, i.e. very low relative volatilities, thermo sensitive products or when huge amount of heat is needed [1] The current methods for design of extractors can be separated into three categories [2]. Graphical Methods, simulation based methods and superstructure optimization based methods. Graphical methods address the design problem using triangular diagrams, where the mass balances are represented by operation lines and the tie lines connect the composition of phases in equilibrium, and therefore are restricted to ternary systems [3,4].
Simulation based methods include approaches that apply numerical methods to solve simulated process formulations using geometric principles employed in graphical methods. Marcilla et al [5] have proposed an analytical extension of the classical Ponchon-Savarit method for distillation columns that allows the direct determination of the number of stages for a given separation. However, simulation based approaches are

usually 'blind' to the final user because they are generally included in a chemical process simulator in which the number of stages is fixed and the design must be done by a trial and error approach. It is worth remark, however, that the process simulators are very robust and reliable

The most complex and flexible approach rely on a superstructure that embeds all the possible alternatives treating the existence or no existence of the different stages with binary variables and taking into account the non linear equations for the equilibrium relations. The design problem is then formulated as an MINLP problem or a Disjunctive Programming Problem (GDP) [6]. The major difficulty with this last approach is related with the non-linear and non-convex nature of the liquid-liquid phase equilibrium that in most situations makes difficult even to find a feasible solution.

Commercial chemical process simulators (Hysys™, AspenPlus™, Prosim™, UnisimDesign™) include unit operations that deal with the vapor-liquid-liquid equilibrium in a fast a reliable way using tailored numerical methods –of course proved that the thermodynamics correctly describes the system- that take explicitly into account aspects like trivial solutions, existence or not of phase separation, etc.

An ideal situation would be taking advantage of the best of both approaches, the numerical reliability robustness included in chemical process simulators and the flexibility and optimization capabilities of a superstructure base optimization. In this line Papadopoulos and Linke [2] presented a superstructure based optimization using stochastic (Simulated annealing, genetic algorithms and ant colony) methods. These methods have the advantage of being very easy of implementing, do not require any special structure in the model and usually obtain near optimal global solutions. However, they usually require a large number of function evaluations, which remarkably increases with the complexity of the problem and usually includes a set of adjustable parameters that affect the performance of the algorithm.

In this work, we propose a mathematical programming approach based on a superstructure that includes implicit equations, in particular each stage of the liquid-liquid extractor that are calculated in a process simulator, and explicit equations (mass balances between stages, purity constraints, recycles, etc). The problem then is reformulated as an MINLP problem –in which some equations are implicit- or a disjunctive programming problem [7].

2. Problem statement

The design problem can be stated as follows: Given a set of feed streams with known composition and a specified desired separation of solutes in the product stream. The problem consists of determining the optimal number of stages, the feed streams locations, the solvent flow rate, and the existence and locations of intermediate solvent streams ,side feed product streams, fractional by-passes of the initial feed stream and the kind of contact (countercurrent, cross flow, mixed flow). The objective is to minimize the total annualized cost.

3. General extractor

The first step to solve the problem consists of generating a superstructure that takes into account all the possibilities commented above embedded in it. All process simulators include the LL extractor as a standard unit operation. However, it is not possible in a straightforward way, changing the number of equilibrium stages. Although, it would be possible to follow an approach similar to that proposed by Caballero et al [8] in distillation systems, in which a special Master problem is derived –in the context of

disjunctive programming- maintaining the distillation column as whole in the process simulator. In this case, it is better explicitly considers the extractor as an inter-related succession of Liquid-Liquid equilibrium stages, a chemical process simulator solves each equilibrium stage.

Figure 1 shows a possible superstructure, (the number of RL streams can be increased, but we include only one for the sake of clarity). The extract stream (normally organic phase) and the raffinate stream (normally aqueous phase) are in contact throughout all the stages. E_1 and R_n represent the final products. The stages are in equilibrium, although experimental efficiency factors could be easily included in order to be more realistic. Different arrangements of equilibrium stages can be used to perform extraction operations, such as single contact, repeated contact with a fresh solvent at each stage (multistage cross flow) countercurrent and countercurrent contact with solvent reflux [9]

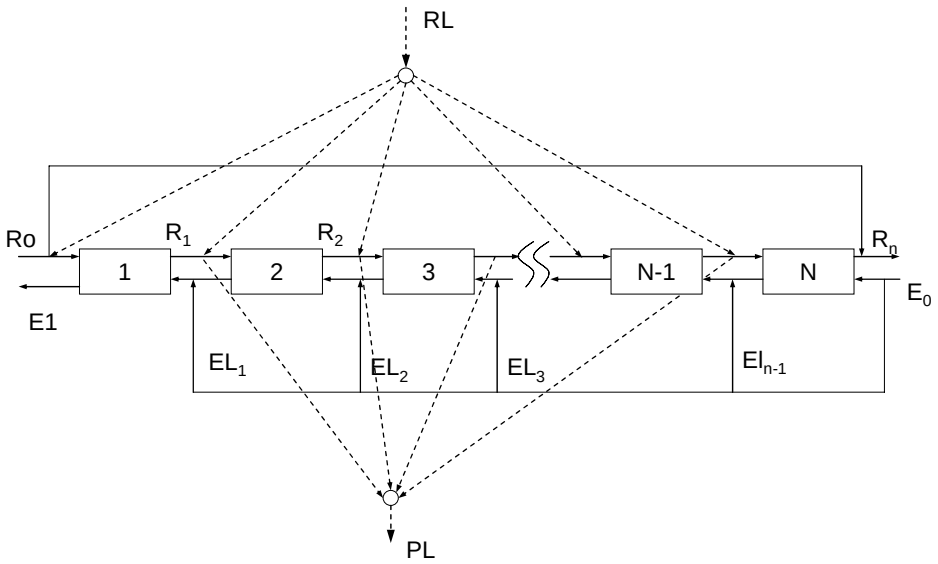

Figure 1. Superstructure of a multi-staged liquid-liquid extractor

In order to achieve a specific separation an upper bound to the number of stages in the cascade must be specified. A value of ten is usually large enough in most of the liquid-liquid multi-staged extractors. If a solution involves ten stages, one can increase the upper bound until the number of calculated staged is strictly lower than the upper bound. Due to the non-linear nature of these models it is convenient maintain this upper bound as low as possible.

The superstructure can be optimized using a big M reformulation forcing the flows entering to a given stage to take a zero value. However, this approach produces numerical problems in the process simulator (we have used UnisimDesign™ or HYSYS™). Yeomans and Grossmann [10] proposed a better approach in the context of distillation columns design, in which, for non-existing stages, the equations considered are simple input-output relations without mass or energy transference. Therefore, the only difference between existing or non-exiting stages is the application of equilibrium equations in the process simulators. This approach also simplifies the model formulation if a pure disjunctive algorithm is used. See Figure 2

4. Disjunctive Model

Conceptually the problem can be represented as follows

$$\min: Z = Total\ Cost$$

$$s.a.\quad Mass\ balances\ in\ all\ mixing\ and\ splitting\ points$$

$$Purity\ and\ recovery\ constraints$$

$$\begin{bmatrix} Y_s \\ \left(R_{i,s}, E_{i,s}\right) = \Omega(EI_{i,s}, RI_{i,s}) \\ Cost\ Stage_s = CS \end{bmatrix} \veebar \begin{bmatrix} \neg Y_s \\ R_{i,s} = RI_{i,s} \\ E_{i,s} = EI_{i,s} \\ Cost\ Stage_s = 0 \end{bmatrix} \quad \begin{matrix} s \in Stages \\ i \in Components \end{matrix}$$

$$Y_s \Rightarrow Y_{s-1}\ \forall s \in Stages \mid s > 1$$

Where Ys is a Boolean variable that takes the value "True" if the stage s exists, and the value False otherwise. Figure 2 shows graphically the disjunction representation.

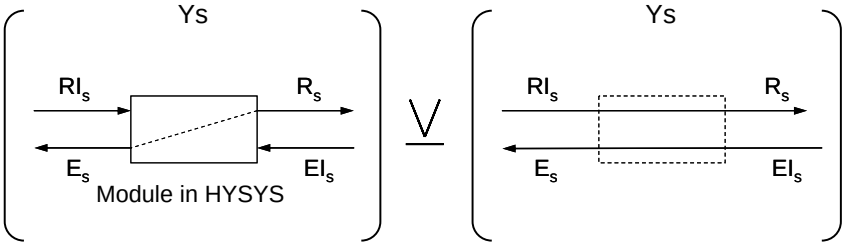

Figure 2. Disjunction for stage existence

The operator Ω refers to the calculations made by the process simulator: outputs (R, E) in terms of the inputs (RI, EI). The mass balances between the input of a given stage, and the output of previous (next) stage must be explicitly included.
Logical relationships between Boolean variables are necessary to avoid degenerate solutions (same number of stages but different locations).
The total cost is the cost of new solvent plus the cost of the stages.

$$Total\ Cost = \sum_{s \in Stages} Cost\ Stage_s + Cost\ Solvent \cdot E_0$$

5. Case study

Consider two water streams that contain acetone, and acetic acid.
The objective is designing a multistage extractor with minimum cost and determining the optimal number of stages and the optimal position of the two aqueous feeds. We want to obtain a final combined water stream with a molar fraction of water greater than 0.98, molar fraction of acetone and acetic acid lower than 0.005 and 0.05 respectively

using chloroform as organic solvent and a recovery of acetone in the organic phase greater than 90 % in molar basis. All relevant data to the problem and the optimal solution found is in Table 1.
The optimal solution found (see Figure 3) shows that the aqueous stream R02 splits in two. The 77% of this stream is introduced in stage 2 and the remaining 13% in stage 3.
The problem was solved in 374 seconds of CPU time using a proprietary implementation of the LP-NLP-BB algorithm for solving MINLP (or Disjunctive) mathematical programming problems. The problem was solved using HYSYS and UnisimDesign as chemical process simulators with identical results.

Table 1. Data and results for the case study

Feed streams

R01 = 3.5348 kmol/h [0.75, 0.12, 0.13] mol fraction Water, Acetone, Acetic Acid

R02 = 3.2810 kmol/h [0.808, 0.1158, 0.0762] mol fraction Water, Acetone AcH.

Thermodynamics: UNIQUAC, HYSYS default parameters

Optimal Number of Stages: 5

Feed Stages: R01 stage 1; R02: split 87 % to stage 2 and 13 % to stage 3

Organic Solvent: Chloroform. Optimal Flow Rate = 9.3236 kmol/h

Objective function = 516.1822 u.m. (stage cost = 10 u.m.; Solvent cost = 50 u.m/kmol·h)

Abstract

This case study focused on optimization of hydrogen production for fuel cell applications. In this case study, glycerol was chosen as a raw material and with autothermal reforming as a process of produce hydrogen. Using a commercial dynamic flow sheeting software, HYSYS 3.1, the process of hydrogen production was successfully simulated. In this research, fuel processor consists of an autothermal reactor, three water gas shift reactors and a preferential oxidation reactor was successfully developed. The purpose of this case study is to identify the effect of various operating parameters such as air-to-fuel (A/F) ratio and steam-to-fuel (S/F) ratio to get the optimum hydrogen production while made carbon monoxide lower than 10 %. From the results, an optimum A/F and S/F ratio are 5.5 and 3.5, respectively to produce hydrogen – 34.7 % (v/v), CO_2 – 60% (v/v), and CO – 0.02% (v/v). Under these optimum conditions, 83.6% of fuel processor efficiency was achieved.
Keywords: glycerol, hydrogen, autothermal reforming, HYSYS.

1. Introduction

Hydrogen will play an important role as an energy carrier of the future. Hydrogen will be used as fuel in almost every application where fossil fuels are being used today, plus the advantages of hydrogen to compare with other fossil fuels is hydrogen fuel will not emission harmful or hazardous gas. There are three categories that been analyzed for input or raw material for hydrogen production. The categories that had been studied was natural gas (consist methane, ethane, propane and butane), alcohol (methanol, ethanol and glycerol) and naphtha (kerosene or fuel jet, gasoline and diesel).

An increase in biodiesel production would decrease the world market price of glycerol. Glycerol is a waste by-product obtained during the production of biodiesel. Biodiesel is one of the alternative fuels used to meet our energy requirements and also carbon dioxide emission is much lesser when compared to regular diesel fuel. Biodiesel and glycerol are produced from the transesterification of vegetable oils and fats with alcohol in the presence of a catalyst. About 10 wt% of vegetable oil is converted into glycerol during the transesterification process. Although glycerol is used in medicines, cosmetics, and sweetening agents, world demand is limited. As such, when mass production of the biodiesel is realized, novel processes that utilize glycerol must be developed.

When biodiesel is produced in large quantity, it is important to find useful applications for the resulting large quantity of glycerol in the world market. Tyson (2003) reported that glycerol markets are limited; an increase in biodiesel production may cause glycerol

prices to decline from $1/L to $0.7/L by 2010. The money invested in purifying the glycerol would also be high (Prakash, 1998). Also, Tyson, 2003 reported that net biodiesel production costs can be reduced from US$0.63/litre of B100 to US$0.38/litre of B100 by adding value to the glycerol by-product.

Glycerol is a potential feedstock, for hydrogen production because one mole of glycerol can produce up to four moles of hydrogen. Hydrogen (H2) is mostly used in refinery hydrotreating operations, ammonia production and fuel cells (Rapagna et al., 1998). When glycerol is cracked at high temperature to produce hydrogen, it is possible to get carbon monoxide as one of the gaseous products. Studies on the degradation of glycerol have been also presented in previous papers, (Herai et al., Bühler et al. and Sadashiv et al.).

One possibility is to use glycerol as a source of hydrogen, and, in this regard, steam reforming of glycerol would be a suitable reaction. In the autothermal reforming of glycerol, synthesis gas that contains both carbon monoxide (CO) and hydrogen (H2) is produced.

Steam-reforming is endothermic and partial oxidation is exothermic. It is possible to reaction glycerol and other hydrocarbon fuels with a mixture of steam and oxygen or steam and air and carry out both reactions simultaneously. The exothermic oxidation supplies the energy for the endothermic reforming. Careful control of the oxygen content of the entering mixture is essential in these processes for maintaining proper reaction temperatures. The products of these reactions are carbon monoxide, carbon dioxide, and hydrogen. The CO requires high- and low temperature water gas shifts to oxidize it and provide additional hydrogen (Brown, 2001).

Autothermal reforming is a combination of steam reforming and partial oxidation and some other reaction that occurred depend on the conversion of raw material, catalyst used, ratio of raw material and the temperature provide during the process (Iwasaki et al., 2005). Lenz et al. (2005) described that autothermal reforming is known as the simultaneous conversion of hydrocarbons with steam and oxygen. The endothermic steam reforming reaction is generally given by four reactions:

Partial oxidation:

$$C_3H_8O_3 + 2O_2 \rightarrow 3CO + 4H_2O \quad (1)$$

Parallel Steam reforming of glycerol:

$$C_3H_8O_3 + 3H_2O \rightarrow 3CO_2 + 7H_2 \quad (2)$$

Series Water-gas shift reaction:

$$CO + H_2O \rightarrow CO_2 + H_2 \quad (3)$$

Overall reaction:

$$2C_3H_8O_3 + H_2O + 2O_2 \rightarrow 5CO_2 + 9H_2 + CO \quad (4)$$

2. Simulation and Optimization

2.1 Problem definition

The hydrogen production from glycerol for fuel cell was simulated using HYSYS software as a Figure 1 shows it. Typically, the simulation process takes the following stages:

i. Preparation Stage
   a) Selecting the thermodynamic model
   b) Define chemical components

ii. Building Stage
   a) Adding and define streams

b) Adding and define unit operations
i. Auto-thermal reforming reactor
ii. Water gas shift reactor
1. High temperature shift reactor
2. Medium temperature shift reactor
3. Low temperature shift reactor
c) Connecting streams to unit operations
d) Add auxiliary unit
i. Heater
ii. Cooler
iii. Heat exchanger
iii. Execution
a) Starting integration
b) Optimization the whole plant

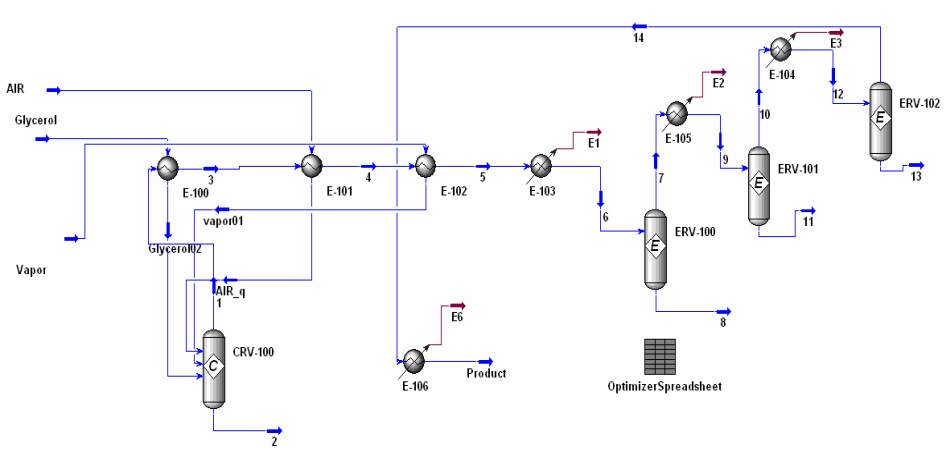

Figure 1 – HYSYS process flow diagram (PFD) of Reforming Glycerol plant.

The system considered in this study were simulated with the same basic data, show within Table 1. The Peng-Robinson Equation of State (EOS) is used to model the thermodynamics of hydrogen production for both steady-state.

Table 1 – Steady state operating conditions.

The parameter of simulation	Value
Feed flow rate of glycerol (kmol/h)	100
Reformer temperature (°C)	500
Reformer pressure (250 kPa)	250
Vapor pressure (kPa)	500
Air temperature (°C)	25

The system fuel processor efficiency can be calculated by:

$$\eta = \frac{n_{H_2} LHV_{H_2} \quad + \quad n_{CO} LHV_{CO}}{n_{C_3H_8O_3} LHV_{C_3H_8O_3}} \tag{5}$$

The lower heating value (LHV) of hydrogen, CO and glycerol are shown in Table 2.

Table 2 - Lower heating value (LHV) for hydrogen, CO and glycerol.

Component	LHV (kJ/kmol)
Glycerol	1470
Hidrogen	241.83
CO	282.00

2.2 Optimization

Optimization of the autothermal reforming of glycerol was conducted searching for the operating conditions (air-to-fuel (A/F) ratio and steam-to-fuel (S/F) ratio) that result in the highest production hydrogen. HYSYS contains a multi-variable Steady State Optimizer. The Flowsheet has been built and a converged solution has been obtained, it can use the Optimizer to find the operating conditions which minimize or maximize an Objective Function. The Objective function is given by optimization of Eq. (5). For maximize of objective functions was used the method SQP - Sequential Quadratic Programming.

CO should decrease because fuel cells (FC) do not tolerate excessive amounts of CO. The FC does not tolerate more than in the order of 50ppm CO; the lower the CO concentration, the higher the efficiency of the cell. H_2/glycerol ratio should be increased because all glycerol would be reacted to product (H_2).

3. Results and Discussions

Optimization for ATR was done by varying the air molar flow rate to get the best flow rate of air to be introduced into the ATR. Two case studies were developed in order to do this optimization. The first case study was developed to monitor the temperature at the ATR vapour stream after varying the air molar flow rate from 350 kmol/h to 800 kmol/h. The second case study was developed to monitor the molar flow rate of carbon monoxide and hydrogen after varying air molar flow rate within the range that was chosen from first case study. The result is shown in Figures 2 and 3.

From Figure 2, the temperature out of ATR is over 800 °C only after the molar flow rate of air greater or equal 600 kmol/h. With that air molar flow rate range, the hydrogen and CO molar flow rate was monitored. From figure 3, the flow rate of hydrogen produced by the reactor reforming of is decreasing when of air molar flow rate greater than 550 kmol/h. Then it began constant after 750 kmol/h.

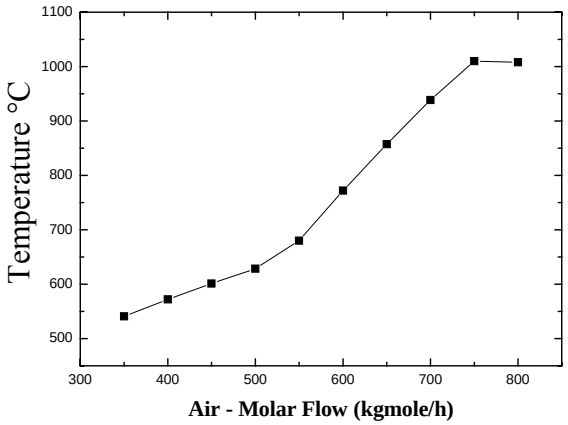

Figure 2 – Temperature of reactor of reforming for varies air Feed molar flow

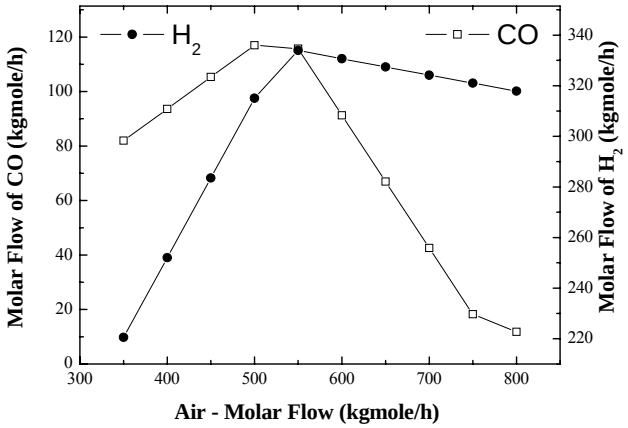

Figure 3 - Molar flow of CO and H2 effluent for varies air feed molar flow.

In Water Gas Shift Optimization , one case study was developed to optimized value of feed water molar flow to reduce concentration of CO through water gas shift reaction. Figure 3 shows the result of case study where the concentration of H2 and CO after water gas shift reactors was monitored.

Water molar flow rate was optimized from 2000 to 8000 kg/h. As we can see from Figure 5.8, the H_2 show an increasing slope and the increasing is a bit slower at 7500 kg/h. The optimum water molar flow rate was taken when hydrogen at its higher molar flow rate. So, the value of water molar flow rate that was chosen was 5500 kg/h. At this point, H_2 produced the greatest flow rate and CO reduced the lowest flow rate.

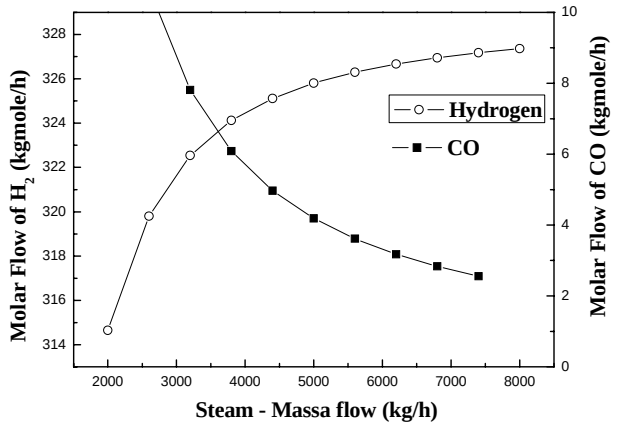

Figure – 3 Molar flow of CO and H2 effluent for varies water feed molar flow.

In the following, the results obtained for an autothermal reforming of glycerol system are presented. With the developed system models which are implemented in the HYSYS 3.1 process simulator, effluents from all reactors are simulated. In this model, the air to fuel ratio is set to 5.5 and the steam to fuel ratio is set to 3.5 In these conditions, 90% glycerol is converted to produce 34% hydrogen, 20.07% CO2 and 0.01% CO. Also, under these conditions, oxygen is 100% consumed. As we know, WGS reaction will convert CO into CO2 and hydrogen with the existence of steam.

Therefore, the percentage of CO is decreasing, while the percentage of CO2 and hydrogen is increasing respectively. In the same time, the percentage of steam is decreasing.

4. CONCLUSIONS

Basically, for 100 kmol/h of glycerol was inserted to the process and it produced about 327.37 kmol/h hydrogen. For the first reactor that is at the reforming reactor, hydrogen that produced after the optimization was 262.65 kmol/h. Optimization had been done for every reactor where by for the ATR reactor, we got 550 kmol/h of air for the highest hydrogen production and the lowest CO besides temperature around 672.9 °C. A number of important observations were noted based on the analysis of conclusions:

1. The simulation of hydrogen production plant model using autothermal reforming of methanol had been successfully developed using HYSYS 3.1.
2. The optimum A/F and S/F ratios are 5.5 and 3.5, respectively to produce hydrogen – 34.7 % (v/v), CO_2 – 60% (v/v), and CO – 0.02% (v/v).
3. With optimum parameters above, 83.6% of fuel processor efficiency was achieved.

Design of heat-integrated distillation processes using shortcut methods and rigorous optimization

Korbinian Kraemer[a], Andreas Harwardt[a], Wolfgang Marquardt[a]

[a]*AVT-Process Systems Engineering, RWTH Aachen University, 52056 Aachen, Germany*

Abstract

The stepwise optimization based procedure for the design of heat-integrated distillation processes as presented by Harwardt et al. (2009) is extended to include complex column designs such as the divided wall column. In the first design step, the optimal flowsheet structure of simple columns is identified using a superstructure formulation and shortcut models based on rigorous thermodynamics. The column pressure is variable in this early design stage to allow for heat integration between the column and the network of heat exchangers. In the second design step, a rigorous MINLP optimization of the most promising flowsheet structure is performed for a thorough assessment of the cost savings potential of heat integration and to determine the optimal column tray numbers and feed stage location. The rigorous optimization can be solved with good robustness, efficiency and reliability due to a continuous reformulation of the MINLP. In a third design step, it is investigated via rigorous optimization whether the energy and capital costs can be further reduced by a fully heat-integrated complex column system such as a divided wall column setup. The design procedure is illustrated by a case study considering the complete separation of a quaternary azeotropic mixture.

Keywords: rectification body method, column sequencing, heat integration, rigorous optimization, dividing wall column.

1. Introduction

The rising energy cost and the promotion of sustainable processes in chemical industry require the design of energy efficient processes. The energy requirement of a distillation train can be significantly influenced by the structure of the column sequence. Further reduction of the energy requirement is possible by heat-integrated column systems. Solving these design problems within one optimization problem, where all important design variables are optimized at the same time is possible, but very time consuming and usually performed without rigorous thermodynamic models. The systematic study of alternatives was first introduced with the concept of a separation task by Hendry and Hughes (1972). Later, Sargent and Gaminibandara (1976) introduced superstructure formulations to deal with the model complexity. Evaluation of the separation cost is performed using the Underwood shortcut method, which restricts the investigation to ideal or near ideal mixtures. In the area of column sequencing with heat integration, only limited work has been published so far. Caballero and Grossmann (2006) performed a single MINLP optimization for the entire superstructure based on the Underwood method. Dünnebier and Pantelides (1999) have investigated the rigorous optimization of thermally coupled column designs but also only considered ideal mixtures. As a consequence of the lack of powerful optimization-based design tools, the design process in industry still relies on tedious simulation studies.

Kossack et al. (2009) proposed a systematic synthesis framework for the optimal design of distillation processes composed of a sequential combination of both shortcut evaluation and rigorous optimization. With this combination of synthesis methods of increasing level of detail, separation processes for homogeneous azeotropic multicomponent mixtures can be efficiently evaluated on the basis of rigorous thermodynamics and the optimal distillation flowsheet, the optimal process operating point and the optimal column specifications can be determined.
Accordingly, in the first step of this work the optimal simple column flowsheet structure is identified using superstructure formulations and shortcut methods, also considering the possibility of heat integration between the reboilers and condensers of the distillation sequence by simultaneously optimizing column pressures in this early design stage. In the second design step, a rigorous MINLP optimization of the most promising flowsheet structure is performed for a thorough assessment of the cost savings potential by heat integration. The aim is to determine the process and column specifications that yield the lowest total annualized cost, taking into account capital and operating costs. In the third step, it is investigated whether the energy and capital costs can be further reduced by a fully heat-integrated complex column system such as a divided wall column setup.

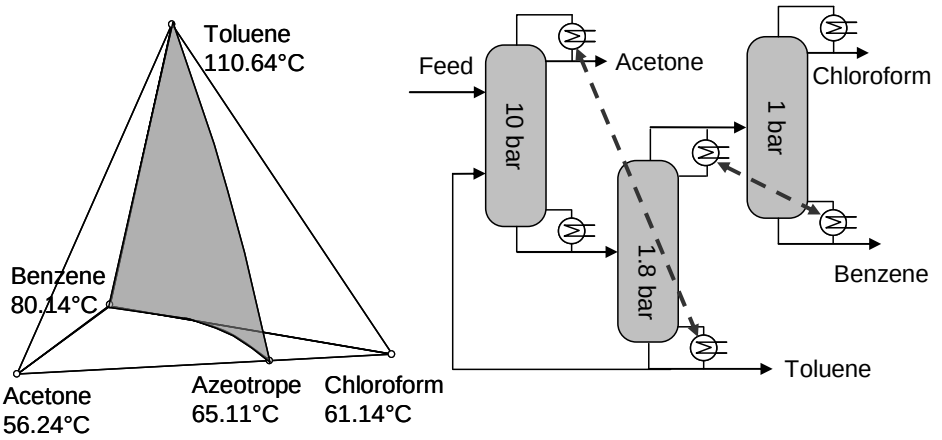

Figure 1: Distillation boundary of the example mixture at 1 bar and optimal flowsheet structure with pressure levels and heat exchange between the columns.

2. Investigation of mixture topology

In the case study, an equimolar feed (10 mol/s, 3129 kg/h) of acetone, chloroform, benzene and toluene is to be separated into its pure components in a multicolumn process. The mixture exhibits a maximum boiling binary azeotrope between acetone and chloroform (see Figure 1). The distillation boundary starts at the azeotrope and runs into the benzene/toluene/chloroform plane as already observed by Brüggemann (2005). Due to this property, acetone can be separated completely in a first distillation column for the given feed, when a recycle of toluene, benzene or a combination thereof is added. An algorithmically accessible formulation of the distillation boundary is given at minimum reflux by the so-called Pinch Distillation Boundary (PDB). The properties and the detection of the PDB have been described in detail by Brüggemann (2005). With the help of the PDB, the minimum recycle flowrate, which allows a complete

separation of acetone in the first column, can be calculated: The minimum required amounts are 5.43 mol/s for a toluene recycle, 4.54 mol/s for a benzene recycle and 4.82 mol/s for an equimolar recycle of toluene and benzene. In the following step, distillation network structures are generated and evaluated for these three alternative recycles.

3. Identification of the optimal flowsheet structure

Multicomponent mixtures can be separated by a large number of alternative distillation sequences. The identification of the optimal sequence structure of simple columns is described in detail by Harwardt et al. (2008, 2009). A brief summary is given here.
A superstructure of alternative flowsheet variants, which is given by a State Task Network representation (Sargent and Gaminibandara, 1976) of unique separation tasks, is evaluated with MILP techniques based on the objective of minimum energy requirement. The minimum energy requirements of the single columns are determined by the rectification body method (RBM, Bausa et al., 1998), a modern, pinch point based shortcut method. The RBM relies on rigorous thermodynamics and is applicable to azeotropic multicomponent mixtures, since it is a non-graphical, algorithmic method. The column pressures are variable within discretized steps in the superstructure optimization, such that the heat sinks (reboilers) and the heat sources (condensers) are combined for a further reduction of the energy demand. The optimization can be performed in just 215 seconds using the CPLEX MILP solver within the optimization platform GAMS on a 1.8 GHz, 1 GB RAM PC.
A structure with a toluene recycle was found to be optimal (c.f. Figure 1). It consists of an acetone column, where the lightest boiling pure component is separated, an indirect split in the toluene column, and the separation of the remaining binary mixture in the chloroform/benzene column. The pressure levels and the heat exchanger connections determined for optimal energy integration are indicated in Figure 1. The total minimum energy requirement is found to be 475 kW, where the equivalent sequence would require 1152 kW if no heat integration were considered.

4. Rigorous optimization

A rigorous process optimization problem is formulated next for the selected promising flowsheet structure and solved by minimizing a total cost function. The rigorous optimization step provides information about the optimal number of column trays and the optimal feed tray locations. Since these design variables are discrete variables while the energy duties, flowrates and compositions are continuous variables, a mixed-integer nonlinear optimization problem (MINLP) has to be solved. Considering the large scale and complexity of the three-column process and the nonlinearity of the underlying nonideal thermodynamics, it is obvious that this MINLP problem is particularly hard to solve. In this work, the robust and efficient solution of the MINLP problem is achieved by a favorable initialization strategy based on the results of the preceding shortcut evaluation and a reformulation as a purely continuous problem. A detailed description of the column model formulation as well as the solution algorithm can be found elsewhere (Kraemer et al., 2009). Here, a brief summary is given.
The column pressure levels and the heat exchanger connections that have been determined in the shortcut evaluation for optimal process heat integration are fixed during this rigorous optimization step. For the continuous reformulation of the MINLP problem, the discrete variables are replaced by continuous decision variables and special integrality constraints are added to the resulting NLP problem in order to force the

continuous decision variables to discrete values. For better convergence to good local optimal solutions, the integrality constraints are relaxed at first and are then successively tightened in a series of a few NLP solution steps until an integer solution is reached. Due to the excellent initialization provided by the shortcut evaluation and the continuous reformulation of the MINLP, the rigorous optimization of the large-scale example problem can be solved with excellent robustness, efficiency and reliability.

The recycle flowrate is defined as an optimization variable and the product purities are set to 99% in the rigorous optimization step. Contrary to the shortcut evaluation, the fresh feed is fed to the process as a boiling liquid at 1 bar. After being pumped to 10 bar it is preheated in an additional heat exchanger by the hot acetone product stream. The distillate stream of the toluene column that is fed into the chloroform/benzene column is not condensed but transferred as saturated vapor, thus effectively reducing the required area of the heat exchanger linking these two columns. Nonlinear cost models by Douglas (1988), updated by the M&S index, are employed for the calculation of the capital cost. A depreciation time of 5 years is considered. While low pressure steam at 3 bar (8 €/t) suffices as additional hot utility for the chloroform/benzene column, high pressure steam at 20 bar (10 €/t) is required for the acetone and the toluene columns. Maximum tray number specifications of 80, 40 and 60 for the acetone, toluene and chloroform/benzene column, respectively, yield a problem size of about 4500 continuous variables, including 440 decision variables. The optimization problem was formulated within the optimization platform GAMS 22.7 and solved by the SQP-based solver SNOPT on a PC with a 3 GHz Dual-Core CPU in 276 seconds.

Table 1: Costs, column configurations and operating point for all columns of the heat-integrated process of simple columns. Results for the same flowsheet without heat integration are shown for comparison.

	process without heat integration			**heat-integrated process**		
	acetone column	**toluene column**	**chl./benzene column**	**acetone column**	**toluene column**	**chl./benzene column**
capital cost (€/a)	110089	76819	83340	116925	76712	82355
operating cost (€/a)	55781	57696	33887	82258	12046	6345
TAC (€/a)		417612			376641	
reboiler duty (kW)	453	511	266	539	75+297	0+320
cond. duty (kW)	462	339	417	0+297	102+320	479
number of trays	51	25	40	70	28	34
feed tray	14	13	17	17	14	15
recycle feed tray	8			8		
diameter (cm)	68.6	72.5	64.3	49.7	70.7	76.5
recycle	8.27 mol/s [0, 0, 0.01, 0.99]			5.86 mol/s [0, 0, 0, 0.01, 0.99]		

The optimization results are displayed in Table 1 together with the results for the same flowsheet without heat integration, where all columns are operated at 1 bar and supplied with low pressure steam. The heat-integrated process yields a total annualized cost (TAC) of about 41000 €/a lower than the process without heat integration, which corresponds to a cost reduction of about 11%. Reboiler energy savings of 50% are observed. Note that the operating cost of the acetone column is higher for the heat-integrated process due to the expensive 20 bar hot utility. However, this cost increase is more than compensated by the energy savings for the remaining columns. The cost optimum for the chloroform/benzene column of the heat-integrated process is found at a

lower tray number when compared to the conventional process since no hot utility is required for this column. Furthermore, the heat-integrated process has a significantly lower recycle flowrate to avoid heat losses in the high pressure acetone column, where the expensive hot utility is used.

	acetone column	DWC
capital cost (€/a)	124978	167735
operating cost (€/a)	66697	13912
TAC (€/a)	373322	
reboiler duty (kW)	518	56+367
cond. duty (kW)	0+367	597
number of trays	66	61
dividing wall between trays		14-54
feed tray	16	27
recycle feed tray	8	
side stream tray		29
diameter (cm)	52.6	85.4
recycle	6.41 mol/s	

Figure 2: Flowsheet with a divided wall column (DWC) and additional heat integration between the acetone column and the DWC. Table 2: Costs, column configurations and operating point for both columns of the DWC process.

The evaluation of the energy savings potential of fully heat-integrated column designs such as divided wall columns (DWC) with shortcut methods is not a simple task, since equivalent systems of simple columns have to be constructed. In addition, the capital cost savings of integrated designs cannot be determined this way. We have however extended the rigorous optimization model to include a DWC, which could be solved robustly and efficiently with initial values from the shortcut evaluation of simple column flowsheets. Again, we reformulate the MINLP problem as a NLP problem.
The flowsheet in Figure 1 is modified to incorporate a DWC as shown in Figure 2. In addition to the energy savings of the DWC itself, heat integration is considered between the condenser of the acetone column and the reboiler of the DWC. Since the DWC operates at 1 bar, the pressure of the acetone column could be lowered to 6 bar and 10 bar steam (9 €/t) was used as hot utility for this column. As suggested by Dünnebier and Pantelides (1999) a surcharge factor of 15% is added to the capital cost of the DWC to account for the increased installation cost of the complex DWC. Despite the increased complexity of the DWC process (about 590 decision variables), the optimization could be solved in 585 seconds due to the favorable reformulation as a continuous problem.
Table 2 lists the optimization results for the DWC flowsheet (cf. Figure 2) with additional heat integration between the acetone column and the divided wall column. The energy requirement of the fully heat-integrated DWC process (574 kW) is only slightly lower than the energy requirement of the heat-integrated simple column process (614 kW). The total annualized cost of the DWC process is slightly lower as well, where the main cost saving can be allocated to the lower pressure of the acetone column.

5. Conclusions

We have presented a stepwise optimization-based design procedure for the rapid synthesis of cost optimal, heat-integrated distillation processes. Powerful shortcut methods based on nonideal thermodynamics and rigorous optimization are used in sequential design steps to obtain the optimal flowsheet structure and the optimal column specifications with outstanding robustness and computational efficiency. The possibility of heat integration is considered from the conceptual design step on such that energy savings can be optimally exploited. The benefit of our approach lies in the ability to deal with nonideal mixture behavior, the detailed column design of simple and complex columns by rigorous optimization, very fast computation times and comparably low engineering effort. With this combination of enumeration, MILP optimization and rigorous optimization, the cost of an optimal distillation process of heat-integrated simple columns for the azeotropic four component example could be determined robustly in less than 10 minutes computational time. Energy savings of 50% can be achieved. Finally, it has been studied whether the energy requirement and the total cost for the separation of the example mixture can be further lowered by applying a divided wall column (DWC) in a fully heat-integrated process. A rigorous optimization of the DWC process yields only marginal energy savings and total cost savings compared to the heat-integrated simple column process.

Modeling and Simulation of Nanoparticles Formation Process: A Diffusive Approach

Luciane S. Ferreira and Jorge O. Trierweiler

GIMSCOP - DEQUI - UFRGS. R. Luiz Englert, s/n°. Porto Alegre. RS. 90040-040. Brazil. Emails: {luciane,jorge}@enq.ufrgs.br

Abstract

In this work the modeling and simulation of nanoparticle formation according to the technique of nanoprecipitation was done. In this method, the particle is formed due to the further diffusion of solvent into the aqueous phase, resulting in the aggregation of the associated polymer chains. In order to predict the characteristics of the nanoparticle and also to improve the process, it was developed a mathematical model that considers: (a) the type of polymer; (b) interaction between solvent and polymer; and, (c) dynamics of solvent diffusion. The diffusivity between polymer-solvent was modeled according to the Vrentas & Duda Free Volume Theory, including the Sanchez-Lacombe equation-of-state. The model was written in terms of Partial Differential Equation, and solved with MAPLE® for a given initial size. Additionally, it is a moving boundary problem because the diffusion of the solvent out of the droplet leads to its size reduction. In this work only the diffusion behavior of one droplet was considered. The dynamic simulation shows both the evolution of the solvent inside the droplet and the variation of size in time.

Keywords: nanoprecipitation, modeling, simulation, diffusion, moving boundary.

1. Introduction

Polymeric nanoparticles are of special interest from the pharmaceutical point of view. First, they are more stable in the gastrointestinal tract than other colloidal carriers, such as liposomes, and can protect encapsulated drugs from gastrointestinal environment. Second, the use of various polymeric materials enable the modulation of physicochemical characteristics (e.g. hydrophobicity, zeta potential), drug release properties, and biological behavior (e.g. targeting, bioadhesion, improved cellular uptake) of nanoparticles. Finally, the particle surface can be modified by adsorption or chemical grafting of certain molecules such as polyethylene glycol (PEG), poloxamers, and bioactive molecules (lectins, invasins, etc.).

In this work, in order to model the nanoparticle formation only one droplet in a high diluted medium will be considered. We suppose that outside the droplet the solvent concentration is null because of the dilution and agitation. It was developed a mathematical model that takes in account: (a) the type of polymer; (b) interaction between solvent and polymer; and, (c) solvent diffusion process. After the description of the nanocapsules preparation, the mathematical model is explained. Then, the numerical simulation and its results are discussed.

2. Nanocapsules Preparation

The nanocapsules that are modeled in this work are usually prepared according to the method of nanoprecipitation (Fessi *et al.*, 1989). This method is based on the spontaneous emulsification of the organic internal phase, in which the polymer is dissolved, into the external aqueous phase. In order to allow the better understanding of the paper by the reader, the nanoprecipitation is then explained.

Nanocapsules of poly(ε-caprolactone) containing 3-benzophenon (solar protection factor) are prepared according to the following procedure: 100 mg of poly(ε-caprolactone) polymer (PCL), 76.6 mg of sorbitan monostearate, 333 mg of Mygliol 810 (caprylic/capric triglyceride) and 30 mg of Benzophenon-3 are first dissolved in acetone (27 ml). The resulting organic solution is poured in 53 ml of water containing 76.6 mg of polysorbate 80. The aqueous phase immediately turns milky with bluish opalescence as a result of the formation of nanocapsules, the wall of which is mainly constituted by PCL, and the oily core by the benzophenon-mygliol solution.

3. Mathematical Modeling

It was considered that the nanoprecipitation produces perfect spherical particles and also that each nanoparticle is originated from one droplet formed immediately after the mixing of organic phase and aqueous phases.

The major model assumptions are:

(a) There is a negligible relative velocity between the droplet and the water, the external mass transfer is approximated by diffusion. This assumption can be done based on the order of the Stokes number, which is related to the particle velocity and is defined as (Crowe, 2005, Rielly and Marquis, 2001):

$$St \equiv \frac{\tau_v}{\tau_F} = \frac{{d_p}^2 \rho_p V}{18 \mu L} \tag{1}$$

where τ_F is the characteristic time of the flow field, τ_v is the particle relaxation time, d_p is the particle diameter, ρ_p is the particle density, V is the fluid velocity, μ is the fluid viscosity, and L the characteristic dimension of the obstacle. For small Stokes numbers the particles follow the fluid motion, but for large St, the particles follow different trajectories from the fluid elements. The Stokes number was calculated for fluid velocities between 1×10^{-3} and 1 $m.s^{-1}$ (based on CFD simulations for a stirred reactor that are not showed here), and particle diameters from 100 to 4000 nm. As the Stoke number is in all cases less than 10^{-5}, the assumption of negligible relative velocity between the droplets and the external phase can be considered valid;

(b) the diffusion is one-dimensional along the radial direction; and,

(c) the diffusivity varies with time and concentration only.

Based on these assumptions, the mass balance equation for the solvent written in spherical coordinates is:

$$\frac{\partial c_1(r,t)}{\partial t} = \frac{D}{r^2}\left(\frac{\partial}{\partial r}\left(r^2\left(\frac{\partial c_1(r,t)}{\partial r}\right)\right)\right) \tag{2}$$

where: c_1 is the concentration of solvent; r is the particle radius; D is the diffusivity; and t is the time. Note that it is a moving boundary problem, since the size of the droplet reduces because of the diffusion.

As the dimensions of dependent and independent variables are not the same, a variable normalization was done including 3 new variables τ, rh, and c_{1h} defined as,

$$t_0 = \frac{r_0^2}{D},\ \{r = rh \cdot r_0,\ t = \tau \cdot t_0,\ c_1(r,t) = c_{1h}(rh,\tau) \cdot \rho_1\} \qquad (3)$$

where: r_0 is the initial droplet radius; D is the diffusivity polymer/solvent; and ρ_l is the solvent density.
After the normalization, eq. (2) is then rewritten as:

$$\frac{1}{t_0} \cdot \frac{\partial c_{1h}(rh,\tau)}{\partial \tau} = \frac{D}{r_0^{\,2} \cdot rh^2}\left(\frac{\partial}{\partial rh}\left(rh^2\left(\frac{\partial c_{1h}(rh,\tau)}{\partial rh}\right)\right)\right). \qquad (4)$$

3.1. Initial and Boundary Conditions
Assuming that the initial solvent concentration inside the droplet is uniform, the initial condition is,

$$c_{1h}(rh,0) = c_{1h0} \qquad 0 \le rh \le r_0. \qquad (5)$$

Where c_{1h0} is evaluated according to the experimental conditions.
The boundary condition at the center of the droplet (rh=0) arises from the symmetry,

$$\left.\frac{dc_{1h}}{dt}\right|_{rh=0} = 0 \qquad t \ge 0. \qquad (6)$$

Additionally, the boundary condition at the interface can written as

$$\left.\frac{dc_{1h}}{dt}\right|_{\mathrm{rh=R}} = \frac{D_{S-W}}{4\pi R^2}\left(c_{1h}(R) - c_{1h}(\infty)\right) \qquad (7)$$

in which R is the actual radius of the droplet, $D_{S\text{-}W}$ is the diffusivity of the solvent in the external phase, $c_{1h}(R)$ is the concentration of solvent at the interface and $c_{1h}(\infty)$ is the bulk concentration.

3.2. Boundary Movement
The boundary movement is calculated based on the assumption that both the mass of polymer, oil and drug remain constant during the diffusion process. The volume of the droplet is defined as

$$V_D = V_2 + V_1 + V_{oil} + V_{drug} \equiv \frac{4}{3}\pi R^3 \qquad (8)$$

where V_D is volume of the droplet, and V_1 , V_2, V_{oil} , V_{drug} are the volume of solvent, polymer, oil, and drug, respectively.
Per definition the volume of polymer and solvent are

$$V_2 = m_2/\rho_2 \qquad V_1 = (c_1/\rho_1)V_D \qquad (9)$$

with m_2 as the mass of polymer and ρ_2 as polymer density.
Substituting eq. (9) in eq. (8)and isolating for R, then the radius can be calculated as

$$R(t) = \sqrt[3]{\left[3 \cdot \left(\frac{m_2}{\rho_2} + V_{oil} + V_{drug}\right) \cdot \left(1 - \frac{c_1(t)}{\rho_1}\right)^{-1}\right] \Big/ 4\pi}. \qquad (10)$$

3.3. Model Parameters
The two main parameters of this model are the diffusivity solvent/polymer and the diffusivity solvent/water.
The experimental data presented by Wild (2003) was adjusted as a polynomial curve to describe the diffusivity of acetone in water.

$$D_{S\text{-}W} = 1\text{x}10^{-9} * (-4.737 w_S + 15.92\ w_S - 14.71\ w_S + 4.738) \qquad (11)$$

where w_s is the molar fraction of water in the external phase.

The diffusivity between polymer and solvent was modeled according to the Free Volume Theory (Vrentas and Duda, 1976, Vrentas and Duda, 1977a, Vrentas and Duda, 1977b, Vrentas and Duda, 1979). Those authors applied the Flory–Huggins thermodynamic model in their free volume diffusion theory to describe the polymer solvent enthalpic and entropic interactions. For the estimation of solvent diffusion coefficient in polymer solution systems, free-volume parameters for the both polymer and solvent must be available. The free volume (FV) diffusion model developed by Vrentas & Duda describes the solvent self-diffusion coefficient (D_1) and the polymer/solvent binary mutual diffusion coefficient (D) as given by eqs. (12) and (13), respectively.

$$D_1 = D_0 \exp\left(\frac{-E}{RT}\right) \cdot \exp\left(\frac{-\left(w_1\hat{V}_1^* + w_2\xi\hat{V}_2^*\right)}{w_1\left(\frac{K_{11}}{\gamma}\right)\left(K_{21} - T_{g1} + T\right) + w_2\left(\frac{K_{12}}{\gamma}\right)\left(K_{22} - T_{g2} + T\right)}\right) \tag{12}$$

$$D = D_1\left(1-\phi_1\right)^2\left(1-2\chi\phi_1\right) \tag{13}$$

In eq.(12) the first exponential term can be considered as the energy factor, and the second exponential term is the free-volume factor. There are 13 independent parameters to be evaluated in eq.(13). Some of them can be grouped reducing this number to the following variables: K_{11}/γ, $K_{21}-T_{g1}$, K_{12}/γ, $K_{22}-T_{g2}$, D_0, E, $\hat{V}_1^*$, ξ, $\hat{V}_2^*$, and χ, that must be determined to estimate mutual diffusivities. All of these parameters have physical significance, and therefore one must be able to evaluate every parameter from sources other than diffusion studies. The guidelines to calculate each one of these parameters, clarified by Zielinski and Duda (1992), were used in this work. Additionally the modification proposed by Wang *et al.* (2007), according to the Sanchez-Lacombe equation-of-state (SL EOS), was also taken in account. The process was considered to be isotermic and isobaric (T=298K, P=1bar and E=0). All parameters are listed in Table 1.

Table 1: Model Parameters.

$\hat{V}_1^*$	0.9695 cm^3/mol	$D_0 \times 10^4$	14.3 cm^2/s	T^*	668 K
$\hat{V}_2^*$	0.8181 cm^3/mol	K_{21}-T_{g1}	-12.12	P^*	4035 bar
δ_1	18.29 $J^{1/2}/cm^{3/2}$	(K_{11}/γ)	0.983 x 10^{-3}	T_{g2}	213 K
δ_2	20.85 $J^{1/2}/cm^{3/2}$	ρ^*	1.1427 g/cm^3		

4. Numerical Simulation

The model was simulated in MAPLE®, which is capable of finding solutions for higher order PDE and PDE systems. Based on the initial size, eq. (4) is solved. After that, the new radius can be thus calculated. If the relative difference (ΔDiam) between the new and old radius is less than $1x10^{-5}$, the process ends; if not, the iteration process goes on as illustrated in Fig. 1. As only one particle is simulated here, it was considered that the acetone concentration at the external phase is equal to zero.

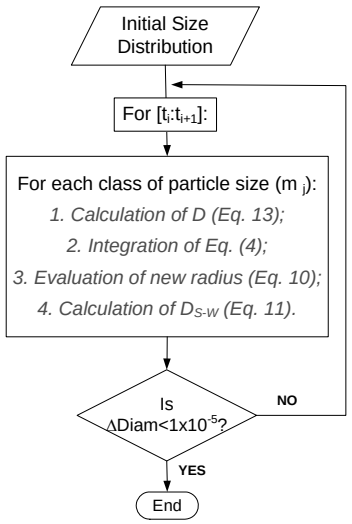

Fig. 1. Scheme of solution implemented in MAPLE®.

5. Results and Discussion

The model predicts that in about 15 ms the particle reaches the final diameter, as shown in Figure 2. This result is in qualitative agreement with what is observed experimentally, that is, as the organic phase is mixed in the aqueous phase, the suspension becomes *immediately* (at least for the human eyes) opaque, as a result of the nanoparticle formation. The evolution of particle size follows a first order kinetic profile, without any detectable delay time. Throughout the diffusion process, gradients of oil, acetone and polymer arise into the droplet leading to the reduction in size and the formation of the nanoparticle, as can be seen in Fig. 3. At the beginning, a slow reduction of acetone concentration at the interface takes place, mainly because of the initial droplet big size. As the acetone diffuses out of the droplet, the diameter reduces and then, the solvent approaches the interface at a faster rate. All these factors allow, for the last 2/3 of the precipitation, a further faster reduction of the solvent concentration at the interface. The order of magnitude of the diffusion time is in agreement with that found by Moinard-Chécot *et al.* (2008). They tried to measure the duration of the solvent diffusion step with a stopped-flow apparatus. In this experiment, only the signal corresponding to the final state could be observed, i.e., the diffusion step is less than 20 ms (the acquisition time of the apparatus).

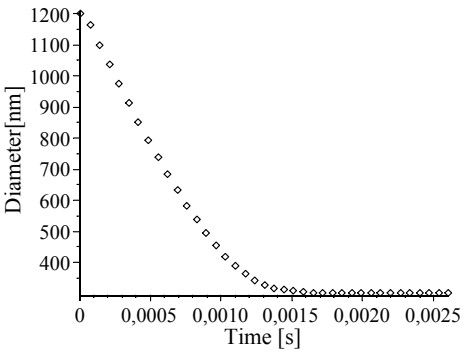

Fig. 2. Evolution of particle size.

6. Conclusions

This work shows that it is possible to obtain satisfactory results using a simplified PDE model for the nanoprecipitation. The adopted approach considers several variables that

have influence on diffusion, like type of polymer, solvent and non-solvent; affinity among them; and, polymer solubility.

As a result, it is then possible to evaluate the particle size during the nanoprecipitation, which takes no more than 20 ms.

The next step in this work is to consider an initial distribution of droplets, and apply the same methodology in order to predict the final distribution of particles. Of course, in this case, the assumption of zero concentration of acetone in the external phase is no more valid. Also, the proposed model could be combined with CFD simulator in order to improve the predictions. From the simulation, one could try to evaluate more accurately the initial droplet distribution. This methodology could thus be applied to study the influence of several configurations/sizes of reactors and mixers in the final properties of the nanoparticles.

Abstract

Many processes in chemical industries consume a lot of energy and often operate inefficiently. This implies high operation costs, which can be reduced through improvements in the use of energy in the process.
Distillation is an important unit operation that is widely used in industry and requires an excessive energy demand.
The exergetic analysis, which is based on the second law of thermodynamics, is an alternative to minimize this demand. Exergy or availability is the measure of the maximum amount of stream energy that can be converted into shaft work if the stream is taken to the reference state. This property may be applied to measure the quality of energy employed in a process. Therefore, the purpose of this study is to develop a program to calculate the exergetic efficiency and suggest, if necessary, possible operational changes that lead to the reduction of energy losses by irreversibilities in distillation columns.
The preliminary conclusion is that exergy analysis is vital for evaluating inefficiencies in industrial processes and thus the exergetic analysis can be used as an important tool not only for process synthesis but also for process optimization activities.

Keywords: exergy, distillation column, exergetic efficiency.

1. Introduction

Among the common utilized in industry processes, most attention was given to distillation, an important unit operation that is widely used and requires an excessive energy demand (Pessoa 2005). To evaluate the energy consumption, efficiencies based in the produced work-supplied energy ratio are often used. But not all energy can be turned into work, according to the second law of thermodynamics (Szargut et al 1988). Thus, it is important measure the availability in industrial plants. The exergetic or availability analysis can be used as alternative to minimize the irreversibility, resulting in a better consume of energy. Exergy is defined as the amount of work obtainable when some matter is brought to a state of thermodynamic equilibrium with the common components of the natural surroundings by means of reversible process, involving interactions only with the above-mentioned components of nature. This state property may be applied to measure the quality of energy employed in a process (Szargut et al 1988).
The purpose of this work is to develop a software capable of calculate the exergetic efficiency in distillation columns, working with a simulator process, and to suggests improvements for a better exergetic utilization.

2. Bibliographic Review

The exergetic analysis has been largely applied in processes of power generation, although not much applied in distillation processes (Maia 2001). This concept was introduced by Rant and is directly related with the second law of thermodynamic.
Smith et al, presenting at chapter 5 a detailed description about the second law and entropic balance. The generated entropy is proportional to the destructed exergy in a process, as shown in the law of Gouy-Stodola:

$$\delta B = T_0 \dot{S}_p$$

where δB is the exergy losses, T_0 is the reference state temperature and $\dot{S}_P$ is the entropy produced.
Szargut et al defined the concept of exergy as in the preview section and deduces the law of Gouy-Stodola abovementioned. They also show various forms of exergy calculation to different thermal, chemical and metallurgic processes; the physical, chemical and radioactive flow exergy calculation. Beyond, they show a data base for the standard exergy to dry air and sea water components, and reference reactions for calculation of the standard exergy to these reference environments.
Røsjorde et al studied the entropy production in diabatic and adiabatic separations of propylene/propane, optimizing lower entropy production, and evaluating and discussing the effects of changing operational conditions and the geometry of the column. The main conclusions are that for less generation of entropy it was necessary increase the areas of heat exchange in the reboiler and condenser and the number of trays.
Araujo et al studied the case of purification of EDC. In his work, showed ways of calculating the exergetic efficiency in different approaches and identified that most of the exergtic lost in the proposed separations occurs in the condenser.
Koeijer et al evaluted the production of entropy and exergetic losses on the experimental column and identified that the column loses less exergy when there is heat exchange in the trays.
Maia explained the concept of the reversible column and quasi-reversible column proposed by Zemp (1994). And also optimizing separations networks through the exergetic analysis for 3, 4 and 5 components systems.
Rivero et al simulated and evaluated the exergy losses in Tertiary Amyl Methyl Esther production comparing the system with the adiabatic and diabatic and measuring the Exergy Improvement Potential.

3. Algorithm development

Exergy is not conservative, opposed to energy (Szargut 1988). This thermodynamic property flows through the system boundaries by three different ways: mass flows, heat and shaft work (Rivero 2001). As previously described, to the system availability balance evaluation of the studied system, it is necessary computing the exergetic inputs and outputs of the system, the holdup factor and also the exergetic losses.
Figure 1 shows a separation system in the process simulator UniSim® Design from Honeywell. It describes a system made by a simple distillation column operating in steady-state; the exergetic inputs are given by the feed (F), and the heat added in the reboiler (E-200). The exergetic outputs are the products (D and B), and also the heat removed in the condenser (E-100). Since the described system is in steady-state, the

holdup term is null. For a more rigorous approach, it is also necessary to consider the heat lost by the column for the surroundings, which can be calculated in a system energy balance.

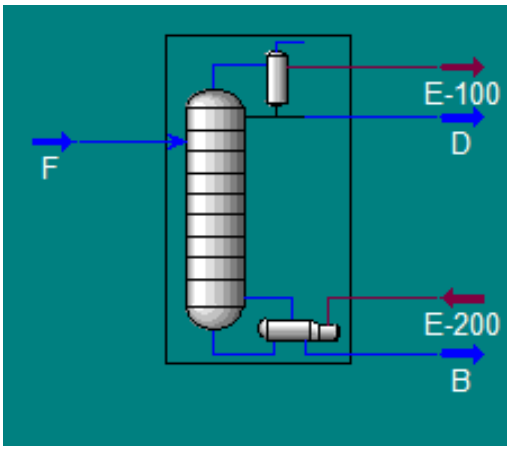

Figure 1 – Distillation column in HYSYS

To measure the exergy of stream, the procedure described by Maia, physical exergy is calculated by H – T_0*S, where H is the flow enthalpy, S is the entropy and T_0 is the reference temperature. The chemical exergy was neglected.
The calorific contribution is given by the involved heat multiplied by the efficiency of Carnot engine for the system. It is easily justified by the fact that the efficiency of this engine is the maximum thermodynamically allowed.
Thus, the exergetic balance is given by the equation:

$$\delta B = B_{feed} - B_{dist} - B_{bot} + \dot{Q}_{reb}\left(1 - \frac{T_0}{T_{reb}}\right) - \dot{Q}_{cond}\left(1 - \frac{T_0}{T_{cond}}\right) - \dot{Q}_{col}\left(1 - \frac{T_0}{T_{col}}\right)$$

where δB is the lost work, B is the exergy of a stream in kJ/h, $\dot{Q}$ is the heat of equipment or column, $\dot{Q}_{col}$ is the heat lost to environment and T_{col} is the mean temperature of the column.
The minimum work of separation W_{min} was computed and is given for the equation:

$$W_{\min} = \left(B_{dist} + B_{bot}\right) - \left(B_{feed}\right)$$

For the calculated the exergetic efficiency, used the following equation:

$$\eta = \frac{W_{\min}}{W_{\min} + \delta B}$$

The algorithm was developed in MATLAB® from The MathWorks, for use with the UniSim® Design process simulator. The flow rate, temperature, pressure, composition, enthalpy and entropy of each flow are the data input, and also the involved heat in the process heat exchangers.

4. Results and Discussion

The model was tested initially with a quaternary separation proposed by Yeomans et al. The column was feed by a current saturated liquid at 12 bar discharge of 100kmol/h with 30% propane, 30% n-butane, 20% n-pentane and 20% n-hexane.
The separation target was to recovery 98% of light and heavy key component of the feed in the top and bottom product, respectively. The model chosen was the thermodynamic equation of state of Peng-Robinson.
Columns were tested, 25 and 13 stages, with food in the trays 11 and 6. In both simulations, the values of the exergetic balance were very close to the law of Gouy-Stodola, resulting in an absolute difference in the order of 10^{-9} and relative difference of 10^{-14}. Table 1 shows the results for these simulations:

Trays/Feed	Exergy Losses	Minimum Work	Exergetic efficiency
25/11	53120 KJ/h	140930 KJ/h	72.63%
13/6	55623 KJ/h	139800 KJ/h	71.54%

Table 1: Results of first simulation of system with propane, n-butane, n-pentane and n-hexane.

It is important to point out that the lost exergy in both cases has a little difference when they are compared to the total exergy, but the difference is significative on the period of one year.
With the validated model, focuses on another system of separation, the distillation of the isomers n-butane and i-butane. The column was fed with a flow of saturated liquid 100kmol / h. The pressure was 12bar and target was 95% purity of the products. Two columns were simulated, which varied was the number of stages, 60/30 and 50/25. The results follow below:

Trays/Feed	Exergy Losses	Minimum Work	Exergetic efficiency
60/30	111500 KJ/h	123350 KJ/h	52.52%
50/20	147520 KJ/h	123570 KJ/h	45.58%

Table 2: Results of simulation of system with n-butane and i-butane.

Observe that in these simulations, the differences were significant. Due to difficulty of separation of these compounds, there is the need greater height of columns to hold it. In a difference of 10 stages of the reduction efficiency is almost 7%.
As the third simulation to evaluate the software, used a system with 50% propane and 50% n-butane. The pressure and flow of the supply current was the same also with previous simulations of saturated liquid, and a target was used for purity of 98%. To evaluated, it was tested columns with 18, 16 and 10 trays, and the feed stage, 7, 6 and 4. The results follow in the table 3:

Trays/Feed	Exergy Losses	Minimum Work	Exergetic efficiency
18/7	122470 KJ/h	170710 KJ/h	58.23%
16/6	147660 KJ/h	170670 KJ/h	53.61%
10/4	512320 KJ/h	170730 KJ/h	24.99%

Table 3: Results of simulation of system with propane and n-butane.

Similarly to the previous example, reducing the number of stages results in higher exergy losses. The system in question has a minimum theoretical stages equal to 6.5. When approaching this value, simulating with 10 stages, occurs a high exergy destruction

The results obtained using the computational program were excellent. One can seen that it is necessary more exergy for components which are more difficult to separate, which can be compensated using more trays. When the number of stages is close to the minimum number of stages there is a big reduction of efficiency.

5. Conclusions

A software was developed and the results demonstrated that it can be used as a powerful tool for process engineer in the evaluation of energetic efficiency of distillation column. Neverthe less it is necessary to use a process simulator to obtain the column data. The software was capable to identify the better process operational conditions and to decrease the exergy lost and the energy consume.

Using this program together an economic evaluation software it is possible to select the best operational conditions, optimizing in all aspects (efficiency and economic).

Abstract

In this paper, desalination systems integrating thermal and membrane processes are investigated. Specifically, a hybrid desalination plant integrating reverse osmosis (RO) and multi stage flash (MSF) systems is mathematically modeled. The non linear programming problem is developed in order to optimize the configuration and operating conditions in order to satisfy fresh water demands at minimum costs.
Both implementations, with one and two reverse osmosis stages are considered at the particular framework RO-MSF adopted. The system is modeled in such a way that the RO unit receives brine feed from the MSF. In addition, partial extractions of flashing brine stream from flash chambers of MSF can be performed in order to feed the RO system. In fact, the flow-patterns and flow-rates of the brine streams of MSF are optimization variables. Heat transfer areas of pre-heaters and the geometric design of stages are design variables to be optimized. The optimization procedure will also decide between one and two RO stages and the number of modules operating in parallel at each stage. Moreover, all the operative conditions will be optimized.
Different case studies considering various seawater conditions were successfully solved without convergence difficulties. It can be concluded that the optimal arrangement of hybrid system depends strongly on the seawater conditions (salinity and temperature) and the fresh water demand as well.

Keywords: optimization, reverse osmosis, multi stage flash desalination, hybrid RO/MSF desalination systems

1. Introduction

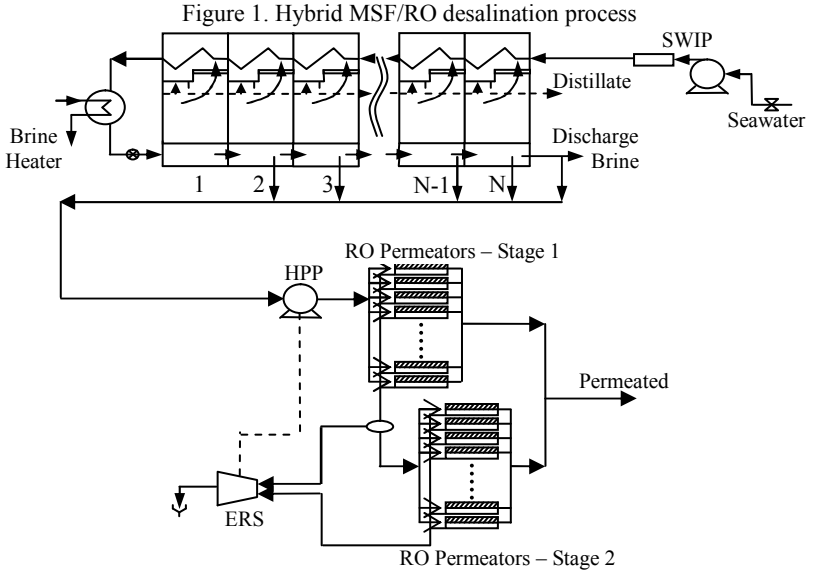
Desalination of seawater has been considered as one of the most promising techniques for supplying fresh water in the regions suffering water scarcity.
Desalination plants require significant amounts of energy in the form of heat and/or electricity. The processes used for desalination include distillation, crystallisation and ion exchange. Reverse osmosis and electrodialysis processes have emerged as alternative for thermal methods. Furthermore, hybrid systems combining thermal and membrane processes are being studied as promising options for improving the economics aspect. Particularly, the hybridization of RO and MSF plants is being investigated by many researchers (Hamed, 2005; Helal et al., 2003; Agashichev, 2004). The hybrid RO-MSF plants have potential advantages of a low power demand, improved water quality and lower running cost as compared to stand-alone RO or MSF plants. Several models have already been described in the literature to find a functional relationship between the MSF/RO hybrid process by assuming a fixed configuration (Helal et al., 2003; Marcovecchio et al., 2005).
In this paper, the particular hybrid configuration modeled by Marcovecchio et al., 2005

has been appropriately reformulated to include more integration between the processes. The possibility to select one or two RO stages and potential brine extractions from the flashing chambers are taken into account for the optimization. Precisely, the partial brine extractions may increase the integration level between the two processes, since not only the mixing temperature could be optimized by the extractions but also the salinity mixing. Moreover, the MSF model is developed by stage and component, allowing the prediction of temperature, composition and flow-rate profiles along the evaporator. Meanwhile the RO model incorporates better approximations for the resolution of the differential equations involved in mass and salt concentrations balances by implemented the finite differences method.
This paper is outlined as follows. The process is briefly described in Section 2. Section 3 introduces the problem formulation. The mathematical model is summarized in Section 4. Section 5 presents applications of the developed model and results analysis. Finally, the conclusions and future works are presented in Section 6.

2. Process description

Figure 1 schematizes the process diagram of the RO/MSF hybrid plant. As it is shown, both processes are coupled by the discharge brine of the MSF desaltor, since part of this stream is fed into the RO process while the remaining part is discharged to the sea.

Figure 1. Hybrid MSF/RO desalination process



The chemically treated seawater is fed into the MSF desaltor, then it is heated stepwise up to the brine heater inlet temperature as it flows through the condensers by recovering the heat of condensation of the vapors released in the flash stages. In the brine heater it is heated up to the brine top temperature by condensing a controlled mass of saturated heating steam coming from an external boiler at 115 °C. The heated seawater flows to the first flashing chamber via an integrated spray pipe. As the brine is superheated, spontaneous boiling takes place and vapor is released until the brine has reached its saturation temperature, the formed vapor flows through a wire mesh demister to remove the entrained brine droplets and then condenses over the condenser tubes. These processes continue right down to all next stages at decreasing temperature and pressure. The brine is flowing from stage to stage by inter-stage brine flow devices being

designed for optimum flexibility in operation and minimized stage to stage vapor leakages. The residual concentrated brine is discharged to the blowdown pump. The distillates forming in each stage are collected in an external distillate pipe and are discharged with the distillate pump.
On the other hand, the RO system involves four major parts: a High Pressure Pumps (HPP), two RO stages and the Energy Recovery System (ERS). At a stand-alone RO plant, the seawater stream is treated chemically before its pressure is raised by the high pressure pumps. Part of the power for the pumps is supply by the energy recovery system, and the rest is provided by an external source. The high pressure stream enters to the permeators of the first stage of reverse osmosis. The feed stream of the second stage, in case that it does exist, is formed with part or the total rejected stream leaving the first stage. Then, the permeated streams of both stages are blended with the product water from the MSF. The remainder rejected flow rate of the first stage, if it does exists, and the rejected flow rate of the second stage will pass through an energy recovery system, before being discharged back to the sea.
In next sections, the optimization problem is described and the hypotheses assumed are presented.

3. Definition of the problem

As was mentioned, the particular hybrid configuration studied in Marcovecchio et al., 2005 is properly extended allowing partial extractions of flashing brine stream from flash chambers of MSF that feed the RO system.
The optimization problem is defined in order to determine the best configuration and optimal operating conditions simultaneously. Flow-patterns and flow-rates of the brine streams of MSF are optimization variables. Water demands, seawater conditions (temperature and salinity), and unitary cost for capital investment and operating costs are given data. The goal is to determine the optimal configuration and operating conditions minimizing the cost per m^3 of product water.

4. Mathematical model and assumptions

The MSF mathematical model involves real-physical constraints for the evaporation process and is derived on the rigorous energy, mass and momentum balances. Physical and chemical properties of all streams are computed by specific correlations. Heat transfer areas of pre-heaters and the geometric design of stages are design variables to be optimized. Due to space limitations the mathematical model is not here presented. The complete mathematical model of the MSF process used in this paper can be found in Marcovecchio et al., 2005.
As regards the reverse osmosis process, dimensions and properties from the hollow fiber DuPont B10 modules are assumed. For these particular modules, the membranes are arranged as bundles of hollow fibers. Some hypotheses are established to formulate the model for the permeation process. It is supposed that the flow of the bulk stream inside the shell is mainly radial. Thus, null axial velocity is assumed. Axial permeated flow inside the fibers is assumed. Module parameters are supposed constant within the permeator. It is considered that the permeator have been operating for enough time to considerate stationary state. Constant fluid properties as density, viscosity and diffusion coefficient are assumed within the permeator.
Under these hypotheses, the permeation phenomenon is modelled. The concentration polarization is modeled according to the film theory. Hagen-Poiseuille equation is used to compute the pressure drop in bore side of hollow fiber. The pressure drop on the shell

side of the fiber bundle is estimated by using the Ergun equation.
An evaluation of the salt concentration of the permeated flow rate accumulated along the fiber is implemented. The flow velocities and concentrations are considered with radial and axial distribution, as well as the mass transfer coefficient.
An appropriated finite difference mesh for a hollow fiber module is implemented (Chatterjee et al., 2004), dividing the module in its axial and radial directions. The finite differences method is applied to solve the involved differential equations. The number of grid points guarantees that the approximation error for each final variable be within an acceptable range.
The complete mathematical model for the RO system implemented in this paper can be found in Marcovecchio, 2007.
Beside, the model includes the mass and energy balances on the mixers and splitters for the interconnection equipments at the hybrid configuration shown in Figure 1. Precisely, the following constraints are included in the model.

$$W_{out,j}^{MSF} = W_{inlet,j+1}^{MSF} + W_{j}^{MSF\_RO} \qquad j=1,...,N \qquad \text{(Eqn. 1)}$$

$$\sum_{j=1}^{N} W_{j}^{MSF\_RO} = W^{RO} \qquad \text{(Eqn. 2)}$$

$$\sum_{j=1}^{N} W_{j}^{MSF\_RO}\ H_{j}^{MSF\_RO} = W^{RO}\ H^{RO} \qquad \text{(Eqn. 3)}$$

where $W_{out,j}^{MSF}$ and $W_{inl,j}^{MSF}$ denote the outlet and inlet flow-rates at stage "j" of the flashing brine while $W_{j}^{MSF\_RO}$ refers to the brine flow-rate coming from stage "j" and feeding the RO system. N is the total number of flashing stages. Finally, $H_{j}^{MSF\_RO}$ and H^{RO} are the enthalpies of the corresponding streams.

It is important to note that the model was formulated in such way that the optimization procedure is able to eliminate internal flows, equipments even a whole system, and it is accurately reflected in the cost function.
The resulting mathematical model to be solved is a NLP problem involving 2533 constrains and 2350 optimization variables. The mathematical model and the solution procedure are implemented in General Algebraic Modelling System GAMS, Brooke et al., 1997 and CONOPT is used as NLP solver.
In the next section, the optimal solution of a representative case study is discussed.

5. Study Case

Many case studies have been solved by varying the seawater conditions but they are not included here due to space limitations. Indeed, a study case is presented in order to illustrate the application of the model. Table 1 lists the constants and parameters used to solve the optimization problem.
It is important to mention that the levels of fresh-water production of both processes are optimization variables.
The optimal process configuration is composed by the MSF desaltor and only one RO stage. Table 2 reports the optimal values of the obtained solution for the MSF system. Similarly, Table 3 shows the obtained solution for the RO system.
The second RO stage was not selected from the superstructure, as it can be expected. In fact, for high feed salinity the RO plants operate with only one stage at optimal

conditions.

Table 1. Parameters for the RO-MSF desalination model

Problem parameters	
Total fresh water demand, m^3/h	2000
Maximum allowed salt concentration, ppm	570
MSF-OT Evaporator	
Max. operating temperature, K	390
Sea-water temperature , K	298
Sea-water salinity, ppm	45.000
Number of stages	29
RO plant	
DuPont's B10 hollow fiber characteristics	
Pure water permeability constant, $kg/m^2.s.atm$	$4.3508955\ 10^{-5}$
Salt permeability constant, m/s	$4.0\ 10^{-9}$
Inner radius of the fiber bundle, m	$1.27\ 10^{-2}$
Outer radius of the fiber bundle, m	$5.334\ 10^{-2}$
Length of fiber bundle, m	0.75
Membrane area, m^2	152
Inner fiber radius, m	$2.1\ 10^{-5}$
Outer fiber radius, m	$5.0\ 10^{-5}$
Void fraction	0.4
Specific surface diameter, m	$1.2\ 10^{-4}$
Operating pressure range, bar	55.2-68.8
Maximum brine flow rate m^3/h	0.917

Part of the brine leaving the MSF desaltor is fed into the RO process. On the other hand, no partial brine extractions from the flashing stages resulted at optimality.
The optimum objective value is 0.8877 \$ / m^3 of fresh water. This cost can be straightly compared to the obtained for the stand-alone RO plant. In fact, under identical conditions, e.g. 45000 ppm for the seawater salinity and a total production of 2000 m^3/hr, the RO single plant produces fresh water at 0.9896 \$ / m^3 at optimality. (Marcovecchio, 2007).

Table 2. MSF optimal values

MSF desaltor	
Production [m^3/hr]	770.9
Feed [m^3/hr]	5595
Hot Utility [Gcal/h]	71.6
Total Heat Transfer Area [m^2]	30624.5
Stage Length [m]	0.6
Stage Width [m]	19.0
ΔTml per stage [K]	7.9
Brine velocity in pre-heater [m/s]	15.0
Number of tubes per stage	595

It is well known that the RO technology is recommended when a desalination plant is built, since it is the best option from an economical point of view. However, the solution obtained here shows that the integration with the MSF system results in 10.3% of saving compared to a RO single plant. Note that the salinity of the RO permeated stream exceeds the maximum allowed. This constraint is satisfied because of the

distillated stream produced by the MSF system.

Table 3. RO optimal values

RO plant	
Production [m^3/hr]	1229.1
Feed flow rate [m^3/hr]	4488.8
Feed salt concentration [ppm]	51607
Operating Pressure [atm]	67.9
Number of permeators, stage1	7107
Number of permeators, stage 2	0
Feed flow rate per module, stage 1 [m^3/hr]	0.632
Brine flow rate, stage 1 [m^3/hr]	3259.7
Permeated concentration, stage 1 [ppm]	854
Brine concentration, stage 1 [ppm]	70745

6. CONCLUSIONS.

A detailed NLP optimization model for a hybrid MSF-RO system has been developed. The hybrid configuration studied in Marcovecchio et al., 2005 has been appropriately reformulated to include more integration between both systems. At the same time, more rigorous model describing RO and MSF processes are been included. For the same problem parameters and cost items, the configuration obtained in this paper leads to a lower specific production cost of fresh water. On the other hand, authors concluded that the optimal arrangement of hybrid systems depend strongly on the seawater conditions (salinity and temperature) and the fresh water demand as well. Therefore, the influence of the main problem parameters (e.g. seawater conditions and fresh water demands) on the process efficiency will be studied in detail in future work.

ACKNOWLEDGEMENTS.

Feasibility of separation of ternary mixtures by pressure swing batch distillation

Gabor Modla, Arpad Kopasz, Peter Lang

BUTE Department of Building Services and Process Engineering, Muegyetem rkp. 3-5 H-1521 Budapest, Hungary, E-mail:lang@mail.bme.hu

Abstract

Feasibility of the pressure swing batch distillation separation of ternary homoazeotropic mixtures in different single and double column configurations is investigated by assuming maximal separation. Feasibility regions where the ternary mixture can be separated into its pure components (by applying in at least one step pressure swing) and the separation steps for different configurations are determined. The method is presented for the most frequent types of ternary mixtures with minimum azeotrope(s).

Keywords: Pressure Swing, Batch Distillation, Azeotropes

1. Introduction

Azeotropic mixtures cannot be separated into their components by traditional distillation. Several mixtures form a homoazeotrope, whose position can be shifted substantially by changing system pressure (pressure sensitive azeotropes). These mixtures can be separated by pressure swing distillation (PSD). Knapp et al. (1992) studied the use of entrainers for continuous PSD. Hence such azeotropes can be separated by PSD which are not pressure sensitive if the entrainer forms a pressure sensitive boundary and the number of mixtures separable by PSD can be increased. Phimister and Seider (2000) studied the separation of a minimum azeotrope by semi-continuous PSD. Repke et al. (2007) investigated experimentally the application of PSD in batch. They studied the separation of a minimum azeotrope (acetonitrile-water) by PSD in a batch rectifier (BR) and in a batch stripper (BS). Modla and Lang (2008) compared different batch configurations for the separation binary (maximum and minimum) homoazeotropes by PSD. The best results were obtained with the two new double column configurations (double column batch rectifier (DCBR) for maximum and double column batch stripper (DCBS) for minimum azeotropes) equipped with a common bottom or top vessel, respectively.
Modla et al. (2008) stated that by the methods of classification of Serafimov (1970) and Matsuyama and Nishimura (M&N, 1977)) the pressure sensitivity of an azeotrope is not indicated though this information is indispensable for the synthesis of PSD separations. They extended the method of M&N by indicating the pressure sensitivity of an azeotrope by writing ‘P’ after the M&N number of an azeotrope if it is pressure sensitive. (They also mentioned that if the type of RCM varies (an azeotrope disappears or the volatility order of components varies with the variation of pressure), it must be given for both pressures.)

The aim of our work is to investigate the feasibility of the batch PSD separation of ternary mixtures in different (single and double) configurations by assuming maximal separation, to determine feasibility regions where the ternary mixture can be separated

into its pure components (by applying in at least one step pressure swing) and to determine separation steps for ternary azeotropic mixtures of different type.

2. Feasibility method

When making feasibility studies we suppose that maximal (perfect) separation (Bernot et. al. 1990) can be produced. This involves the following assumptions: 1) large number of stages (*N*), 2) large reflux/reboil ratio, 3) negligible liquid plate hold-up, 4) negligible vapour hold-up.

The method is based on the determination of the feasible compositions of products (continuously withdrawn) and those of residues (remaining in the vessel) by analysing the *vessel path*s in the residue curve maps at the two different pressures (P^1, P^2).

For the different column configurations separation steps and *feasibility region(s)* of the separation, which means all feed compositions, from where all components can be purely recovered by maximal separation at the given pressure or by applying pressure swing, are determined.

In order to determine the sequence of the cuts (products) for a given charge composition by maximal separation we have to study the batch distillation (BD) regions. From any point of a BD region we get the same cuts (fractions) by rectification. The method to divide the composition diagram into BD regions can be summarised as follows:

1. First the composition triangle is divided into regions containing one unstable node.
2. In each of these regions the other batch distillation boundaries are found by joining the unstable node to all the saddles and nodes of its region.

Since we make feasibility studies not only for BRs but also for batch strippers we have to define also the batch stripping (BS) region: from any point of a BS region we get the same cuts by stripping. In the case of strippers the maximal separation means large reboil ratio (and *N*). In order to distinguish better the BD regions (used for rectification) and BS ones in this paper the BD regions will be called batch rectification (BR) regions.

In a ternary mixture containing pressure sensitive azeotrope(s) the *location of the boundaries* involving this (these) azeotrope(s) varies. (We suppose that the boundaries are straight lines.)By changing the pressure we can cross these boundaries. Between the boundaries concerning to the two different pressures there is a region from where at the different pressures different products (distillate in a BR, bottoms in a BS) can be obtained.)

3. Feasibility results

Results will be shown for the two most frequent Serafimov's types of mixture, only. Sketch of the residue curve map (RCM), simple distillation, BR/BS regions, separation steps and vessel-paths for the recommended configuration(s) are presented.

3.1. Separation of mixtures of class 1.0-1a

The classification of original residue curve map is 1.0-1a (21.6%) by Serifamov (S) and it is 1-0-0 by N&M.

The azeotrope *L-I* is the unstable, vertex *H* is the stable node, respectively (*Fig. 1a*). Vertices *L* and *I* are saddles. The RCM (M&N: 1P-0-0, e.g. CCl4(*L*)-ethanol(*I*)-acrylic acid(*H*)) contains only one simple distillation (the whole triangle) but two BR and BS (maximal separation) regions. For this type of mixture the BR and BS regions coincide but the sequence of the products (cuts) is just the opposite as it is indicated in *Table 1* where sequence of the vertices of the different regions (triangles) corresponds to that of the cuts.

The location of the boundary (line between Az_{LI} and vertex *H*) considerably varies and so the areas of the BR and BS regions change with the pressure.
Configurations recommended: batch stripper or double column batch stripper.
The separation steps are as follows:
1. Production of *H*:
In the case of DCBS only one column is operated; at the end of this step the vessel path (*Fig. 1b*) arrives at the *LI* edge. This step is feasible at either of the two pressures but if the charge composition is located
- in the area I and P^2 is applied or
- in the area II and P^1 is applied
there is no need for pressure change at the end of this step.
2. Production of *L* and *I* by pressure swing distillation (in the case of DCBS both columns are operated).
Remarks:
-The separation of the ternary mixture can be reduced to that of binary systems.
-This type of ternary mixture cannot be separated in one operation step by double column system.
The feasible region is the whole area of the triangle.

Region	I.	II.
BR	Az_{LI}-*I*-*H*	Az_{LI}-*L*-*H*
BS	*H*-*I*-Az_{LI}	*H*-*L*-Az_{LI}

Table 1. BR and BS regions for a mixture 1-0-0

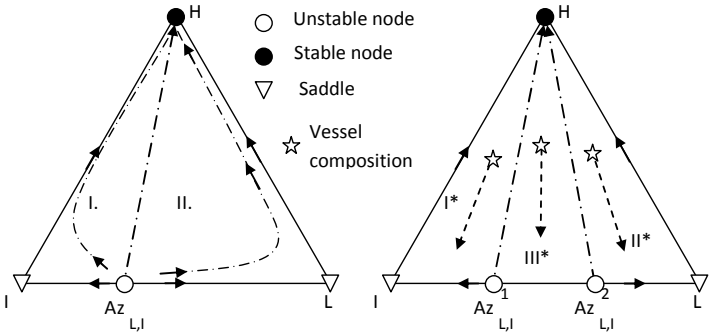

Fig. 1. Sketch of the RCM (a) and vessel paths of a BS for a mixture 1P-0-0

3.2. Separation of mixtures 2.0-2b
The class of original residue curve map is 2.0-2b (21%) by Serifamov and it can be 1-2-0 or 1-0-2 or 0-2-1 by N&M.
The azeotrope *I*-*H* and vertex *L* are saddles, vertices *I* and *H* are stable nodes and the azeotrope *L*-*I* is the unstable node, respectively (*Fig. 2*). The RCM contains two simple distillation and three BR/BS regions (*Table 2*).

If only one azeotrope is pressure sensitive it can be
- the unstable node, (by extended classification of RCM: 1P-2-0 (Case1 e.g. acetone(*L*)-methanol(*I*)-benzene(*H*)) or 2-1P-0 or 0-2-1P) or
- a saddle (by extended classification of RCM: 1-2P-0 (e.g. methanol(*L*)-toluene(*I*)-n-butanol(*H*)) 1-0-2P, 0-2P-1; not shown).
The other possibility is that both azeotropes are pressure sensitive (Case 2).

Region	I.	II.
BR	Az_{LI}-*I*-*H*	Az_{LI}-*L*-*H*
BS	*H*-*I*-Az_{LI}	*H*-*L*-Az_{LI}

Table 2. BR and BS regions for a mixture 1-0-0

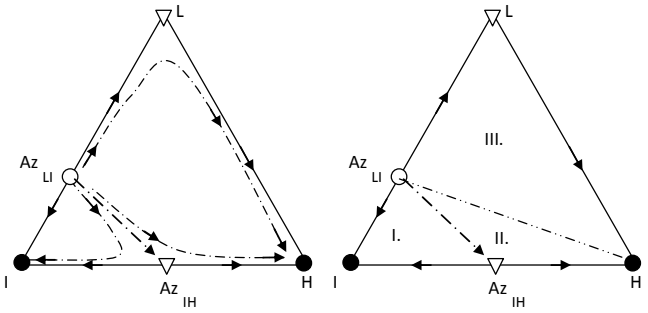

Fig. 2. Sketch of RCM (a) mixture and BR/BS regions (b) for a 1-2-0 mixture (2.0-2b)

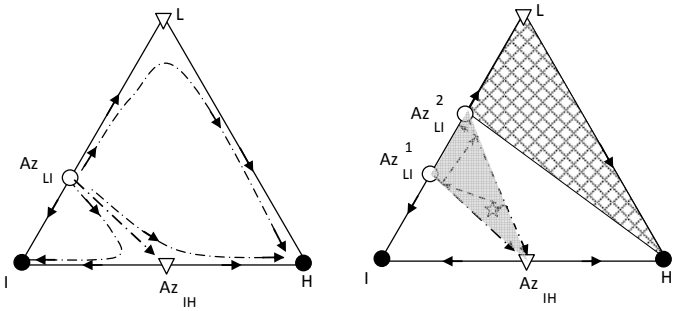
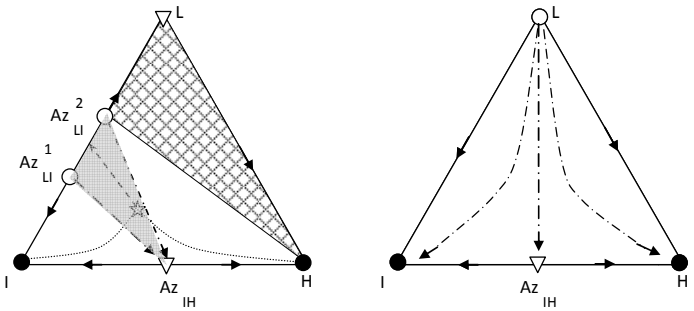
3.2.1. Case 1 – Only one azeotrope is pressure sensitive

The pressure sensitive azeotrope is the unstable node (e.g. Az_{LI}, *Figs. 3*)

The location of the boundary (line between Az_{IH} and Az_{LI}) considerably varies with the pressure (due to the movement of Az_{LI}) .



a. Sketch of RCM at P1 *b. Vessel path for the PS-BS*



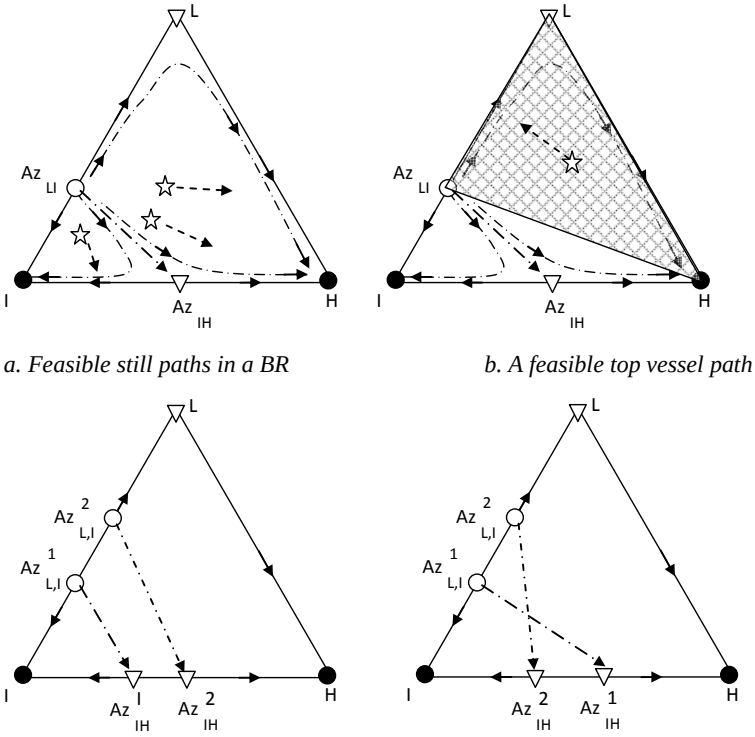
c. Vessel path for the DCBS *d. Sketch of RCM at P3*

Fig.3. Separation of 1P-2-0 mixtures

The configurations recommended: batch stripper (*Fig. 3b*) or double column batch stripper (*Fig. 3c*).
The separation method contains the following steps:
0. (optional). Production of some *I* or *H*: in the case of DCBS by operating only one column, if the charge composition is out of the darkened triangle.
1. Production of *H* or *I* alternately in a BS, (vessel path (dashed) in *Fig. 3b*) or simultaneously in a DCBS (*Fig. 4c* the liquid concentration profiles are dotted)). (In the case of BS this step consists of several parts and requires several changes of *P*.)
2. Production of *L* and *I* by PSD.
If the charge composition is located in the BS Region III (hatched area for P^2 in *Fig. 3b*) in the first production step the whole amount of *H* can be withdrawn as product.
It must be still noted that with the variation of the pressure (e.g. at P^3) the azeotrope *L-I* can even disappear (*Fig. 3d*). In this case the topology of the residue curve map varies (to Class S: 1.0-2, M&N: 0-2-0). The recommended configurations are the same as above. In this case the separation *L/I* (at P^3) does not require pressure swing.
The feasible region is the whole area of the triangle.

3.2.2. Case 2 – Both azeotropes are pressure sensitive
In this case there are two boundaries whose location varies with the pressure. We have to focus on the variation of the concentration of that component (e.g. component *I* in *Fig. 4*) which is present in both azeotropes. Two different cases are possible. The concentration of that component in the two azeotropes can vary with the pressure
- in the same direction (increases or decreases (*Fig. 4c*) in both azeotropes, e.g. acetone(*L*)-methanol(*I*)-ethyl-acetate(*H*))
- in the opposite direction when the boundaries intersect.
Recommended separation methods:
1. Removal of Az_{LI} by BR which is pressure sensitive so it can be separated by pressure swing BS or DCBS (*Fig. 4a*). The residue can be binary mixture *I-H* or *L-H*. The mixture *L-H* is zeotropic so it can be separated by both BR and BS while the mixture I-H can be separated by pressure swing in BS or DCBS.
2. If the charge composition is located in the BS region III (the hatched area in *Fig. 4b*) the first step is production of *H* in BS. In this case the remaining binary mixture *L-I* which can be separated by pressure swing in BS or DCBS.
The feasible region is the whole area of the triangle.

The most frequent types of ternary mixtures were investigated. We studied 5 types of mixture by the classification of Serafimov corresponding to 11 different types of mixture by the classification of Nishimura and Matsuyama (N&M), and 41 different cases by the extended N&M classification taking into account the pressure sensitivity of the azeotropes, as well. From these 41 cases studied
-in 14 cases the whole area of the composition triangle proves feasible,
-in 15 cases in the triangle there is at least one region where the separation is feasible,
-in 12 cases there is no feasible area within the interior of the triangle.
We stated that, the composition triangle contains a feasible part only if
- both the azeotrope which is unstable node and
- the separatrice(s) between stable node(s) and saddle(s)
are pressure sensitive.
Moreover we concluded that if the cuts of a BR/BS region are only pure component(s) and/or pressure sensitive binary azeotrope(s) this region is feasible.



a. Feasible still paths in a BR *b. A feasible top vessel path in a BS*

c. Movement of the boundaries with P in the same direction *d. in the opposite direction*

Abstract

This study presents a set of models of activity and information infrastructure required for practical risk-based process design. In this process design, local risk and global impact are evaluated and interpreted comprehensively by integrating risk assessment (RA) and life cycle assessment (LCA). The type-zero method of Integrated DEFinition language, or IDEF0 and the Unified Modeling Language for information system, or UML, were applied for enabling systematic and effective definitions of requirements for process designers and supporting information infrastructure. In this study, a case study is performed on metal cleaning process, where various chemical substances have been utilized. With the description of developed IDEF0 and UML models, risk-based process design involving on-site engineers was proposed.

Keywords: life cycle assessment, risk assessment, activity and information modeling

1. Introduction

Global environmental impact and local risk due to the use of chemicals have become issues in decision making in process management, which covers planning, design and operation phases, and process improvement of production processes. A decision making in industrial process design is imposed to various constraints. Process managements should focus on the way how to apply and what to be utilized for process chemicals or raw materials under such constraints. For implementing global impact and local risk into such process management, risk assessment (RA) and life cycle assessment (LCA) have been key technologies to quantify such non-monetary evaluation indices. RA can consider the critical concerns for decision makers in industry, such as occupational health, and safety issues. Based on LCA results, decision makers can identify the life cycle impacts associated with their decisions. For risk-based decision making, integrated application and interpretation of RA and LCA has been discussed with actual case study (Kikuchi and Hirao 2008).

Business modeling approach is useful to activate a smooth implementation of new business activities (Naka 2006). Because environmentally-conscious design of processes needs systematically connected activities and information in process evaluation, simulation and optimization (Chen and Shonnard 2004), effective information technology support is important for process engineers (Shneider and Marquardt 2002).

In this paper, plant-specific risk and life cycle assessments are integrated with sustainable process design. This integration is visualized as business and information models. Activity model represents a method of integrating RA and LCA for a risk-based

decision making in industrial process management. Required information infrastructure is visualized by information model. A case study is performed on the design of metal cleaning process, which has been a big issue in Japan on environmental managements by small and medium-sized enterprises (SMEs).

2. Activity and information infrastructure

2.1. Process design and evaluation knowledge

Chemical process should be continuously improved on global impact and local risk due to the change of the needs from society on such non-monetary issues. Fig.1 shows process improvement procedure with required knowledge. All knowledge for process design can be divided into five knowledge units: mechanisms of risk specification (RSM), evaluation (EvM), alternative generation (AGM), process simulation (PSM), and risk interpretation (RIM). Knowledge has individual roles of performing the phases of process improvement. As well as the single role of knowledge, the combination among them was addressed, and activities were visualized with appropriate knowledge to be referred. The systematization of the five units of knowledge enables the continuous improvement on site according to the change of chemical risk concerns.

2.2. Activity and information modeling

The type-zero method of integrated definition language or IDEF0 have widely been used for breaking down all administrations and operation procedures into “activities” and systematic relationships among them are described by ICOM: Input, Control, Output, and Mechanism. Each activity can be hierarchically decomposed into subactivities. A developed model can make it visible what knowledge, technique and information are actually required for certain activity. In process design field, several authors applied the activity and information modeling approach to integrate new or existing engineering methods and tools for environmental protection and EHS risks (Gabber et al. 2004, Sugiyama et al. 2008). Unified Modeling Language (UML) for systems modeling has a large potential to visualize clearly system/data requirements for software tools from design stages. Several researches on risk-based decision making have been developed in a couple of decades. They could have solved actual problems based on tactful application of environmental management methodologies by researchers. To enhance the efficiency and practicability of risk-based decision, such research achievements should be generalized and shared systematically enough to implement them into other fields and sectors.

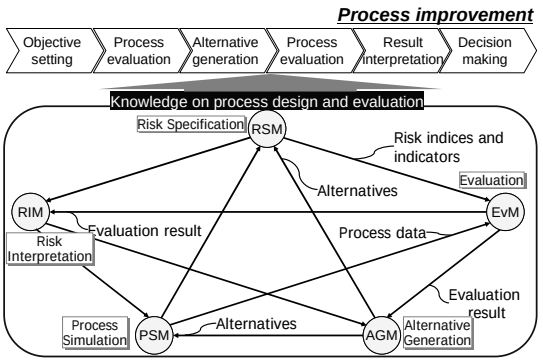

Figure 1 Knowledge structure for process design and evaluation

Fig. 2 shows the process evaluation activities utilizing different assessment methodologies. The evaluation indices must be specified on the industry-specific conditions on chemical usage and the social sense of value, which could be formalized into the constraints on alternative process and design. Based on the specified evaluation indices, the sufficient assessment methodologies are selected and executed in the centered activities in Fig.2. The information required assessments can be shared in the last activity "Collect information". The first and the last activities enable the effective settings of evaluation objectives and execution for avoiding redundant procedures during evaluation. Fig. 3 shows one of the developed diagrams, use case diagram of evaluation tool. This diagram describes a snapshot of processing in system with its user. By developing the software system of performing RA and LCA on individual conditions, the applicability and practicability of assessment methodologies for non-monetary issues can be enhanced significantly.

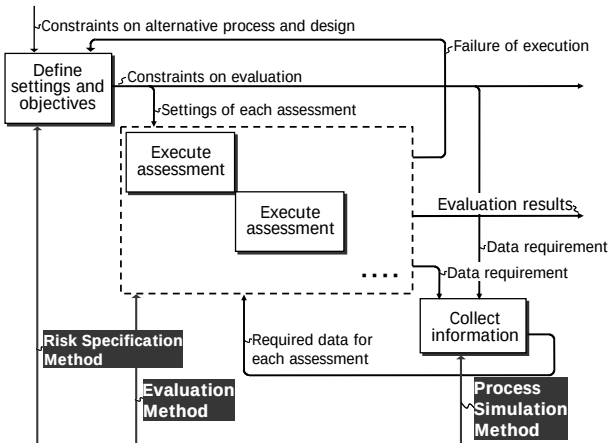

Figure 2 Process evaluation activities with information infrastructure

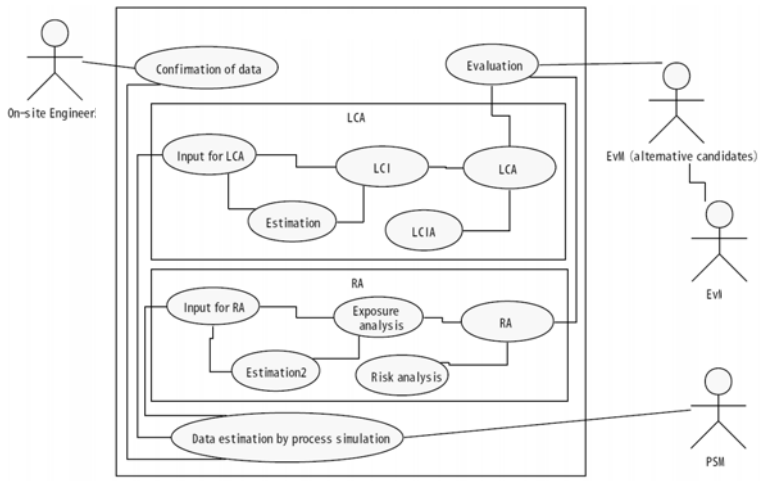

Figure 3 UML use case diagram for information infrastructure of implementing LCA and RA into process design by on-site engineers

3. Case study of process design in metal cleaning

Actual case study of enhancing the practicability of RA and LCA was addressed in the design of metal cleaning process. Metal surface treatments are inevitable processes for any kinds of products including metal parts, which are electroplated and surface converted. A metal cleaning process is important for the quality of such metal parts treatment. For supporting risk-based process design in metal cleaning process, the developed activities model was applied and the requirements of actual information infrastructure were defined. The evaluation procedures are based on the existing researches (Kikuchi and Hirao 2007, 2008), where RA and LCA are performed simultaneously to design an economically viable process on the basis of local risk and global impact.

Fig. 4 shows the developed UML sequence diagram for RA in metal cleaning process design. This diagram illustrates the temporal sequence among existing domains inside of software program. The domains include graphical user interface (GUI) and databases assembled in the software tool. The exposure and effect analyses in RA can be supported by the software system illustrated in Fig. 4. According to the sequence, the databases storing the background exposure and the hazardous properties of targeted chemical substances should be available. The connection with existing risk assessment tools is also required for effective RA. Fig. 5 shows the UML sequence diagram for LCA in metal cleaning process. The main steps in LCA are the life cycle inventory analysis and life cycle impact assessment. In these steps, a wide range of information is required such as process inventories in the production plants of inputted materials. Databases storing such information should be available. In addition to the databases required for both RA and LCA, the calculation modules for the steps of assessments should be able to accessible in the system. The temporal sequences of such modules were developed by UML sequence diagrams as well.

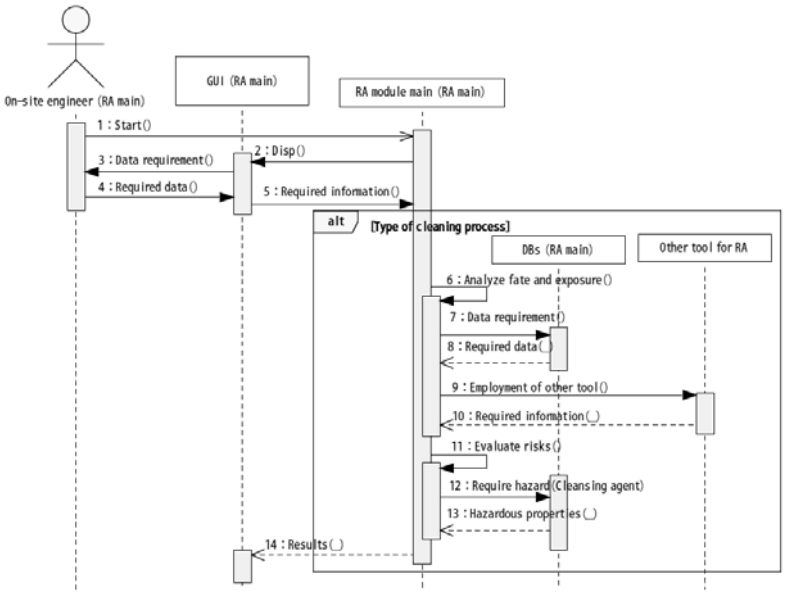

Figure 4 UML sequence diagram for risk assessment in metal cleaning process design

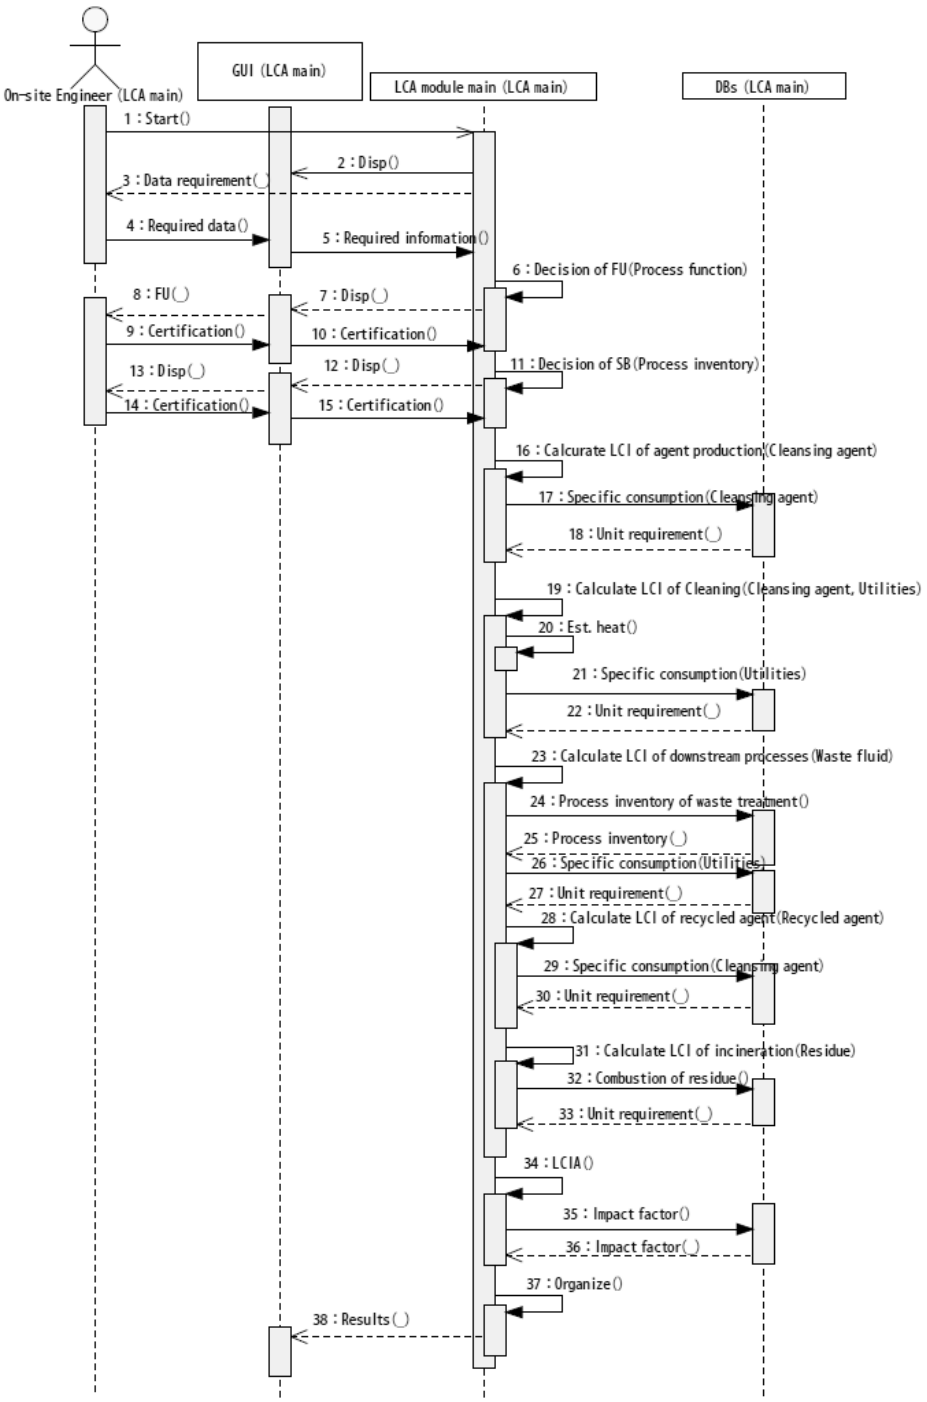

Figure 5 UML sequence diagram for life cycle assessment in metal cleaning process

The effectiveness of software tool to implement RA and LCA into practice was verified through the development of actual software tool of designing metal cleaning process on Microsoft ® Excel. Based on the software system, the on-site engineers became able to

perform RA and LCA only by their own process information, because the system implements all other required information with calculation modules.

4. Conclusion

This study aims to enhance the applicability and practicability of developed engineering knowledge on risk-based process design. The knowledge on process design and evaluation is classified and categorized into five different units, the function of which was defined to establish logical connection. Especially on assessment methodologies for non-monetary issues, the actual procedures and information infrastructure of them was visualized in clearly and logically-practical styles in business process by IDEF0 activity modeling language. In addition to the business activity modeling, the required information system for implementing the assessments into practice was designed by UML diagrams, which can visualize the system requirements. Actual case study on the design of metal cleaning process was performed to show the effectiveness of software system to enhance the applicability of RA and LCA. The databases and calculation modules to be implemented in software system could be defined by UML based on the business model defined by IDEF0. Actual software system verified the enhancement of the applicability of RA and LCA by system development.

Business activity and supporting software system models can stimulate a fast and appropriate implementation of structured knowledge on process design and evaluation. Implemented system enables the continuous improvement of processes, which had been designed correctly on the previous constraints. The visualization of such activities and information enables the effective discussion on scenario-based selection of engineering and scientific knowledge for improving decision making toward sustainable future.

Abstract

Inulin is a fructan found in many plants as a reserve carbohydrate. It is an ingredient that integrates the group of "functional foods" improving physiological function, preventing diseases, replacing fat and sugar, and acting as a stabilizer. This work carried out the modeling and experimental data simulation obtained in the inulin extraction process from garlic in continuous flow. The extraction system comprehends a column of 60cm^{3}filled with garlic and glass pearls. The study was conducted in flow rate of 0.59, 2.4, and 4.7 cm^3/min at 60°C with single passage of solvent and recirculation. For all configurations studied, the model described satisfactorily the inulin extraction tendency. Were obtained low values of Peclet number, indicating the importance of the bed dispersive nature.

Keywords: extraction, simulation, inulin

1. Introduction

Inulin is an important carbohydrate resource in the plants. It is a fructan synthesized by a wide range of plants, approximately 36,000 species, representing 10 families (Roberfroid, 1993).

By presenting a very high level of fructose (around 94%), the inulin has excellent prospects for obtaining pure fructose syrup. Their functional properties, among them the low calorific value, contribution to improving the balance and mineral factor "bifid", which is the regulation of the intestinal flora. Inulin was recently identified as an ingredient to replace fat or sugar, but commercial production in Brazil does not yet exist (Narinder et al., 2002; Gibson et al., 1993).

In this work was carried out the modeling and experimental data simulation obtained by the extraction process in fixed bed column. This work has great importance, because it has the ability to predict the system behavior, besides facilitating the improvements in process implementation, allowing more efficient design of extraction systems.

2. Methodology

2.1. Experimental Procedure

The extraction system in continuous flow was composed of a cylindrical glass column with internal capacity of 60 cm^3, filled with sliced garlic and glass pearls in the proportion of 1:2 (inert:garlic) in mass (Figure 1).

The inulin extraction study in continuous process was carried out with a single step and solvent recirculation, at flow rate of 0.59, 2.4 and 4.7 cm^3/min for both cases. In all conditions study were accomplished the inulin extraction kinetics and sugars exhaustion from garlic to the equilibrium.

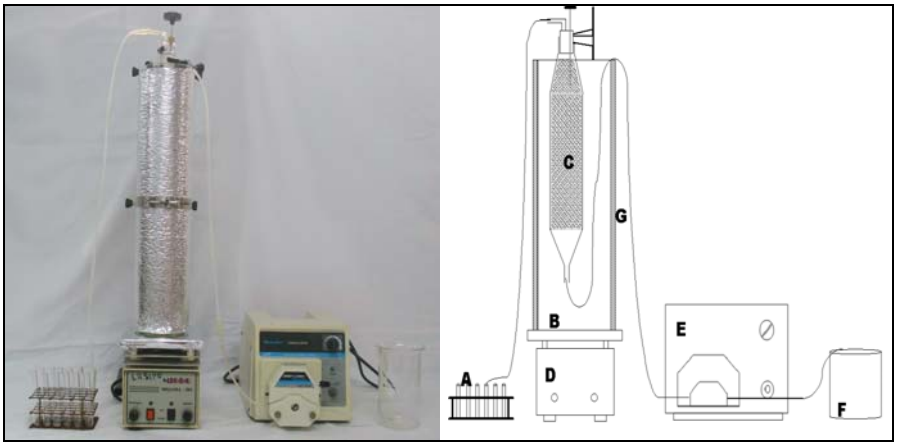

Figure 1 - Extraction system scheme: (A) collector test tubes, (B) glass cylinder, (C) column, (D) heating plate, (E) peristaltic pump, (F) solvent tank and (G) insolating.

2.2. Modeling for extraction in column with only passage of solvent

The used model divides the liquid phase in two fractions: a mobile, which flows along the bed and other immobile, consisting of liquid stagnated that doesn't participate in the flow. It took into account the following considerations: was included in model the partition phenomenon of solute initially present in the solid phase, through the Freundlich isotherms; was considered despicable the diffusive fraction associated with immobile fraction in the balance differential of solute mass; was included the relative portions to extraction transient; a first order kinetics was assumed, therefore, was obtained:

$$\left(\theta_m + \rho_{ap}\ f\ k\ n\ C_{im}^{n-1}\right)\frac{\partial C_m}{\partial t} + \frac{3\,k_{conv}\,\theta_{im}}{R}\left(C_m - C_{im}\right) = \theta_m D_m \frac{\partial^2 C_m}{\partial z^2} - \theta_m\ v\frac{\partial C_m}{\partial z} \qquad (1)$$

where: θ_m and θ_{im} = volumetric fractions of mobile and immobile water respectively; ρ_{ap} = dry bed apparent density [M L^{-3}]; f = retention sites fraction of solute on solid phase in contact with the mobile liquid fraction; k and n = Freundlich isotherm constant; C_m and C_{im} = solute concentration [M L^{-3}]; t = time [t]; D_m = hydrodynamic dispersion coefficient [L^2 t^{-1}]; z = coordinated space [L]; v = average speed interstitial pore [L t^{-1}]; R = particles radius, spherical considered [L] and k_{conv} = convective coefficient of mass transfer [$L.t^{-1}$].

In the model construction that describes the physical situation of solvent injection in a finite column of length L, for permanent flow, apply to Equation 1, the following conditions:

- Initial condition:

Concentration of inulin in this column, uniform, constant and equal to the C_{ini}:

$$C_m = C_{im} = C_{ini} \quad \text{for } t = 0 \text{ and } \forall z \qquad (2)$$

- Contour condition:

Input: the solvent solution enters with concentration C_0 and speed v, for times greater than zero.

$$v\,C_m - D_m \left.\frac{\partial C_m}{\partial z}\right|_{z\to 0^-} = v\,C_0 \quad \text{for} \quad t > 0 \quad \text{and} \quad z = 0 \tag{3}$$

Output: disregarding any dispersion effect in column output and given to the continuity condition of the variable C_m have been:

$$\left.\frac{\partial C_m}{\partial z}\right|_{z\to L^+} = 0 \quad \text{for} \quad t > 0 \quad \text{and} \quad z = L \tag{4}$$

The mathematical model described is solved using the finite volume numerical method (Patankar, 1980). All differential equations are discretized, obtaining a linear algebraic equations system, which are resolved through the matrices solution traditional method. The formulation implemented is fully implied, with linear interpolation functions.

2.3. Modeling for extraction in column with solvent recirculation

To simulate the inulin extraction in column with solvent recirculation, the model suffers alteration in the outline condition in the entrance of the column (Equation 3). In the new situation, the concentration at the column entrance will be equal to the solvent tank ($C_{reserv.inst}$) (Equation 5).

Input contour condition:

$$v\,C_m - D_m \left.\frac{\partial C_m}{\partial z}\right|_{z\to 0^+} = v\,C_{reserv.inst} \quad \text{for} \quad t > 0 \quad \text{and} \quad z = 0 \tag{5}$$

It is included in the model a relative equation to the mass balance in solvent recirculation tank (Equation 6).

$$A\,v\,C_m\big|_{z=L} - A\,v\,C_{reserv.} = V_{reserv.}\frac{dC_{reserv}}{dt} \tag{6}$$

Where: A = area of column traverse section [L^2]; v = interstitial velocity [$L\,t^{-1}$]; C_{reserv} = concentration in the recirculation tank [$M\,L^{-3}$]; $C_{reserv.\ inst}$ = concentration in the recirculation tank for some time t_{inst} [$M\,L^{-3}$] and V_{reserv} = volume of liquid accumulated in the recirculation tank on a permanent regime [L^3].

For column extraction, 3 tests were analyzed in total for each configuration, one test for each flow rate studied (0.59, 2.4 and 4.7 cm^3/min). For those cases the Table 1 shows the experimental conditions used.

The garlic particle was admitted spherical, the radius is considered as the ratio between the volume and area of the garlic slice, multiplied by 3 to maintain the same relationship with the volume and area of the sphere.

The operating conditions (Table 1) were corrected according to Equations 7 to 10 in order to take into account the glass pearls presence in bed. The introduced corrections preserved the initial inulin mass contained in garlic and the volume occupied by the particles bed.

$$v = \frac{Q}{A\,\varepsilon_{bed}} \tag{7}$$

$$\rho_{aps} = \frac{\left[m_g\left(1 - X_g\right) + m_s\right]}{A\,L_{bed}} \tag{8}$$

$$X_\infty = \varepsilon_{bed} + X_{gV}\left(1 - \varepsilon_{bed} - \frac{V_s}{V_{bed}}\right) \tag{9}$$

$$\theta_m = \frac{\varepsilon_{bed}}{X_\infty} \quad (10)$$

where: ε_{bed} = bed porosity; Q = flow rate [$L^3\ t^{-1}$]; ρ_{aps} = dry apparent density [$M\ L^{-3}$]; m_g = garlic mass [M]; m_s = spheres mass [M]; X_{gV} = garlic moisture (in volume terms); X_∞ = middle moisture; V_s = volume occupied by the spheres [L^3]; V_{bed} = bed volume [L^3] e θ_m = mobile water fraction.

Table 1 – Experimental conditions for column extraction and the parameters adjusted in the simulations.

Experimental data
Extraction Temperature - 60°C
n – 1 (isotherm equilibrium parameter)
k – 0.0268 (isotherm equilibrium parameter)
Bed particle radius (R_{bed}) – 0.1336 cm
Proportion used in bed– 34% glass pearls / 66% sliced garlic
Bed porosity (ε_{bed}) – 0.5800
Solution volume within the column (V_0) – 35 cm^3
Molecular diffusivity Coefficient – $2.048.10^{-6}$ (cm^2/seg) (Bunim et al., 1937)
Middle moisture (X_∞) – 0.8220
Dry apparent density (ρ_{aps}) – 0.3628 g/cm^3
Interstitial velocity (v) - 0.0096 cm/seg (0.59 cm^3/min)
0.0390 cm/seg (2.40 cm^3/min)
0.0764 cm/seg (4.70 cm^3/min)
Hydrodynamic dispersion coefficient(D_{ap}) –
0.0082 cm^2/seg (0.59 cm^3/min)
0.0184 cm^2/seg (2.40 cm^3/min)
0.0922 cm^2/seg (4.70 cm^3/min)
Initial solute concentration in immobile phase –
0.1650 g/ml (0.59 cm^3/min)
0.2315 g/ml (2.40 cm^3/min)
0.0689 g/ml (4.70 cm^3/min)

In simulations of column process, the adjusted parameters were the convective mass transfer coefficient (k_{conv}) and mobile water fraction (θ_m). The mobile water fraction, although it was estimated by Equation 10, has been changed according to the need for adjustments to the experimental data. This is due to the fact that stagnant water fraction depends on the bed arrangement and the flow regime.

3. Results

3.1. Modeling for column extraction with only passage of solvent

The Table 2 presents the adjusted parameters in the simulation in only passage of solvent in the flow rate of 0.59, 2.4, 4.7 cm^3/min.

Table 2 – Adjusted parameters in the simulation without solvent recirculation.

	Flow rate (cm^3/min)		
	0.59	2.40	4.70
Mobile water fraction (θ_m)	0.55	0.55	0.55
Convective mass transfer coefficient (k_{conv}) (cm/seg)	$1.0.10^{-5}$	$1.4.10^{-5}$	$2.2.10^{-5}$

*Modeling and simulation the fixed bed column extraction of inulin from garlic (*Allium sativum L. *var. Chonan)*

During the simulations, the model capacity was verified of adjusting to the experimental data. The Figure 2 shows the simulations results accomplished together with the experimental data for the flow rate of 0.59, 2.4 e 4.7 cm^3/min. The abscissa axis shows the ratio of the solvent volume injected in the column and the pore volume (empty spaces); already the ordinates axis represents the ratio between the solute concentration in the column output and the solute concentration in the immobile phase, in other words, the inulin concentration in the liquid phase interns to the garlic.

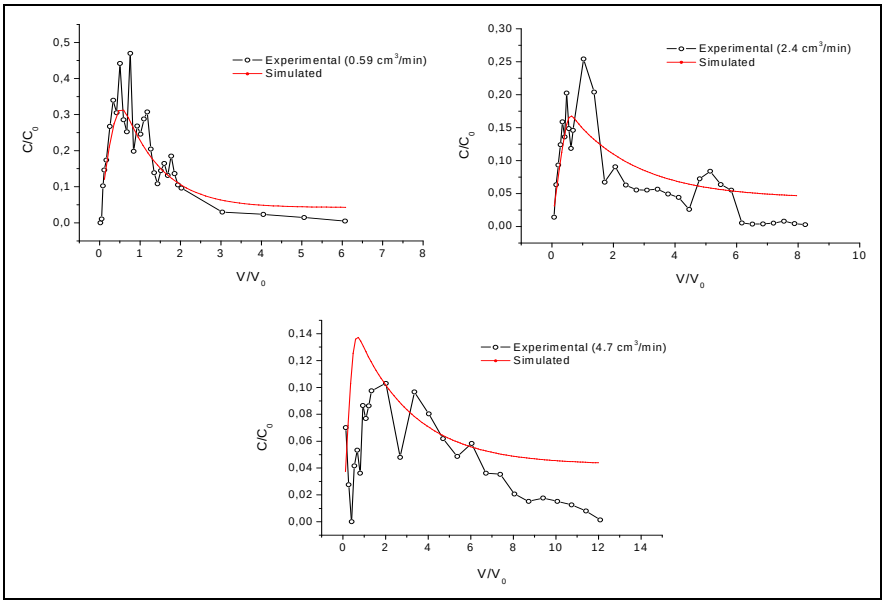

Figure 2 – Column experiments simulations with single passage of solvent.

Observed in Figure 2 deviations among the adjusted curve for the model and of the experimental data, being more evident in the flow rate of 4.7 cm^3/min. It is noted that, in adjustment the parameters, for a coherence subject, the same values were used for both column extraction configurations (single pass and recirculation).
Therefore, those deviations could be improved if each case had been analyzed individually. But, in general, adequately describes the behavior of inulin extraction from garlic.

3.2. Modeling for extraction in column with recirculation of solvent

The input data were the same used in the configuration of single passage, presented in the Table 1.
The Figure 3 shows the simulations results accomplished together with the experimental data relating to the column extraction with solvent recirculation in the flow rate of 0.59; 2.4 and 4.7 cm^3/min.
In the adjustment of parameters, tried to preserve the values for both configurations, with and without recirculation (Table 2). Therefore, the experimental data simulation represents an effort in the sense of assisting the results group through a single model and with the broad parameters of all tests. In general, the model presented good agreement with the experimental data, reproducing the inulin extraction tendency appropriately along the process.

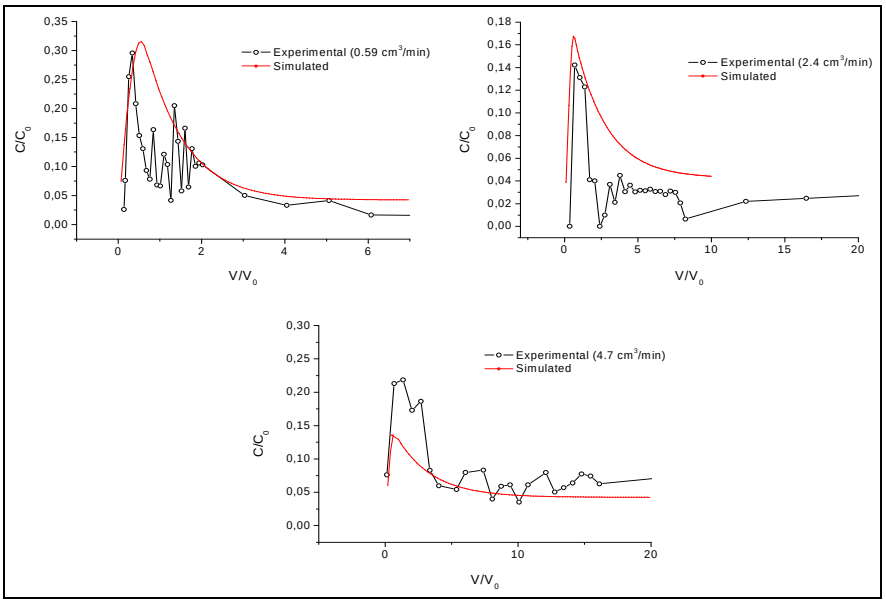

Figure 3 – Column experiments simulations with solvent recirculation.

The values found for column Peclet number were close to 40, 72 and 28 for the flow rate of 0.59 cm^3/min, 2.4 cm^3/min and 4.7 cm^3/min respectively. The column Peclet number lists the hydrodynamic dispersion mechanisms and convection in the solute displacement, even taking into account the bed length. These values are considered low and indicate the importance of the bed dispersive nature (porous medium) for carrying out such experiments.

4. Conclusion

In the column process simulation, were obtained low values for Peclet number, indicating the bed dispersive nature.

Overall, the studied models acted in a satisfactory way the inulin extraction tendency, for the experimental data adjustment.

Abstract

In this work, a methodology for the retrofit of heat exchanger network (HEN) considering simultaneously the possibilities of reuse of exchangers for different junctions and the inclusion of new units is proposed. The developed methodology is based in a superstructure simultaneous optimisation model for the HEN synthesis considering stream splitting, with an additional constraint of including all the existent equipments among the possibilities of heat exchange. This superstructure takes into account the operational and capital costs, by maximizing the recovery of energy and minimizing the installation costs. The case is treated as a constrained optimisation problem whose objective is to minimize the global cost of the HEN. The object function considers the total cost composed by the cost of the utilities used in the HEN and the cost of the new equipments. The constraints are the thermodynamics limits and the obligation of reusing all the existing heat exchangers. The problem was solved using Particle Swarm Optimization (PSO), giving consistent and promising results. The main contribution of this paper is, besides the retrofit of heat exchanger networks in industrial processes, the optimization technique used. PSO is able to avoid local optima and suits very well to non-linear problems.

Keywords: Retrofit of Heat Exchanger Network, Optimization Problem, Particle Swarm Optimization.

1. Introduction

The synthesis of heat exchanger networks (HEN) is an important field in process systems engineering, and has been the subject of considerable research efforts over the last 40 years. Many studies and methodologies were proposed to make possible the energy recovery between process streams, minimizing the utilities consumption and the number of heat transfer equipment. Most of these formulations have been developed to the synthesis of new plants. Industrial processes in operation, however, can often be made more energy-efficient by a retrofit.

As pointed in Briones and Kokosis (1999), retrofit problems represent a large amount of industrial process design. However, retrofit technology when compared to grassroots designs has a less intense progress, considering both, mathematical programming and methods based on thermodynamic analysis.

According to Westerberg (1989) and Yee and Grossmann (1991), the systematic work on retrofit is considerably harder than grassroots designs. It is due to the necessity of considering reuse of existing heat exchangers in despite of new unities design.
There are two groups of papers related to the retrofit of heat exchanger networks. The first one is based on thermodynamic concepts and Pinch Analysis (Asante and Zhu, 1996 and Silva and Zemp, 1998 and Panjeh Shahi *et al*. 2008). The second one is based on mathematical programming (Singh and Castillo 2002, Mizutani, 2003 and Bjork and Nordman, 2005).
The first papers in the retrofit of heat exchanger networks were published during the eighties, involving thermodynamic concepts. Tjoe and Linnhoff (1986) proposed for the retrofit the calculus of the optimum heat transfer area based in Pinch Technology. The authors related this optimum area with the current network area, but they didn't take into account the equipment location.
The first paper based on mathematical programming was the work of Ciric and Floudas (1989). The authors presented a two stage methodology to the retrofit of heat exchanger networks. In the first stage a MILP formulation selects the matches between the streams, minimizing the investment costs. In a second stage, a NLP formulation is used to optimize the network with the matches defined in the first step.
Yee and Grosmman (1990) proposed a MILP formulation model to establish the structural modifications on the heat exchanger network.
In the works of Ciric and Floudas (1990) and Yee and Grosmman (1991) the authors used superstructures whose models has the formulation of MINLP problems.
Using both, Pinch Analysis and mathematical programming, Zhu and Asante (1999) developed a methodology considering the costs of modifications in the process utilities as well as in the network topology. Firstly the network pinches are identified as well as the heat exchangers that cause a bottleneck in the process due to the violation of the minimum temperature difference. This is done by a LP formulation in which the maximum energy recovery is searched with modifications on the network topology. After this, by using a MILP the modifications on the network topology are calculated (new heat exchanger incorporation, stream splitting and position changes in the equipment) aiming to maximize the energy recovery without considering the costs of installation of these modifications. The propositions of modifying the original network can be adopted or discharged by the user, in an ulterior evaluation stage. Finally, the proposed chosen changes can be optimized considering the global, operational and fixed costs, with the topologies maintained unaltered, i. e., the variables of optimization in this stage are the flowrates of the stream split and stream temperatures maintaining fixed the network structure. The authors did not take into account pumping costs in their proposition.

2. Problem Definition

The developed methodology is based on the superstructure model presented by Yee and Grossmann (1990). The difference is that the authors considered the number of stages equal to the maximum number of hot or cold streams. In the present paper, the number of stages of the superstructure is a variable to be optimized and not a parameter as fixed by Yee and Grossmann (1990).
The difference between the grassroots design and the retrofit is in the inclusion of the condition of including obligatorily all the existent heat exchangers in the heat exchange possibilities. The equipments are used in the same matches or in other positions in the future heat exchanger network structure.

The problem consists in determining a heat exchanger network considering a set of hot and cold streams with known inlet and outlet temperatures and flowrates. Besides, it must be known hot and cold utilities and the corresponding temperatures.
To the current heat exchanger network must be considered the known matches in each existent heat exchanger in the network as well as its heat transfer areas. The costs of the minimum utility consumption and for the addition of new heat transfer equipment must be also considered.
In the present paper for the solution of the constrained optimization problem of the retrofit of heat exchanger networks an objective function considering the utility costs used in the generated heat exchanger network associated with the cost involving the increase of new heat exchangers. The constraints are the thermodynamic restrictions in the heat matches. Equations (1) to (4) present the constrained optimization problem.
The proposed problem was solved with Particle Swarm Optimisation (PSO). PSO is a stochastic optimisation technique developed by Kennedy and Elberhart (2001), inspired in the social behaviour of bird flocking or fish schooling. PSO as an optimisation tool provides a population-based search procedure in which individuals called particles change their position (state) with time. In a PSO system, particles fly around a multidimensional search space. During flight, each particle adjusts its position according to its own experience, and according to the experience of a neighbouring particle, making use of the best position encountered by itself and its neighbour.
According to the proposed methodology to solve the problem, 5 variables are initially randomly generated. These variables are modified at each iteration according to Equations (5) and (6). Each particle is formed by the following variables: Stream splitting fraction for the hot and cold streams, number of stages, position at each heat exchanger is allocated and the heat duty for each heat exchanger.
After the particle generation the area of each new heat exchanger is calculated, as well as the hot and cold utilities demand. This is done for all the particles, being the particle the solution of the problem or not. The objective function value (global network cost) is achieved and case the particle is not the problem solution (some constraint is violated), the objective function is penalized.

Minimize: $\mathrm{C}_{\text{total}} = \mathrm{C}_{\text{area}} + \mathrm{C}_{\text{utility}}$

Subject to:
$$\begin{cases} \left(T_h^{in}\right)_k > \left(T_c^{out}\right)_k \\ \left(T_h^{out}\right)_k > \left(T_c^{in}\right)_k \end{cases} \quad (1)$$
$\mathrm{k} = 1,\ldots,$ number of equipments

$$\mathrm{C}_{\text{area}} = \sum_{1}^{k} \mathrm{aa}_1 \cdot (A)^{\mathrm{aa}_2} \quad (2)$$
$\mathrm{k} = 1,\ldots,$ number of equipments

$$\mathrm{C}_{\text{utility}} = \mathrm{C}_{\text{HU}} \cdot \mathrm{HU} + \mathrm{C}_{\text{CU}} \cdot \mathrm{CU} \quad (3)$$

$$k^{MAX} = N \cdot ncq \cdot ncf \quad (4)$$

$$v_i^{k+1} = w \cdot v_i^k + c1 \cdot r_1 \cdot \left(p_i^k - x_i^k\right) + c2 \cdot r_2 \cdot \left(p_{GLOBAL}^k - x_i^k\right) \quad (5)$$

$$x_i^{k+1} = x_i^k + v_i^{k+1} \quad (6)$$

In Equations (5) and (6), $\mathbf{x}_i$ and $\mathbf{v}_i$ are, respectively, position vectors and velocity of the particle *i*, *w* is the inertial weight, *c1* and *c2* are constant, $\mathbf{r}_1$ and $\mathbf{r}_2$ are vectors containing random numbers with uniform distribution in [0, 1], $\mathbf{p}_i$ is the position with the best value of the objective function that the particle *i* has found and $\mathbf{p}_{global}$ is the position of the best value found for the set of particles.

3. Case Study

An example with various set of different parameter for the PSO was used and the influence of each set in the algorithm performance was studied (Table 1).

The case studied was presented in Panjeh Shahi *et al*. (2008). The heat exchanger network has 2 heat exchangers, 3 heaters and 2 coolers. The utilities demands are 23.498 kW for the cold utility and 1.708 kW for the hot utility. One can assume that the individual heat transfer coefficients are 0.2 kW/m2 ºC for all the streams. Figure 1 presents the existent heat exchanger network and Table 2 shows the heat transferred and the area values for the existing heat exchangers.

Table 1 – Parameters for the PSO

c1	c2	w	Npt
1.0	1.0	0.65	30

By applying the developed methodology, the new heat exchanger network presents 1 heater, 3 coolers and 4 heat exchangers, being 2 new and 2 old reused equipments. Table 3 shows the heat duty, the area to be increased in the network (2 new equipments) and the costs. Hot and cold utilities are, respectively, 23.00 $/kW/year and 1.52 $/kW/year. Additional heat exchangers costs were calculated using Equation (7), with *A* in m^2.

$$C_{area}(\$) = 37643 + 7529 \cdot A^{0.7} \tag{7}$$

The global cost for the new heat exchangers network is $ 68,068. It means saving 21,478 $/year in utilities use. Table 4 shows the consumption and utilities cost for the current and for the proposed heat exchanger network. The payback period is 3.2 years. Figure 2 shows the new heat exchanger network. (The new equipments are in bold).

The computational time at Pentium IV 170 GHz was approximately 500 minutes. Success rate of PSO was 32%.

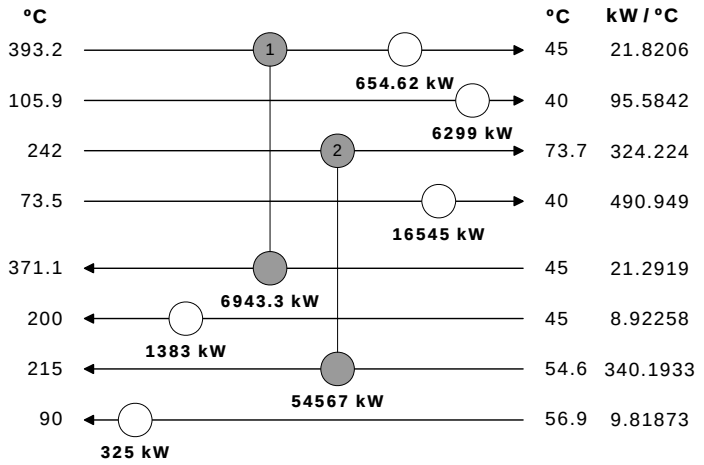

Figure 1 – Current heat exchanger network

	Consumption (kW)	Cost ($/year)	Consumption (kW)	Cost ($/year)
UQ	1708	39284	832	19136
UF	23498	35717	22623	34387
Total		75001		53523

4. Conclusions

In this paper it was presented a new methodology for the retrofit of heat exchanger networks. The goal is to find the best configurations for a heat exchanger network with minimum cost, taking into account the area and utilities costs, considering streams physical properties and cost parameters. The existing heat exchangers must be considered in the analysis. The methodology is based on the superstructure proposition of Yee and Grossmann (1990) and the optimization problem is solved using Particle Swarm Optimization.

An example from the literature was used to test the developed methodology. Results showed the best configurations for the heat exchanger network, considering the existing equipments and saving energy.

Being a highly complex problem, the computational time is acceptable. Success rate is low because of considering the existing heat exchangers as a constraint to the problem, decreasing the convergence in the viable region solution.

Nomenclature

A	heat transfer area
aa_1, aa_2	constants
C_{area}	heat transfer area cost
C_{CU}	cold utility cost
C_{HU}	hot utility cost
C_{total}	global cost
$C_{utility}$	utilities cost
CU	cold utility demand
HU	hot utility demand
k^{MAX}	maximum number of heat transfer equipments
N	number of stages in the superstructure
ncf	number of cold streams
ncq	number of hot streams
T^{in}	inlet temperature
T^{out}	outlet temperature

Improving energy performance of a hydrazine hydrate plant by applying hot feed

Xiao Feng, Junkun Yang, Taofeng Cao

Department of Chemical Engineering, Xi'an Jiaotong University, Xi'an 710049, China

Abstract

When analyzing a heat exchanger network, it can be often found, that a given stream is cooled first and then heated or in reverse. In such a situation, one of the available energy-saving methods is a hot feed strategy. In this paper, the heat exchanger network in a hydrazine hydrate plant is analyzed and retrofitted. From the analysis, it can be found that the extensive energy consumption takes place is some coolers above the pinch. Additionally, the product is cooled before leaving the unit, and heated afterwards when entering the downstream plant. By eliminating cooling and the subsequent heating, some streams will be the hot feeds for the downstream processes. In this way, 60.7% of the current heating utility can be saved after the optimization.
Keyword: hot feed, heat integration, hydrazine hydrate plant, pinch technology

1. Introduction

Energy saving is a pressing issue. In the chemical industry, where the processes are usually complex and the energy consumption is high, the optimization of heat exchanger networks has been always a concern. Since Hwa proposed the structure optimization of heat exchanger networks in 1965(Hwa, 1965), the heat exchanger network synthesis and retrofit became an important branch of process integration. It is worth to note that one of the most widely used methods (Mubarak and Kawari, 2000; Feng, 2004) for heat exchange network optimization is pinch technology.

When integrating a heat exchange network via pinch technology, the first step is to extract stream data, next is to determine the "bottleneck" of the system, and then to optimize it. (Mubarak and Kawari, 2000) The optimization of energy system is especially complex in large-scale process systems, where there are large numbers of streams linked with each other. When analyzing a heat exchanger network, it can be sometimes found that a stream may be cooled first and then heated, or heated first and then cooled. It means that a stream may be both a hot stream and a cold stream at different locations. More often, the feed of a plant is a cold stream, but it is a hot stream in the upstream plant. In this case, a more effective energy-saving method is to change the process itself. Although much research on the pinch technology and its application has been reported (Linnhoff and Townsend, 1982; Sorin and Paris, 1997; Singhvi et al, 2004; Herrera et al, 2003), there are no publications on changing process by using hot feed to achieve energy-saving effect.

Hydrazine hydrate is an important chemical raw material used in production of pesticides, pharmaceuticals, chemical intermediates, dyes, imaging agents, antioxidant materials. A hydrazine hydrate plant is consisted of three units: the reaction unit, the evaporation and fractionation unit, and the fractionation and concentrating unit. The heating utility in the process is steam.

In this paper, the heat exchanger network of the hydrazine hydrate plant in Yibin Tianyuan Group Company Limited, Sichuan, China, is analyzed. The unreasonable energy utilization is detected by pinch technology. The hot feed strategy is utilized to synthesize the heat exchange network.

2. The stream data of the hydrazine hydrate plant

There are 11 hot streams, as shown in Table 1, and 13 cold streams, as shown in Table 2, in the plant. There are some batch processes in the plant. Their heat loads are averaged, basing on 24 hour values, when calculating the pinch position. The batch processes are shown in Table 3. The current heat exchange network consumes 44195 kW heating utility and 33070 kW cooling utility.

3. System analysis

Considering the recovered energy, the heat transfer area, the retrofit cost, and the stability of operation, the minimal temperature difference is taken as 10 ºC. According to the stream data in Table 1 and Table 2, the average pinch temperature can be calculated as 50 ºC, that is, the temperature of the hot streams at the pinch is 55ºC, and that of the cold streams is 45ºC. The minimum heating utility is 21294 kW, and the minimum cooling utility is 10168 kW. Therefore, the energy-saving potential of the network is 22902 kW, which accounts for 51.8% of the current heating utility. The T-H composite curve is shown in Figure 1.

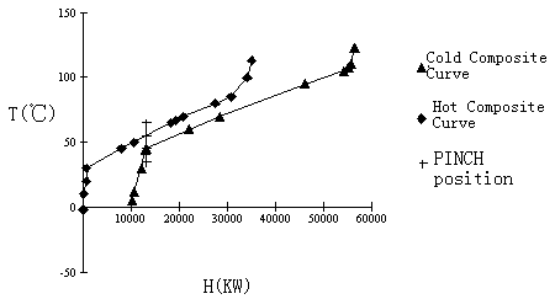

Figure 1. The composite curve of the hydrazine hydrate plant

The current heat exchange network of the hydrazine hydrate plant is shown in Figure 2. According to the three basic principles of pinch technology: (1) no heat transfer across the pinch; (2) no heating utility below the pinch; (3) no cooling utility above the pinch, we can find the unreasonable energy utilization in the hydrazine hydrate plant, as shown in Table 4. From Table 4, it can be found that in the current heat exchange network, ten coolers, two exchangers and three heaters are set unreasonably.

Table 4. The unreasonable energy utilization in the hydrazine hydrate plant

Heat exchanger	*Stream*	*Unreasonable heat load/kW*	*Type of unreasonable heat match*
E1105a	Synthetic fluid	471.06	Cooling utility above the pinch

E1112	Mother Liquid	86.28	Heating utility below the pinch
Total		22902	

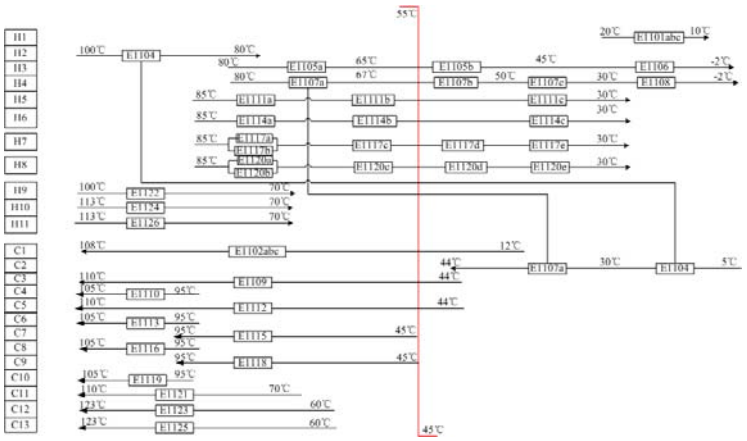

Figure 2. The current heat exchange network of the hydrazine hydrate plant

4. The retrofit scheme

The current heat exchange network of the hydrazine hydrate plant consumes steam and is composed of many batch processes. To recover the 22902 kW unreasonably used utility, large investment in equipment is needed. So, in such a situation, the economic benefit of the retrofit would be less. It can be found when inspecting the current process,

that the following heat matches are unreasonably set, and so can be retrofitted without affecting the production process.

(1). In the evaporation and fractionation unit, the mother liquid is fed into fractionation columns (T1101a, T1101b, T1101c, and T1101d). The overhead products (H5, H6, H7 and H8) are cooled from 85ºC to 30ºC by coolers, and then flow out of the plant and are fed into the ammonia stripping process in the downstream plant. These coolers use cooling utility above the pinch, which accounts for 58% of the unreasonably used energy. However, these streams are heated when entering ammonia stripping column. Figure 3 gives the flow sheet of the current process.

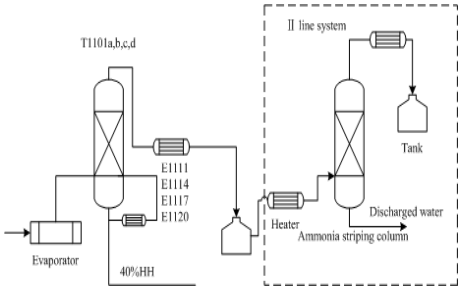

Figure 3.The current process between the plant and its downstream plant

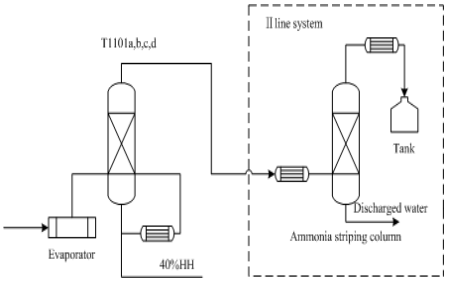

Figure 4. The retrofit scheme between the plant and its downstream plant

Therefore, the overhead products of the fractionation columns go through the processes first cooled then heated before they are fed into the ammonia stripping column. The overhead products of the fractionation columns can be fed into the ammonia stripping column directly without cooling. After such retrofit, 24445 kW steam and the equivalent of cooling water can be saved. The process after the retrofit is shown in Figure 4. It is seen from the pinch analysis, presented in Section 2, that H5, H6, H7 and H8 consume 13333 kW cooling utility above the pinch. That means that at most 13333 kW can be saved by retrofit of the heat exchanger network according to the traditional pinch technology. However, by using hot feed, 24445 kW heating utility can be saved without adding a new heat exchanger. (2). In the fractionation and concentrating unit, the raw product flows into the product column (T1102). The overhead product (H9) is cooled from 100ºC to 70ºC in E1122 and flows into the raw product tank. Then it is split into two streams (C12, C13), heated from 60ºC to 123ºC, and fed into product columns (T1103a, T1103b) separately. The current process is shown in Figure 5.

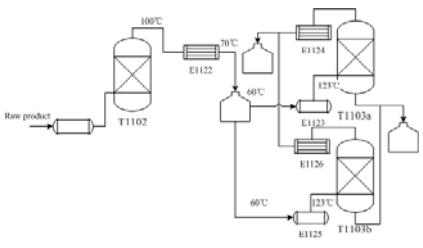

Figure 5. The current process around the product columns

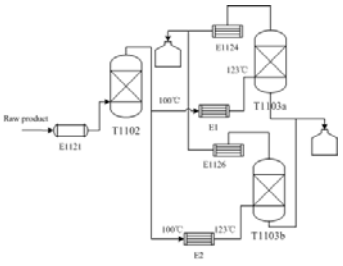

Figure 6. The retrofit scheme around the product columns

Therefore, the overhead product of column T1102 go through the processes first cooled and then heated before it is fed into the product columns (T1103a, T1103b). In consequence, the cooling process can be skipped. Then the overhead product of column T1102 can be heated from 100ºC to 123 ºC and fed into the product columns (T1103a,

T1103b). In this way, 2361 kW steam and the equivalent cooling water can be saved. The process after retrofit is shown in Figure 6.
In the current process, the heat exchanger H9 consumes cooling utility above the pinch. The unreasonable energy utilization is 2361 kW. By using hot feed, 2361 kW heating utility can be saved without adding a new heat exchanger. The results obtained from pinch analysis show that the energy saving potential is 22902 kW. However, after the retrofit by using hot feed, 26806 kW heating and cooling utilities can be saved, which accounts for 60.7% of the current heating utility. Therefore, the retrofit gets higher energy saving effect and reduces two heat exchangers and two tanks. The economic benefits are obvious.

5. System analysis after considering hot feed option

After introducing the above hot feeds, the stream data will change, as shown in Table 5 for hot streams and in Table 6 for cold streams. The heat exchange network consumes 41834 kW heating utility and 6265 kW cooling utility.

Table 5. The hot stream data after considering hot feeds

C7	Mother liquid	45	95	9611.11
C8	Mixture of hydrazine hydrate and water	95	105	1638.89
C9	Mother liquid	45	95	9611.11
C10	Mixture of hydrazine hydrate and water	95	105	1638.89
C11	Mixture of hydrazine hydrate and water	70	110	2583.33
C12	Raw product	100	123	393.77
C13	Raw product	100	123	509.01

The minimal temperature difference is still taken as 10 ºC. According to the stream data in Tables 5 and 6, the average pinch temperature is calculated as 15ºC. The minimum heating utility is 35951 kW, and the minimum cooling utility is 391 kW. The energy-saving potential of the network is 5884 kW, which accounts for 14ºC of the current heating utility. The T-H composite curve is shown in Figure 7. This time the unreasonable energy utilization is shown in Table 7.

Because E1105a, E1105b, E1106, E1107c, E1107b, E1108, E1124 and E1126 are batch operations, and the small heat load in E1104 will result in high retrofit cost, the heat exchanger network is not retrofitted further.

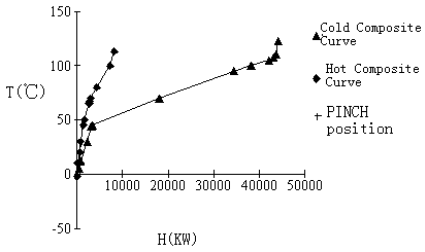

Figure 7 The composite curve after considering hot feed

Table 7. The unreasonable energy utilization after considering heat feed

Heat exchanger	*Stream*	*Unreasonable heat load/kW*	*Type of unreasonable heat match*
E1104	Mother liquid	277.8	Heat transfer across the pinch
E1105a	Synthetic fluid	471.06	Cooling utility above the pinch
E1105b	Synthetic fluid	636.57	Cooling utility above the pinch
E1106	Synthetic fluid	72.03	Cooling utility above the pinch
E1107b	Synthetic fluid	597.44	Cooling utility above the pinch
E1107c	Synthetic fluid	694.44	Cooling utility above the pinch
E1108	Synthetic fluid	18.08	Cooling utility above the pinch
E1124	Distillate from product column T1103a	1362.85	Cooling utility above the pinch
E1126	Distillate from product column T1103b	1753.47	Cooling utility above the pinch
Total		5884	

6. Conclusion

In this paper, the heat exchange network in a hydrazine hydrate is analyzed. It is found that the unreasonable energy utilization is coolers above the pinch. The main hot streams which are cooled above the pinch will be heated afterwards. Based on the analysis, a retrofit scheme with hot feeds is proposed, by eliminating all the streams which are first cooled and then heated. In this way, 26806 kW heating utility and cooling utility is saved, which account for 60.7% of the current heating utility and 81.1% of the current cooling utility.

Abstract

Based on cleaner production concepts, a methodology for water use minimization has been developed by the Clean Technology Network of Bahia at one of the largest industrial complex in Latin America, in Camaçari, Bahia, Brazil. Here we present the methodological tools and results of the water and wastewater minimization program at a petrochemical plant operated by Braskem's Raw Material Unit (UNIB) at this complex. The set of tools used includes reconciled aqueous stream balances, database of aqueous streams, definition and analysis of water and wastewater indicators, as well as regional analysis in a search for more environmentally friendly water sources. Water mass balances had to be built with assumed values as poor measurement or rather lack of water measurement is a constant inside the industrial complex. Because of this, the proposed indicators had to be analyzed with caution. The studies have identified the possibility of recovering about 1,500 m^3/h of the overall 5,700 m^3/h water consumed by the industrial complex at the moment. The effluent flow rate has been reduced by 250 m^3/h since 2002. Process variability was found to be an important cause of both effluent generation in total flow rate and its continuity.

Keywords: Water Mass Balance; Environmental Indicators; Petrochemical Industry.

1. Introduction

Water and wastewater minimization techniques have been widely studied and case studies applied to petrochemical/refinery industries (Bagajewicz, 2000; Zbontar and Glavic, 2000) and water user surveys on industrial sites have been reported in the literature (Al-Muzaini, 1998; Féres et al., 2008; Kiperstok et al., 2006). A methodology for water use minimization based on cleaner production concepts has been developed by the Clean Technology Network of Bahia. This method has evolved over a ten-year period in research cooperation programs with chemical, petrochemical and copper metallurgy industries located in Camacari's Industrial Complex in Brazil.

1.1. Clean Technology Network of Bahia (TECLIM)

The Clean Technology Network of Bahia (TECLIM) was set up in 1997 by the Departments of Environmental Engineering and Chemical Engineering at the Federal University of Bahia, Brazil, to promote cleaner practices in industry. Both water and effluent minimization are parts of these objectives. Institutions taking part in this program include universities and technical schools, public offices, industrial

associations and centers for technology training, environmental agencies as well as industrial and consulting firms, and industrial water and wastewater treatment firms (Kiperstok, 2000). As a clear result of the interaction between these institutions, cleaner production attitudes have been widely recognized at the Camaçari Industrial Complex. This, together with the financial support from the Research and Development Sectorial Funds from the Brazilian Ministry of Science and Technology, has stimulated the setting up of cooperative research projects to optimize water and energy use on industrial sites. The cooperative project between TECLIM and Braskem's Raw Material Unit (UNIB) is the most long-lasting of these projects, having started in 2002.

1.2. The Industrial Complex of Camaçari and Braskem's Raw Material Unit (UNIB)

The Industrial Complex of Camaçari is one of the most industrialized area in Latin American and consumes approximately 5,700m^3/h of water to produce more than 11.5 million tons per year of primary, intermediate and final chemical and petrochemical products. The majority of the companies at the Complex are connected through a pipe network to UNIB. This company processes petroleum-by-products, mainly naphtha, into primary olefins (mainly ethylene) and aromatics. Its utility facilities also include water treatment units which produce clarified, drinking and demineralized water for internal use and for almost all the other companies at the Industrial Complex.

About 2,500 m^3/h of inorganic and organic effluent are produced by the Complex, and through two separate wastewater systems the organic effluent is directed to an activated sludge treatment system and then to a submarine outfall. This outfall also receives inorganic effluents. Major contributions come from UNIB and from a metallurgic industry with *c.a.* 350 m^3/h and 140 m^3/h, respectively. Both systems are operated by Cetrel, an environmental protection company.

2. Methodology

TECLIM's methodology includes, among others, three basic tools: water mass balances, building environmental indicators and a regional analysis in the search for more environmentally friendly water sources.

2.1. Water Mass Balances

Water mass balances were built from the larger to the more specific areas and processes. Water intake from surface and underground water reservoirs, final effluent destination and rainfall were considered in the larger control volume. Smaller internal control volumes were built for each operational unit. With the difficulties of getting quality data where identified, reconciliation techniques came as the natural step. Lack of information related to flow and quality of aqueous streams hampered the task of building the desired water balance. This difficulty was initially overcome by getting available data from process flow sheets, experience and feeling of operators and expedite measurements. Then, a quality of information record (QI) was attached to each of the values considered in the data bases (Kiperstok et al., 2006). QI values were defined from a range from 0.4 to 10.0 and enabled operators to understand how good their information about water flow rate was. Afterwards, QI values were adapted to behave as the inverse of uncertainty value which were then used to define the minimization problem for data reconciliation. Eq. (1) describes the objective function of this problem.

$$\min \sum_{i=1}^{N} \left[\left(V_{Ri} - V_{Mi}\right)^2 \cdot \frac{QI_i^{\,2}}{V_{Mi}^{\,2}} \right] \tag{1}$$

V_R and V_M are the reconciled and estimated flow rates for each stream i; N is the total number of input and output streams for each control volume.

2.2. Building Environmental Indicators

Environmental practices lead to a more comprehensive and quantitative characterization of environmental performance (Perotto et al., 2008). Thirty eight environmental indicators were proposed in the first survey exercise where eighteen aimed to cover water consumption and the other twenty to evaluate effluent generation by all UNIB plants. Here, effluent generation refers to aqueous streams contaminated by organic compounds from the processes and inorganic compounds from utilities. Water losses evaporation in cooling towers is not considered as effluent. However, it was considered in another project dealing with heat exchange optimization. A systematic and transparent approach was needed to derive these indicators which should both reflect eco-efficiency development and could be implemented with available data. Some of the proposed indicators are shown in Table 1.

Table 1: Proposed environmental indicators.

Environmental Indicator	Status
• OE * / petrochemical production • IE * / petrochemical production	Statistical analyses performed
• OE from each plant / petrochemical production • IE from each plant / petrochemical production	Effluent data not available at the moment
• Clarified water / petrochemical production • Demineralized water / petrochemical production	Statistical analyses are not reliable because water flow rate are poorly measured

* OE and IE: organic and inorganic effluent flow rates, respectively.

The data records were analyzed on a monthly basis going back over a seven-year period, 2001 to 2007. Time series plots included the indicator and its respective raw data. Plant maintenance periods were highlighted in these graphs and were correlated with water and wastewater flow rate variations. Figure 1 shows a close view of UNIB's total organic effluent per petrochemical production indicator. The thicker the horizontal line, the greater the expected impact of the maintenance procedures on effluent generation.

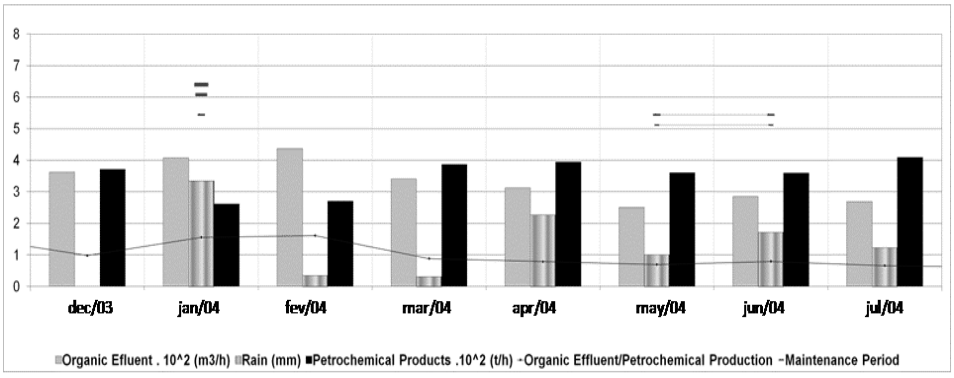

Figure 1: UNIB's total organic effluent per petrochemical production indicator.

Since UNIB's drainage effluent system is mainly composed of open channels and the site is located in a tropical region runoff contribution was estimated and discounted from both organic and inorganic effluents flow rates.

2.3. Considering Regional Analysis Seeking in the search for more Environmentally Friendly Water Sources

Two alternative centralized water reuse options were investigated while water conservation practices were partially proposed. Harvesting stormwater from three wastewater reservoirs built to operate as accumulation basins for pumping inorganic effluents and rain water into a submarine outfall is one of the options (Oliveira-Esquerre et al., 2008). The Complexo Básico, Bandeira and Cobre basins show a reserve capacity of *c.a.* 1,600, 800 and 400 thousand m^3, respectively. A mass balance was performed with historical data to assess water availability from all three basins based on the daily volume variation and inorganic effluent inflow from 2001 to 2007. Even though stormwater is usually of better quality than industrial discharges (Mitchell et al., 2002), few cases of industrial stormwater use have been reported in the literature (Thomas et al., 2002).

Another option considers reusing groundwater removed by a pump-and-treat system operated in the Industrial Complex and designed to protect both the São Sebastião Aquifer and surface water sources. This system is composed of fourteen wells strategic located and screened at different levels to groundwater extraction. Identification, assessment and remediation of large-scale groundwater characteristics require a profound knowledge of the conceptual model to predict the water quality in the subsurface (Wysic et al., 2003). To identify reuse alternatives, time series and dot plots were used to evaluate pumping flow rates, water quality levels and their variability.

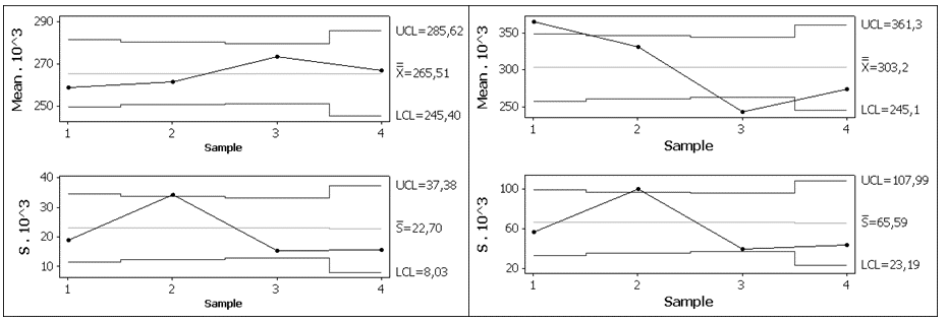
3. Discussion and Results

3.1. Water Mass Balances

In total 1,400 flow rates are considered in the water mass balance, where about 20% were not registered by UNIB information system. Although water use and wastewater generation minimization tools are well known, lack of quality data in plants, limited the contribution that this tool could offer. Braskem's effluent flow rate has been falling in a reasonably constant pattern over recent years, both in absolute and relative numbers. The activities related to the quantification of the aqueous streams in reconciled mass balances and the search for reduction opportunities among the plants' collaborators may account for the reduction in specific waste water generation by more than 40% in less than two years. According to Smith and Petela (1992), traditional approaches to water minimization such as changing washing operations, when complemented with water pinch analysis methodology have been shown to achieve 30% to 60% fresh water savings in industrial applications. Further work is needed to identify means to reduce the contributions to the inorganic system both at the source and outside production limits. After reconciliation, the balances will be transferred to the operational areas and updated with online data from existing flow rate metering and manual reports. Reconciled water balances and the efforts to maintain them up to date partially fulfill the need to enable operators to know how water is used inside the industrial plants. This knowledge is considered to be a basic requirement to enhance water conservation practices at source. It also provides basic support for the identification of reuse and recycling opportunities closer to the processes.

3.2. Environmental Indicators

No reliable analysis of water indicators could be carried out because of either the lack of water metering or the low QI of the measurements. The absence of adequate water metering may be due to a persistent regional view of water as an infinite and low cost resource. In the case of the UNIB's inorganic and organic effluents, the flow rates are measured by Parshall flumes. The estimated runoff contribution areas for the organic and inorganic effluents were 0.7 and 4.0 km2, respectively. Time series plots showed a reduction in the petrochemical production variability and organic effluent flow rate. The cause effect relationship was confirmed by comparing the biannual mean (X-bar) and standard deviation (S) for both measurements (Figure 2).



(a) (b)

Figure 2: Control charts (X-bar, S) of the (a) petrochemical production (t/month) and (b) organic effluent (m^3/h).

3.3. Considering Regional Analysis Seeking for more Environmental Friendly Water Sources

The use of both water accumulated in the attenuation basins and the extracted water from the pump-and-treat system means the decentralization of industrial water withdrawal at the Industrial Complex. Time series and frequency data indicate an averaged annually water recovery from Complexo Básico, Cobre and Bandeira basins of 1,140, 870 and 440 m^3/h, respectively. For the pump-and-treat system, 50 to 120 m^3/h of extracted water may be used. These waters have been considered for use as cooling water after simple dilution. Another option is to incorporate these new sources into the UNIB's water treatment input. This option requires the segregation of potable water production which is easily feasible considering the system's characteristics. Any 1000 m^3/h of water from new sources represent a reduction of 17% in the actual industrial water withdrawn from regional resources.

4. Conclusion

This paper describes some results and methodological tools used in a cooperative project proposed by the Clean Technology Network for water and wastewater minimization at a petrochemical plant. An understanding of the water flows throughout water mass balance development, together with other initiatives on the part of the company, have contributed to a reduction of about 40% of total effluent generation in the first three years of the studies. A systematic and transparent approach was needed to derive indicators which on the one hand reflect the concerns of eco-efficient development and on the other are defined in terms of data requirements. This approach

has enabled, among others, the identification of the process variability as a relevant cause of both organic effluent flow rate and variability. Lack of quality data in current plants limited both the development and the interface of mass balance and indicator studies. New water sources were proposed here taking advantage of wastewater streams which indicate a reduction of at least 17% in extraction from regional water sources. This has stimulated the development of engineering projects and the proposal of new operational procedures that guarantee the minimizing of water use and wastewater generation as well as discharge.

Synthesis of Energy efficient Complex Separation Networks

Seon B. Kim, Gerardo J. Ruiz, Jeonghwa Moon, Libin Zhang, and Andreas A. Linninger

Departments of Chemical Engineering and Bioengineering, University of Illinois at Chicago Laboratory for Product and Process Design. Chicago, IL 60607, USA

Abstract

Separation processes account for about fifty percent of capital and operating costs including the highest energy demand in the chemical industry. The rise in energy consumption, the high cost of the fuels, and combined with the environmental impact increases the demand for energy saving separation processes such as optimal complex column networks which are estimated to achieve energy savings of up to 70%. This paper introduces a novel algorithm to create optimal complex column arrangements which encode the cost and states of global solutions with minimum user input. In the complex column networks, several combinations and internal connections increase the difficulty to optimize these processes. The proposed configuration algorithm generates all possible network configurations expressed as a continuous sequence of column section profiles and discriminates suboptimal solutions taking the column network structure as input. Simultaneously, a robust feasibility test is applied to the generated systematic network based in thermodynamic transformations called temperature collocation where the operating conditions, structure, and length of the separation network for realizing the desired product purities are not predefined. This robust hybrid algorithm combines the advantages of deterministic and stochastic search techniques.
This computational approach guarantees rigorous column profiles validated with industrially accepted simulation software such as ASPEN. The capabilities will be illustrated using multicomponent realistic case studies especially quaternary systems.

Keywords: Complex Column, Temperature Collocation, flowsheet simulator

1. Introduction

Chemical distillation is one of the most predominantly used and versatile method of separation, in the petrochemical and commodity industry. It continues to occupy 40-70% of capital and operating costs of chemical manufacturing. Distillation processes account for more than 60% of the total process energy for the manufacture of commodity chemicals (DOE 2005).
Previously energy consumption in separations was a minor important factor, because of low energy prices and less stringent environmental standards. Thus, mainly simple distillation column configurations were built. However the rising energy cost and concerns over atmospheric carbon emissions redefine the design objectives for industrial separations with a new focus on energy conservation and the emission reduction associated with it. In the past ten years, several research groups have advanced systematic methods for identifying optimal distillation network.
Recently, computer-aided separation synthesis methods for energy savings in distillation have been revisited critically. Specifically it was demonstrated that

substantial energy savings can be achieved by designing the network simultaneously. These complex column configurations have the potential of achieving up to 70% energy savings over simple column networks (Hilde K. Engelien 2005). The well considered Petlyuk complex column configuration is an excellent example to realize energy efficient separations.

Complex column configuration is a kind of mathematical model which has problems for two reasons. First, problem size increases as the number of stages approximates infinity close to singular points of the composition space (e.g. saddle, pinch points). Secondly, in column design problems it is not known aprior whether a set of desired specifications has a feasible solution. In case of an infeasible specification, all direct solution methods don't converge. Hence, we have developed a set of collocation based methods specially for its use in column design including simple and complex column configuration. The method proposes variable transformations which enable it to successfully solve columns design problems even near pinch and saddle points with acceptable accuracy. We also present a new algorithm to test the feasibility of a distillation network. The key novelty of our procedure exploits a view of physically meaningful design variable to distinguish between feasible region and unattainable composition range. The method is shown to be effective in constant relative volatility, idea and even non-ideal equilibrium models.

2. Methodology

Our approach towards a general solution of the separation synthesis problem has three major components: (i) systematic network generation, (ii) thermodynamic problem transformation to tame numerical challenges and reduce size, and (iii) advanced algorithm engineering to seek simultaneously in the structural and parametric design space.

2.1. Generating Complex Column Configurations

Complex distillation configurations have been studied previously by Agrawal and Fidkowski (Agrawal and Fidkowski 1998; Agrawal 2003). They systematically evaluated the energy consumption of basic feasible configurations of complex networks and advocate the energy savings that can potentially be achieved through feasible thermal coupling. Another important advancement is Agrawal's procedure for the exhaustive enumeration of complex flowsheets, which always contains the network structure of the most energy efficient solution. This complete synthesis of candidate flowsheet structures is an important element in a fully automatic separation synthesis methodology. To complete the synthesis, the optimal operating parameters like reflux, intermediate product purities, column height and diameter for all the candidate networks in the superstructure would have to be determined.

We propose to combine network generation methods like Agrawal's with robust global search to systematically identify optimum distillation schemes for given product purity targets. The solution seeks to determine both structural as well as parametric design decisions. Unfortunately, the resulting synthesis problem is NP-hard and suffers from challenges associated with the thermodynamic topology of the feed mixture which cannot be anticipated a priori for multi-component streams with different vapor-liquid interactions. At present, our evolving design method comprises two stages:

Step 1. Generic structure synthesis: Generate all possible basic network configurations using only structural information thus yielding a superstructure containing all potentially optimal networks for the separation of a given feed. The superstructure could be enumerated exhaustively or incorporate equipment constraints when addressing retrofit problems with existing column inventory.

Step 2. Network Task Optimization: Rigorous optimization of all candidate solutions in their respective parametric design spaces to find the globally optimal structure. Network optimization task should take into account the specific feed composition and product targets as well as the specific thermodynamic properties of the chemical species to be separated. In a brute force approach to the synthesis problem, one could advantageously solve independent optimization sub-problems for each network in parallel on separate processors. More elegant would be deployment of thermodynamically motivated implicit pruning criteria, which would allow us to discard inferior designs without explicitly performing network optimization. Such an *admissible heuristics*, however, have not been developed for complex column networks.

2.2. Continuous Complex Column Model

Complex columns have multiple feed and product steams requiring some modifications to profile computations. Fortunately, Hildebrandt and Glasser worked out a continuous model called difference point equations model, valid for complex column sections in any possible network configuration (Tapp, Holland et al. 2004). A complex column section is defined as a column segment between feed or product trays. Eq. (1) expresses the liquid composition profiles of a complex section in terms of the generalized reflux R_Δ and the difference point composition $X_{\Delta i}$. It also applies to simple sections as a special case, thus rendering a single mathematical expression for all sections in any separation network composed of complex or simple columns. Columns – simple or complex – are said to be feasible if and only if every pair of composition profiles belonging to adjacent column sections intersect. A network is feasible, if all its columns are feasible.

$$\frac{dx_i}{dn} = \left(1+\frac{1}{R_\Delta}\right)(x_i - y_i) + \frac{1}{R_\Delta}(X_{\Delta i} - x_i) \qquad (1)$$
$$R_\Delta = L/\Delta \quad X_{\Delta i} = (Vy_i - Lx_i)/\Delta$$

Where x_i is the liquid composition, y_i is the vapor composition, n is the number of stages, and $\Delta = V - L$ is the flow rate difference point. Unfortunately, in higher dimensional space of multicomponent mixtures, it is not a simple task to ascertain the intersection of column section profiles with modest computational effort. We discovered that a thermodynamics transformation of the column stage number, n, into the equilibrium bubble point temperature, T. This thermodynamically motivated transformation offers massive size reductions in the column profile computations and is a key feature in a rigorous feasibility criterion based on minimum bubble point distance functions which eases the search.

2.3. Bubble-Point Distance(BPD)

We eliminate the tray number in favor of the bubble point temperature as independent variable. Theoretically, this transformation requires the implicit function theorem for a one-to-one relationship between column height and temperature; this assumption may not hold in highly non-ideal mixtures, but has been tacitly assumed for well-behaved separation tasks we have so far investigated. Applying the thermodynamic transformation called *temperature collocation* changes the continuous column profile equations in eq. (1) to a new composition profiles with temperature instead of height as new independent integration variable like shown in eq. (2)

$$\frac{\partial x_i}{\partial T} = -\left(\left(1+\frac{1}{R_\Delta}\right)(x_i - y_i) + \frac{1}{R_\Delta}(X_{\Delta i} - x_i)\right) \frac{\sum_{i=1}^{c}\left(\frac{\partial K_i}{\partial T} x_i\right)}{\sum_{i=1}^{c}\left[\left(\left(1+\frac{1}{R_\Delta}\right)(x_i - y_i) + \frac{1}{R_\Delta}(X_{\Delta i} - x_i)\right) K_i\right]} \qquad (2)$$

Design for distillation process relies on the specifications of distillate composition and reflux ratio which make it feasible. For the binary and ternary mixtures the reflux ratio can be found within some ranges obviously with the existing graphical methods. The *bubble-point distance* (BPD) is defined as the Euclidean distance between two equilibrium compositions belonging to the stripping and rectifying profiles with the same bubble-point temperature. In the case that there exists a pair of compositions with BPD = 0, it guarantees feasible design and other cases vice versa.

Once compositions profiles have been calculated as functions of temperature, the column height can easily be recovered with the help of eq. 3. The calculation of the column height from bubble point temperatures has been used in the case studies to estimate the capital cost.

$$\frac{dn}{dT} = \frac{\partial n}{\partial x_i}\frac{\partial x_i}{\partial T} = -\frac{\sum_{i=1}^{c}\left(\frac{\partial K_i}{\partial T}x_i\right)}{\sum_{i=1}^{c}\left[\left(\left(1+\frac{1}{R_\Delta}\right)(x_i - y_i) + \frac{1}{R_\Delta}\left(X_{\Delta i} - x_i\right)\right)K_i\right]} \tag{3}$$

To apply this method onto complex column, this analysis should be applied for the adjacent sections *i* and *j* in complex column *k* simultaneously. According to this generalization of the minimum bubble point distance approach, a complex column is feasible if the sum of all profile distances of all adjacent sections *i* and *j* at column *k* in the network is within a small tolerance (eq. 4). It is worth pointing out that the aggregated bubble point distances for a complex column is still a scalar delineating the vicinity to a realizable design. The ability to judge the closeness of a design to realizable specifications is of key importance in the genetic search deployed successfully for the synthesis of simple configurations (Zhang and Linninger 2006) . The entire network is feasible if all its columns are feasible as in eq. 5. Where *N* is the total number of column sections in each column *k*.

$$Z(k) = \sum_{i=1}^{N-1} BPD(i, i+1) < \varepsilon_1 \tag{4}$$

$$\Psi(k) = \sum_{k=1}^{K} Z(k) < \varepsilon_2 \tag{5}$$

3. Case Study

In mixtures with four or more components, the design problem involves the search for one or more compositional degree of freedom of any product stream. This multidimensional global optimization problem is solved using a hybrid method that combines stochastic genetic algorithm (i.e. product specification) with rigorous finite element collocation of column profiles (Zhang and Linninger 2006).

3.1. Separation of Quaternary Mixture

First example illustrates the potential energy saving of complex column configuration over simple column sequences for the separation of a quaternary mixture of methanol, ethanol, 1-propanol, and acetic acid. This complex network uses two simple columns and one complex column as shown in *Figure 1*(a). The composition profiles diagram for column I and column III are showed in *Figure 1*(b) and (c). The dimension (height) and minimum vapor rate (V_{min}) for all columns are collected on Table 1. We also estimated the total cost of the complex network. The complex configuration analyzed uses half total vapor rate and saves 20% of total costs compared to the simple column

configuration. This case study illustrates a feasible solution to the synthesis problem using a complex network, and potential energy savings realizable with complex columns.

Table 1. Height and V_{min} for each column in the network

	Col. I	Col. II	Col. III
Height (m)	10.9	26.6	30.5
V_{min} (kmol/h)	13.2	58.9	71.3

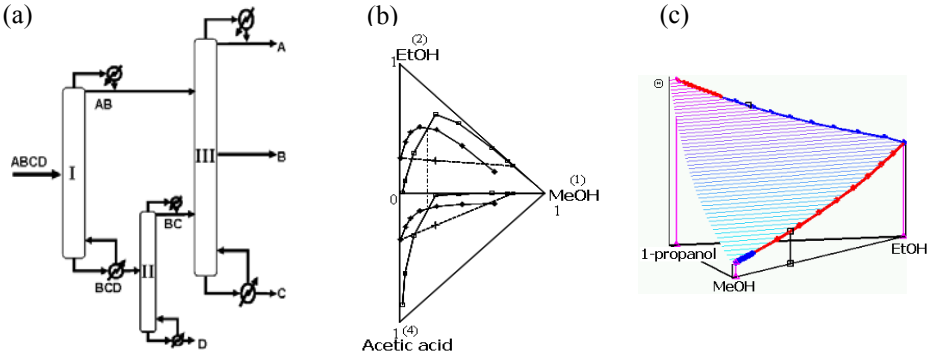

Figure 1. (a) Complex column configuration, (b) The quaternary simple column profile, and (c) Temperature Collocation profile for ternary complex column

3.2. Initialization of complex distillation networks with Aspen HYSYS

Figure 2(a) shows the complex network used to separate the same quaternary mixture of the first case study. The composition profiles found with *Aspen* HYSYS are indicated in *Figure 2*(b). *Figure 2*(c) shows the composition profiles using temperature collocation transformation. These profiles as well as the equivalent number of equilibrium stages were computed using eq. (3).

We initialize the *Aspen* HYSYS flowsheet with our column profiles as initial guesses. The *Aspen* simulation converged with only one or two iterations. This result confirms the accuracy of our methodology is acceptable for a rigorous simulator. In a similar approach we anticipate all separation networks synthesized with our methodology will be easily verified using automatic interface with *Aspen*, this will be a very useful tool for implementing this design idea in the industrial practice.

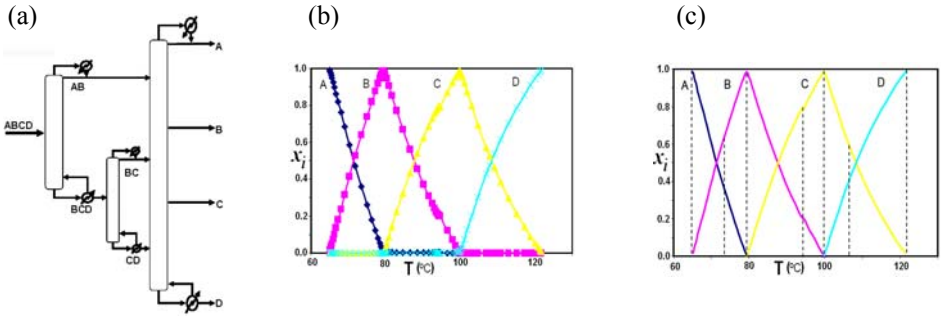

Figure 2. Complex column configuration (a), Aspen HYSYS simulation profiles for tray temperature (b), and Temperature Collocation profiles (c)

4. Conclusions

In this article, we advocated the recent progress for synthesizing energy efficient complex distillation networks. An approach towards a generalized solution of the separation synthesis problem is presented. Difference point equation with temperature as an independent variable instead of tray number was employed to find the composition profiles of complex column sections. Temperature collocation and minimum bubble point distance (MIDI) algorithm were effective to find a feasible separation by intercepting profiles. The first case study demonstrates the potential to 50% of energy savings using a complex column network compared to the simple column configuration. The second case study demonstrates current state of the art of separation synthesis in conjunction with computer simulations to fully integrate complex separation networks. Finally, the seamless integration of rigorous flowsheet simulators to validate the predictive results of our scientific method was demonstrated.

Abstract
The knowledge of phase and chemical equilibrium is clearly important in the analysis and design of a wide variety of chemical processes. These problems are described mathematically by complex systems due to the nonlinear nature of the thermodynamic models. This equilibrium state is characterized by the minimization of the Gibbs free energy. Usually, this problem is calculated by using the method of Lagrange multipliers together with the mass balance conditions as necessary subsidiary conditions. However, the convergence is highly dependent of initial estimates of the Lagrange multipliers. The development of robust and efficient methods for the computation of thermodynamic multi-phase systems has long been a challenge in both chemical engineering and materials science. In this context, both heuristic methods, Genetic Algorithms and Differential Evolution, are able to escape from local minima and saddle points. As main disadvantage the high number of objective function evaluations as compared with classic methods can be mentioned. To overcome this disadvantage, this work proposes the dynamic updating of the population size to reduce the number of objective function evaluations. The methodology is applied to determine phase compositions at the chemical equilibrium of real systems. The results demonstrated that the methodology used represents a promising alternative for the problem studied.

Keywords: Gibbs free energy minimization, real systems, heuristic methods, dynamic population.

1. Introduction

The phase and chemical equilibrium problem is extremely important for predicting fluid phase behavior for a very large number of separation process applications, such as reactors, reactive distillation columns, azeotropic and three-phase distillation. Moreover, the chemical equilibrium problem can also predict the maximum conversion as well as the selectivities of pre-fixed reactants and products molecules sets. Process simulators need to be able to reliably and efficiently predict the correct number of phases that will exist at equilibrium, and the distribution of components within those phases (McDonald and Floudas, 1995). In this sense, the thermodynamic function of foremost interest is the Gibbs free energy as it can be used to describe equilibrium at conditions of constant temperature and pressure. A global minimum of the Gibbs free energy corresponds to the true equilibrium solution (Castillo and Grossman, 1981).
The main difficulties in solving Gibbs free energy are the selection of the number of phases and the initial conditions used as starting point in the optimization solver. Traditionally, this problem has been solved by using the method of Lagrange multipliers. However, the convergence is highly dependent on initial estimates of the Lagrange multipliers (Castillo and Grossman, 1981; Xiao *et al*, 1989; McDonald and Floudas, 1995). Other methodologies can be found in the literature, such as the one by Ohanomah

and Thompson (1984), where the authors used the Newton method for the computation of multiphase equilibria. Lantagne *et al.* (1988), on the other hand, presented a mixed penalty function method for the computation of complex equilibria.
To overcome the difficulty associated with the initial estimates, non-deterministic solvers have been employed for this purpose (Lin and Miller, 2004; Srinivas and Rangaiah, 2007). However, theses methodologies use fixed population sizes during the evolutionary process that can affect the robustness and the computational cost of the algorithms associated with these methods. Small population size may result in local convergence; large population size will increase computational efforts and may lead to slow convergence. So, an appropriate population size can assure the effectiveness of the algorithm (Vellev, 2008).
This work is organized as follows. Section 2 presents the general aspects regarding the formulation of the Gibbs free energy minimization. A review about Genetic Algorithms and the Differential Evolution Approach and its extension to deal with dynamic updating of the population size are presented in Sections 3 and 4, respectively. In Section 5, the proposed methodology is applied to a real system. Finally, the conclusions are outlined in Section 6.

2. Gibbs Free Energy Minimization

For a multi-component and multi-phase system at temperature T and pressure P, the Gibbs free energy function *Gibbs* can be expressed in terms of fugacity and Gibbs free energy of formation:

$$Gibbs = \sum_{i=1}^{N}\sum_{k=1}^{\pi} n_{ik}\left(\Delta G_{ik}^{f} + RT\ln\frac{f_{ik}}{f_{ik}^{o}}\right) \tag{1}$$

where ΔG_{ik}^{f} is the Gibbs free energy of formation of component i in phase k at T, R is the gas constant, f_{ik} is the partial fugacity of component i in phase k and f_{ik}^{o} is the fugacity of pure component i at the standard state.
At equilibrium, *Gibbs* should be the global minimum with n_{ik} satisfying mass balances. For phase equilibrium, the conservation of moles of the individual component must hold:

$$\sum_{k=1}^{\pi} n_{ik} = n_{iT}, \quad i = 1,\ 2,\ ...,\ N \tag{2}$$

where n_{iT} is the total number of moles of component i in the system (feed).
For simultaneous phase and chemical equilibrium, the conservation of chemical elements must hold:

$$\sum_{i=1}^{N}\sum_{k=1}^{\pi} a_{ji} n_{ik} = b_{j}, \quad j = 1,\ 2,\ ...,\ M \tag{3}$$

where a_{ji} represents the number of gram-atoms of element e in component i, b_j is the total number of gram-atoms of element j in the system and M is the number of elements.
Non negativity conditions can be satisfied. For phase equilibrium:

$$0 \le n_{ik} \le n_{iT}, \quad i = 1,\ 2,\ ...,\ N;\ \ k = 1,\ 2,\ ...,\ \pi; \tag{4}$$

For simultaneous phase and chemical equilibrium:

$$0 \le a_{ji} n_{ik} \le b_{j}, \quad i = 1,\ 2,\ ...,\ N;\ \ k = 1,\ 2,\ ...,\ \pi;\ \ j = 1,\ 2,\ ...,\ M; \tag{5}$$

Thus, to obtain phase compositions at equilibrium it is necessary to find the minimum of the Gibbs free energy as given by Eq. (1) subject to the constraints imposed by Eq. (2) and Eq. (4) (or Eq. (3) and Eq. (5) for chemical equilibrium).

3. Heuristic Methods

3.1. Genetic Algorithm

Genetic Algorithms (GA) are probabilistic search algorithms combining the mechanics of natural selection and survival of the fittest. These algorithms are capable of efficiently finding an optimal solution for complex problems without necessitating reformulation for the evaluation of individual solution candidates. In this approach, a set of feasible designs constitutes a generation, which has a fixed number of individuals. A set of better designs is derived from the previous generation where the individuals are allowed to reproduce and cross among themselves with bias allocated to the fittest members. Combinations of the most favorable characteristics of the mating members of the population result in a new generation that is more fit than the previous one. The GA is implemented with three basic operations: reproduction, crossover and mutation. Besides, the main control parameters of the algorithm implemented are the number of individuals in the population, probability of crossover, probability of mutation and number of generations.

3.2. Differential Evolution

Differential Evolution (DE) is a recent optimization technique in the family of evolutionary computation. It is proposed as a variant of genetic algorithms to achieve the goals of robustness in optimization and faster convergence to a given problem. DE differs from other evolutionary algorithms in the mutation and recombination phase. Unlike some meta-heuristic techniques such as genetic algorithms and evolutionary strategies, where perturbation occurs in accordance with a random quantity, DE uses weighted differences between solution vectors to perturb the population (Storn and Price, 1995).

The crucial idea behind DE is a new scheme of mutation. DE executes its mutation by adding a weighted difference vector between two individuals to a third individual. Then, the mutated individuals will do discrete crossover and greedy selection with corresponding individuals of last generation to produce offspring. There are three strategy parameters in DE, i.e., population size, crossover rate and perturbation rate.

4. Update of Parameters in Heuristic Methods

All classical selection algorithms keep the population size fixed during the evolutionary process. This aspect simplifies the algorithms but it is an artificial restriction and does not follow any analogy to the biological evolution, where the number of individuals in a population varies continuously with time, increasing when there are highly-fitted individuals and abundant resources, and decreasing otherwise. Intuition hints that it may be beneficial for the population to expand in the early generations when there is high phenotype diversity and there is opportunity to "experiment" with different characteristics of the individuals, and to shrink with the increase of population convergence, when the unification of the individuals in terms of structure and fitness no longer justifies the maintenance of a large population and the higher computational costs associated with it (Vellev, 2008).

In this context, Sun *et al* (2007) studied the influence of two strategies for the dynamic updating of the individuals number of the population during the evolutionary process:

$$NP = \left(NP_{\max} - NP_{\min}\right)\left(\frac{Iter_{\max} - iter}{Iter_{\max}}\right) + NP_{\min} \tag{6}$$

$$NP = \max\left(\frac{NP_{\max}}{2}\sin\left(\frac{iter}{A}\right) + \frac{NP_{\max}}{2}, NP_{\min}\right) \tag{7}$$

where $Iter_{max}$ is the generation maximum number, *iter* is the current generation, NP_{min}, and NP_{max}, are the minimal number and maximum number of individuals in the population, respectively and A is the amplitude in *sin* function.

In this work, an adaptive population size method with partial increasing or decreasing number of individuals according to diversities in the end of each generation is adopted. Besides, initially the convergence rate is defined as:

$$r = \frac{f_{average}}{f_{worst}} \tag{8}$$

where $f_{average}$ is the average value of the objective function and f_{worst} is the worst value of the objective function.

Consequently, the defined convergence rate evaluates the homogeneity of the population in the evolutionary process: if r is close to zero, i.e., the value "worst" of the objective function is different of the average value of the objective function; if r is close to one, the population is homogeneous. Thus, a simple equation for dynamic updating of the population size is proposed:

$$NP = \text{round}(NP_{\min} r + NP_{\max}(1-r)) \tag{9}$$

where NP_{min} and NP_{max} represent the minimum and maximum values for the population size, respectively, and the operator round(.) indicates the rounding to the nearest integer.

It should be emphasized that the equation (9) updates the population size as based on the convergence rate, differently from equations (6) and (7) in which any information regarding the evolution of the process is considered.

The next section presents the application to a real system using Genetic Algorithm (GA), Adaptive Genetic Algorithm (AGA), Differential Evolution (DE) and Adaptive Differential Evolution (ADE).

5. Numerical Results

A classical example of complex chemical equilibrium calculations involving two phases is the esterification reaction in an equimolar mixture of ethanol (EtOH) and acetic acid (HAc) reacting reversibly to form ethyl acetate (EtAc) and water (H_2O) (Castillo and Grossman, 1981; Xiao *et al* 1989; McDonald and Floudas, 1995; Peng Lee *et al*, 1999):

$$\text{EtOH (1)} + \text{HAc (2)} = \text{EtAc (3)} + \text{H}_2\text{O (4)} \tag{10}$$

Gibbs free energy of formation of a component in liquid state is related to the one in vapor state (ΔG_{iV}^{f}) by (McDonald and Floudas, 1995):

$$\Delta G_{iL}^{f} = \Delta G_{iV}^{f} + RT \ln\left(P_i^s\right) \tag{11}$$

where P_i^s is the saturated vapor pressure for pure component i at T. R is the gas constant and the parameters in Antoine equation for calculating P_i^s are given in Table 1.

Table 1: Data and parameters used in case study (McDonald and Floudas, 1995).

	ΔG_{iv}^{f} (cal/mol)	τ_{ij} in the NRTL model				Antoine constants		
	355 K	EtOH	HAc	EtAc	H_2O	a_i (-)	b_i (K)	c_i (K)
EtOH	-37091.8	0.0000	1.3941	0.6731	-0.2019	9.95614	1440.52	-60.44
HAc	-87303.1	-1.0182	0.0000	0.0070	-0.4735	9.68450	1644.05	-39.63
EtAc	-79840.6	0.1652	0.5817	0.0000	1.7002	9.22298	1238.71	-56.15
H_2O	-54093.4	2.1715	1.6363	1.9257	0.0000	10.0917	1668.21	-45.14

$\alpha_{ij} = 0.3$ (with α_{ii}=0) and Antoine constants in $\log_{10}(P_i^s) = a_i - b_i/(T + c_i)$.

Equality constraints arising from the conservation of chemical elements expressed by Eq. (3) for the esterification of 0.5 mol of ethanol with 0.5 mol of acetic acid are:

$$2(n_{11} + n_{12}) + 2(n_{21} + n_{22}) + 4(n_{31} + n_{32}) + 0(n_{41} + n_{42}) = 2 \tag{12}$$

$$6(n_{11} + n_{12}) + 4(n_{21} + n_{22}) + 8(n_{31} + n_{32}) + 2(n_{41} + n_{42}) = 5 \tag{13}$$

$$1(n_{11} + n_{12}) + 2(n_{21} + n_{22}) + 2(n_{31} + n_{32}) + 1(n_{41} + n_{42}) = 1.5 \tag{14}$$

for the conservation of carbon, hydrogen and oxygen, respectively.

Non-Random Two Liquid (NRTL) equation (Prausnitz *et al*, 1986) for the activity coefficient of component i in liquid phase k (γ_{ik}) is given by:

$$\ln(\gamma_{ij}) = \frac{\sum_{j=1}^{N} \tau_{ji} G_{ji} x_{jk}}{\sum_{j=1}^{N} G_{ji} x_{jk}} + \sum_{j=1}^{N} \frac{G_{ji} x_{jk}}{\sum_{l=1}^{N} G_{lj} x_{lk}} \left(\tau_{ji} - \frac{\sum_{l=1}^{N} \tau_{lj} G_{lj} x_{lk}}{\sum_{l=1}^{N} G_{lj} x_{lk}} \right) \quad (15)$$

where x_{jk} is the mole fraction of the component j in the phase k, τ_{ij} are the non-symmetric binary interaction parameters (with τ_{ii}=0) and G_{ij} is a parameter defined as:

$$G_{ij} = \exp(-\alpha_{ij} \tau_{ij}) \quad (16)$$

Parameters used in algorithms: NP_{min}=10 (AGA, ADE), NP_{max}=50 (GA, AGA, DE, ADE), perturbation rate and crossover probability (0,8), mutation probability (0.01), $Iter_{max}$=1000 generations. Finally, the stopping criterion is associated to the difference between the results calculated by the algorithms used and the one obtained by Peng Lee *et al* (1999): this difference should be smaller than 10^{-8}.

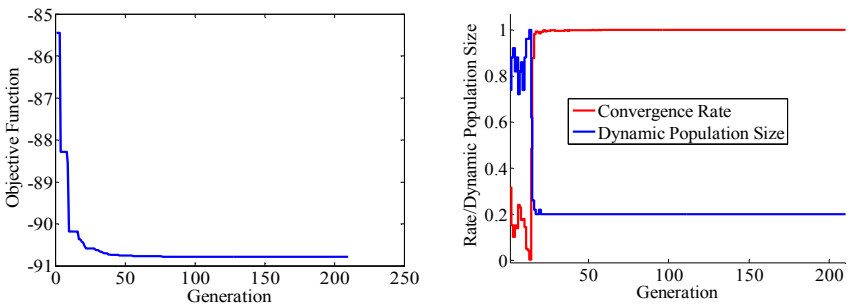
Table 2 shows the results obtained for liquid (x_i) and gas (y_i) phase using the Luus-Jaakola Algorithm (Peng Lee *et al*, 1999), GA, AGA, DE and ADE algorithms. All the algorithms were executed 100 times for obtaining of average values.

Table 2: Results obtained by LJ, GA, AGA, DE and ADE algorithms.

	LJ	GA	AGA	DE	ADE
x_1	0.039748	0.039747	0.039747	0.039748	0.039747
x_2	0.201850	0.201862	0.201847	0.201850	0.201847
x_3	0.081425	0.081425	0.081409	0.081421	0.081409
x_4	0.676977	0.676982	0.676981	0.676970	0.676981
y_1	0.078272	0.078273	0.078296	0.078277	0.078296
y_2	0.069894	0.069887	0.069882	0.069884	0.069882
y_3	0.441308	0.441311	0.441305	0.441312	0.441305
y_4	0.410526	0.410535	0.410521	0.410534	0.410521
Gibbs	-90.770474	-90.779501	-90.77952	-90.779491	-90.779499
OFE	-	**23950**	**17600**	**18100**	**10750**

In table 2 it is possible to observe a reduction of 24.43% in the number of objective function evaluations (*OFE*) when comparing the algorithms DE and GA without considering the population size updating. On the other hand, when the strategy for the population size updating is used, this reduction is 26.52% for the AGA in comparison with the GA, and 40.61 % for the ADE in comparison with the DE.

Figure 1 shows the objective function, convergence rate and population size as obtained by the ADE approach.



(a) Objective function (b) Dynamic updating of the population size

Figure 1: Results obtained using ADE approach.

In this figure it is important to observe that when the convergence rate (r) is close to one, the population size is at its minimum value, i.e., 10 individuals are found in the

population (normalized values). On the other hand, if the convergence rate is close to zero, the population size is at its maximum value, i.e., 50 individuals are found in the population. This aspect is very important, since in this case ADE or AGA preserve the characteristics of DE and GA algorithms, respectively.

6. Conclusions

In this paper a new strategy for the dynamic updating of the population size was presented for dealing with optimization problems. This methodology permits the reduction of the population size during the evolutionary process and, as a consequence, a reduction of the number of objective function evaluations. It was shown that the proposed methodology can be easily incorporated in classical evolutionary strategies, such as the DE and GA algorithms. The methodology was tested in a typical example of complex chemical equilibrium calculations involving two phases, namely the esterification reaction in an equimolar mixture of ethanol and acetic acid reacting reversibly to form ethyl acetate and water. The results showed that the proposed algorithm represents an interesting alternative for the treatment of optimization problems, once the same solution quality achieved by other techniques can be obtained by using a smaller number of generations. Further research work will be focused on the solution of phase stability problems combined with the methodology proposed in this paper.

Abstract

Modelling and simulation of a flotation circuit usually involve identifying the structure of the flowsheet, deriving model equations to represent each operation, and solving the resulting total model equations according to one of various available simulation strategies. The flotation circuit synthesis problem determines the type of operations and their sequence needed to achieve the extraction of valuable metals from the ore minerals. The flotation circuit design problem determines the optimal values for the conditions of operation and for other operation/equipment related variables for the synthesized circuit. It can be noted that the circuit modelling, synthesis and design problems are related since for generation and screening of circuit alternatives (synthesis/design), some form of flotation circuit models are needed. Also, circuit models are needed for verification of the synthesis/design problem solution. In flotation circuit synthesis, as in other process synthesis problems, three types of approaches exist: a) the methods that employ heuristics or are knowledge based; b) the methods that employ mathematical or optimization techniques, and c) the methods that employ physical insights. d'Anterroches and Gani (2005) have introduced the concept of process-group contributions for process flowsheet property estimation and process flowsheet synthesis and design. In this work a group contribution model have been development for flowsheet properties for flotation circuit.

Keywords: Flotation circuit, process synthesis, group contribution.

1. Introduction

Flotation is a practical method to separate valuable minerals based on differences in surface properties of the particles from milled mineral mixtures. Also new applications as the separation of plastics of different density in waste streams containing a mixture of plastics have appeared. In froth flotation, various types of equipment exist which promote particles-bubbles encounter which contribute to controlling the balance between high recovery of the desired metal, and a high grade value of the metal in the product outflow. Past experience has shown single step separation is inefficient, and the inclusion of several complementary and supportive steps are required. Taking into account the large volume of material to be treated and its associated costs, choices related to the configuration of the separation system are critical.
Modelling and simulation of a mineral process flowsheet usually involve identifying the structure of the flowsheet, deriving model equations to represent each operation, and

solving the resulting total model equations according to one of various available simulation strategies. The flowsheet synthesis problem determines the type of operations and their sequence needed to achieve the extraction of valuable components from the raw materials. The flowsheet design problem determines the optimal values for the conditions of operation and related variables for the synthesized flowsheet. It can be noted that the flowsheet modelling, synthesis and design problems are related since for generation and screening of flowsheet alternatives (synthesis/design), some form of flowsheet models are needed. Also, flowsheet models are needed for verification of the synthesis/design problem solution. In mineral process synthesis three types of approaches exist: a) the methods that employ heuristics or are knowledge based (Connolly and Prince, 200); b) the methods that employ mathematical or optimization techniques (Goria et al., 2005; Cisternas et al., 2006), and c) the methods that employ physical insights (Gálvez, 1998). A review of methods for conceptual flotation circuit design has been recently published (Mendez et al., 2009). d'Anterroches and Gani (2005) have introduced the concept of process-group contributions for process flowsheet property estimation and process flowsheet synthesis and design, and they presented a property model for distillation operations. The objective of this work is to develop a group contribution model for flowsheet properties applied to flotation circuit.

2. 2. Group Contribution Model Development

The generation of the group contribution method was carried out in two steps: 1) data generation of flotation circuit properties and 2) model development and model adjustment.

2.2. Data generation

The supposition that the flotation process corresponds to a first order reaction is broadly used. If a group of solid particles transported in a pulp collide with bubbles within certain defined volume, the valuable (hydrophobic) mineral will adhere to upward bubbles, becoming separated from the gangue. This phenomenon can be considered as a simple mechanism where flotation is a pseudoreaction between the solid particles (*A*) and the bubbles (*B*) where $A+B \rightarrow AB$. If the concentration of bubbles is constant, then the flotation kinetic can be represented as a first order pseudoreaction. Then, the mineral flotation can be modeled considering that a mineral is formed of different classes or pseudospecies that have the same floatability. It means floatability represents the propensity of the particles to be floated according to its composition and size given certain flotation environment conditions (pH, Eh, reagent type, concentration), in such a way the most valuable particle, i.e., the most completely liberated valuable particle, has the greater floatability value in an intermediate particle size. Then, in figure 1, the following equations can be written:

$$C_i = T_i \, F_i \tag{1}$$

$$W_i = (1 - T_i) \, F_i \tag{2}$$

Where T_i is the mass ratio of concentrate and feed of class specie *i*. The ratio T_i may be obtained from plant data, values from pilot plants, or theoretical or empirical models. For example, for a bank of *N* cells,

$$T_i = 1 - \frac{1}{(1 + k_i \tau)^N} \tag{3}$$

Where k_i is the first order kinetic constant of class specie i, and τ the retention time in one cell.

In order to adjust a group contribution model, recovery values for different flotation circuits were generated by the simulation of several flotation circuits. Figure 2 shows a superstructure that represents a total of twenty four flotation circuits: two circuits with two flotation stages, four circuits with three flotation stages and eighteen circuits with four flotation stages. Each flotation stage was simulated using the equation 2, for multiple hypothetical classes of minerals. Each hypothetical mineral was generated with random values for the kinetic constant, cell retention time, and *N*=1, 3, 5 and 7 in equation 3. Figure 3 shows T_i values for different first order kinetic constant, retention time, and *N*=1, 3, 5 and 7.

2.2. Model adjustment

To generate the group contribution model two types of contribution were considered. First, it was considered each flotation stage can be characterized by the ratio of flow of concentrate and feed, T_i. Then the interconnections among flotation stages were considered, represented by the product of the ratios of concentrate/feed or tail/feed and concentrate/feed or tail/feed as it is the case: $T_i\ T_i, T_i\ (1-T_i)$, or $(1-T_i)\ (1-T_i)$. Then the model for recuperation of a pseudospecie has the following form:

$$R = \alpha + \sum_i \beta_i\ N_i\ T_i + \sum_i \sum_j \gamma_{i,j}\ N_{i,j}\ \Lambda_{i,j} \tag{3}$$

Where α, β_i and $\gamma_{i,j}$ are adjusted parameters, and T_i and $\Lambda_{i,j}$ are process-group contributions. The adjusted parameters were fitted to simulated recovery values for mineral class with low recovery (0 to 10%), medium recovery (10 to 60%) and high recovery (60 to 100%). The α values were -3.5542, -5.9192, and -2.5507 for low, medium and high recoveries. The values for β_i are given in table 1 and some $\gamma_{i,j}$ values in table 2. Good results have been obtained in the prediction of recovery (see figure 4).

3. Example

To explain the use of the equation 3, let us consider the flotation circuit shown in figure 5, where a mineral conformed by two pseudospecies, one with high recovery and another with low recovery, is fed. The equation 3 for this case corresponds to:

$$\begin{aligned} R = {} & \alpha + \beta_{T_R} T_R + \beta_{T_C} T_C + \gamma_{T_R T_C} T_R T_C + 2\gamma_{T_R (1-T_C)} T_R (1-T_C) + \\ & \gamma_{(1-T_R)(1-T_C)} (1-T_R)(1-T_C) \end{aligned} \tag{4}$$

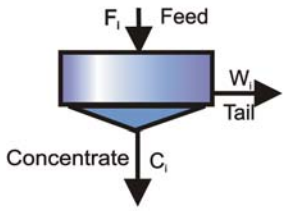

Figure 1. Flotation Stage

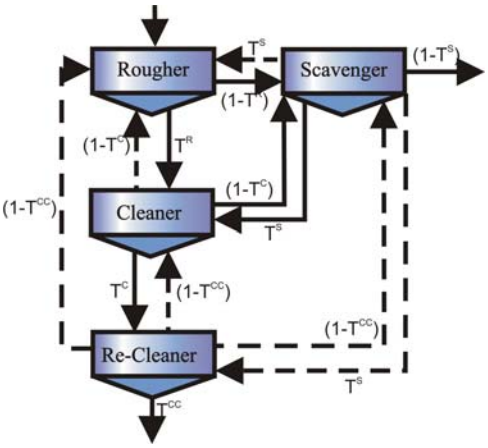

Figure 2. Superstructure of flotation circuit

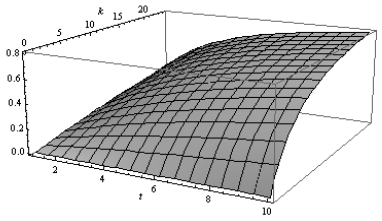
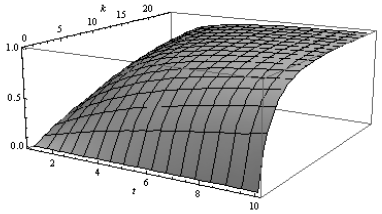
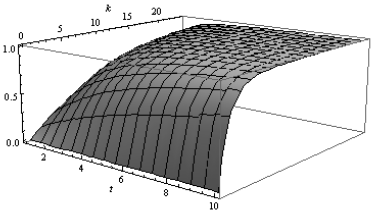


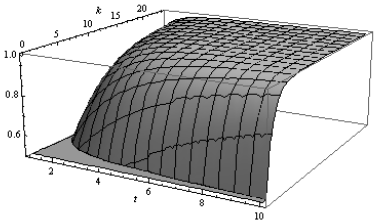
(N = 1)



(N = 3)



(N = 5)



(N = 7)

Figure 3. T_i values from equation 3 for different values of k_i, τ and *N*.

Table 1. Values for β_i groups.

Recovery	Flotation stage groups			
	T_R	T_C	T_{CC}	T_S
Low	1.8913	1.9870	-3.2947	0.0348
Medium	2.0104	2.3000	-5.1205	-1.0106
High	1.3011	1.2367	-1.0042	-1.3571

Table 2. Some values of $\gamma_{i,j}$

Flotation stages groups, $\Lambda_{i,j}$		$\gamma_{i,j}$ values		
I	j	low	medium	High
T_R	T_C	0.4251	2.6465	1.2645
$1-T_R$	T_S	0.7060	1.3288	0.6314
T_C	T_S	-0.3160	0.8209	2.6079
T_{CC}	T_S	-0.2917	1.1177	3.4985
T_R	$1-T_C$	1.8040	3.1885	1.1269
$1-T_R$	$1-T_C$	3.0154	6.0501	2.5505

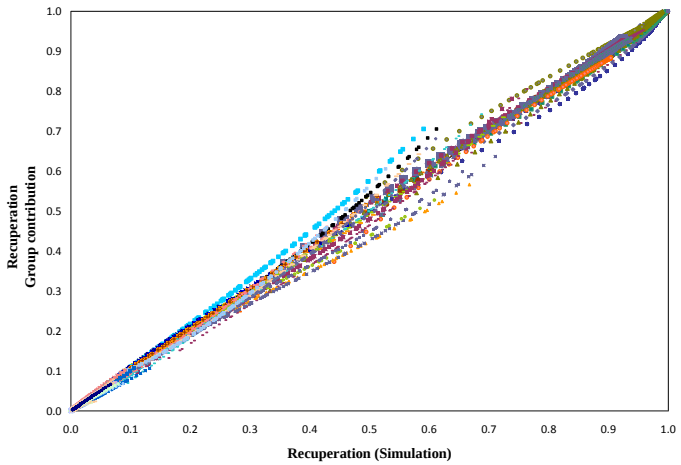


Figure 4. Recuperation values: Group contribution versus simulated values

For values of $T_R = 0.906$ and $T_C = 0.716$ for the high recovery speudospecie, the calculated valor of *R*, in equation 4, corresponds at 0.867, while the mass balance value of *R* corresponds at 0.873. On the other hand, for the low recovery speudospecie, with

values of $T_R = 0.07$ and $T_C = 0.05$, R correspond at 0.009 and 0.007 for equation 4 and mass balance respectively.

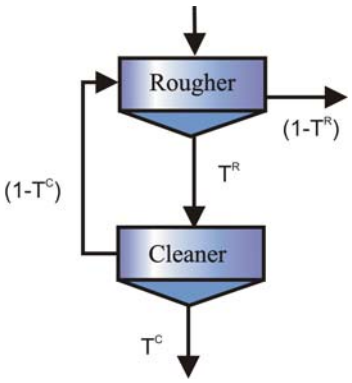

Figure 4. Flotation circuit for the example.

4. Conclusion and future work

A group contribution model was presented for the recovery estimates in flotation circuits. For the analyzed circuits the method gives acceptable results for process synthesis purpose. Works to include circuits with more flotation stages, development of an approach for the selection of T values, and an approach for the determination of the maximum number of flotation stages are under way.

Abstract

The obtaining of alternative sources to generate energy has been a worldwide focus of research in the last years, mainly due to scarcity of fossil fuels in a close future. A very promising source to obtain combustion gases (especially methane and hydrogen) consists of gasification of biomass wastes generated by tanneries and footwear-leather industries. The Brazilian state of Rio Grande do Sul has a very privileged position concerning this industrial area, because it owns a large number of companies of these branches. The objective of this work is the design and simulation of a biomass gasification reactor, by using the technique of computational fluid dynamics. A commercial computational package of simulation, CFX 11.0, was the software employed for the development of this work. The gasification process may be carried out in two types of reactor configurations: fluidized and fixed bed. The present work has been developed upon fixed bed reactors in downdraft operation, considering four steps of gasification zones develop along the gasifier: drying, devolatilization, reduction, and combustion. The single and two-phase reactions were simulated coupled with the transport equations (momentum, mass, and energy) and the tracking of biomass particles. Several design configurations were tested in order to verify how they could influence the fluid flow and the temperature distributions inside the reacting chamber. Finally, one has been chosen a configuration that counterbalances project features, easiness, and operation costs. The remaining simulations have been run from this last configuration. The preliminary results show a good consistency with experimental data obtained previously from a pilot plant. Also, based on the results obtained with different scenarios, a new and modern pilot plant will be built. Forthcoming simulations will have the objective of optimizing and improving the operating conditions of the equipment.

Keywords: gasification, computational fluid dynamics, leather, simulation.

1. Introduction

The industrial activities that involve physical or chemical transformations of leather materials show a large environmental impact. Foot-wear industries are the most consuming raw materials based on leather, around 60% as observed by Bahillo *et al.* (2004). Solid wastes derived from tanneries have high levels of chromium, which is a

toxic and hazardous metal for health. Moreover, liquid and gaseous effluents are the consequence of several reaction steps that occur along the process of leather treatment. According to Vieira (2004), the state of Rio Grande do Sul generated over 189000 ton/yr of dangerous solid wastes from companies that handle with leather products, which demonstrates the importance to treat this issue. According to the same author, only 3% of these wastes are recycled and over 85% have been sent to deposits or urban embankments. A study carried out by Font *et al.* (1999) evaluated several gases as products of volatiles emitted from leather, as light hydrocarbons, some alcohols, and aromatic compounds.

2. Gasification: theoretical aspects

The definition of gasification considered by Belgiorno *et al.* (2003) is the thermal conversion of a liquid or solid material with large content of carbon, into a gaseous fuel with the use of a gasification agent (that is, another gas). The fuel generated in this process may be burnt to obtain energy or be purified to a further separation step, in order to manufacture several other substances. Gasification may be classified as direct (gasification agent partially oxidizes biomass), indirect (occurs in the absence of oxygen) and pyrolysis (indirect gasification that occurs in inert atmosphere), according to Godinho (2006). The reactors also may be classified as fluidized and fixed bed, as described by Belgiorno *et al.* (2003). Fixed-bed gasifiers have lower velocities of the gasification agent and may operate in counter-current (updraft) or co-current (downdraft) mode. In updraft configuration, biomass is inserted in opposite direction to the gasification agent. The major drawback is the dragging of tar together with fuel gas formed in the reactor. The downdraft operation minimizes this problem because the gasification agent is inserted perpendicularly to biomass feeding section. Fixed bed reactor presents four theoretical zones with different temperatures and chemical processes, as classified by Filho (1988):

- Drying zone: Placed on the top of the gasifier, it is where the coal or biomass depletes water and is pre-heated by hot gases that emerge from the bottom of the reactor.
- Devolatilization zone: The volatiles are removed in this zone. The most common gases obtained are CO_2, CO, light hydrocarbons, nitrogen, and sulphur-based compounds.
- Reduction or gasification zone: It is where the gasification reactions occur. Temperatures vary between 800ºC and 960ºC, approximately. The main reactions considered are:

$$C + H_2O \rightleftharpoons CO + H_2 \quad \text{(I)}$$
$$C + 2H_2 \rightleftharpoons CH_4 \quad \text{(II)}$$
$$C + CO_2 \rightleftharpoons 2CO \quad \text{(III)}$$

By inverting reaction (III) and adding it to equation (I), one obtains the water gas-shift reaction:

$$CO + H_2O \rightleftharpoons CO_2 + H_2 \quad \text{(IV)}$$

- Combustion zone: Occurs the complete oxidation of char. The heat of this reaction is transferred to the previous zones described. Temperatures may reach up to 1400ºC. The reaction that occurs is:

$$C + O_2 \rightleftharpoons CO_2 \quad \text{(V)}$$

3. Mathematical modeling and operating conditions

The governing equations applied to the problem are the following:

Moment Balance (Navier-Stokes equations)

$$\frac{\partial(\rho u_i)}{\partial t}+\frac{\partial(\rho u_j u_i)}{\partial x_j}=-\frac{\partial P}{\partial x_i}+\frac{\partial}{\partial x_j}\left(\mu\frac{\partial u_i}{\partial x_j}\right)+S^{u_i} \quad (1)$$

Total mass balance (Continuity equation)

$$\frac{\partial \rho}{\partial t}+\frac{\partial}{\partial x_j}(\rho u_j)=0 \quad (2)$$

Energy balance

$$\frac{\partial(\rho T)}{\partial t}+\frac{\partial}{\partial x_j}(\rho u_j T)=\frac{\partial}{\partial x_j}\left(\frac{k}{c_P}\frac{\partial T}{\partial x_j}\right)+S^T \quad (3)$$

Component mass balance

$$\frac{\partial C_i}{\partial t}+\frac{\partial(u_j C_i)}{\partial x_j}=\frac{\partial}{\partial x_j}\left(D\frac{\partial C_i}{\partial x_j}\right)+S^{C_i} \quad (4)$$

Turbulence model (k-ω) - Turbulent kinetic energy

$$\frac{\partial(\rho k)}{\partial t}+\nabla\cdot(\rho U k)=\nabla\cdot\left[\left(\mu+\frac{\mu_T}{\sigma_k}\right)\nabla k\right] \quad (5)$$

Turbulence model (k-ω) - Turbulent frequency

$$\frac{\partial(\rho\omega)}{\partial t}+\nabla\cdot(\rho U\omega)=\nabla\cdot\left[\left(\mu+\frac{\mu_T}{\sigma_\omega}\right)\nabla\omega\right]+\alpha\frac{\omega}{k}[(\mu_T\nabla U\cdot(\nabla U+\nabla U^T)-\beta\rho\omega^2] \quad (6)$$

In conservation equations above, u is the velocity vector in $m{\cdot}s^{-1}$, P is the pressure in Pa, x represents the dimensional variable in m, μ is viscosity in $Pa{\cdot}s$, T is temperature in K, ρ is the gas density in $kg{\cdot}m^{-3}$, C represents the concentration of each gaseous species in $kg{\cdot}m^{-3}$, and S accounts for the source terms in momentum (buoyancy force), energy (heat of reaction) and component (source of each gaseous species) balances. The system under consideration is three-dimensional and operates at steady-state conditions, so the transient terms (where t is time, in s) of the equations (1-6) are dropped out. About the turbulence model, k is the turbulent kinetic energy, in $m^2{\cdot}s^{-2}$, ω is the turbulent frequency, in s^{-1}, U is the velocity vector in $m{\cdot}s^{-1}$, μ_T is the turbulent viscosity in $Pa{\cdot}s$, and the parameters σ_ω, σ_k, α, and β are model parameters. The homogeneous gas phase reactions are:

$$H_2+1/2\,O_2\rightarrow H_2O \quad (VI)$$
$$CH_4+3/2\,O_2\rightarrow CO+2H_2O \quad (VII)$$
$$CH_4+2O_2\rightarrow CO_2+2H_2O \quad (VIII)$$
$$CO+1/2\,O_2\rightarrow CO_2 \quad (IX)$$
$$CO+H_2O\rightleftharpoons CO_2+H_2 \quad (X)$$

The rate expressions for reactions (II, and V-X) are the following (Filho (1988), ANSYS® CFX 11.0 User Manual):

Methane Formation

$$r_{II}=-k_{II}\left(p_{H2}{}^2-\frac{p_{CH4}}{K_{eq}}\right) \quad \text{Reaction (II)} \quad (7)$$

Water-gas shift reaction

$$r_{IV}=-k_{IV}(p_{CO}p_{H2O}-p_{CO2}p_{H2}) \quad \text{Reaction (X)} \quad (8)$$

Char Oxidation

$r_V=-\left(k_c{}^{-1}+k_d{}^{-1}\right)^{-1}p_{O2}A_P$, where: Reaction (V) (9)

$$k_C = A_C e^{-T_C/T_P} \quad - \quad (10)$$

$$k_d = \frac{D_{ref}}{R_P}\left(\frac{T_P + T_g}{2T_{ref}}\right)^{\alpha}\frac{P_A}{P} \quad - \quad (11)$$

Gas Phase Oxidation

$$r_{comb,n} = -A\frac{\epsilon}{k}\min\left(\frac{[I]}{\alpha_{I,n}}\right) \quad \text{Reactions(VI - X)} \quad (12)$$

The reaction rate r is expressed as $mol \cdot m^{-3} \cdot s^{-1}$ in equations (7) and (8), and as $kg \cdot m^{-3} \cdot s^{-1}$ in equation (9). The terms p_i represent the partial pressure of each gaseous compound i, expressed as Pa, K_{eq} is the equilibrium constant in Pa^{-1}, k_j is the specific reaction velocity of the reaction j in units according to each reaction order. The terms k_c and k_d are the Arrhenius reaction rate of char oxidation and resistance of oxygen diffusion into the particle, expressed in $kg \cdot m^{-2} \cdot s^{-1}$ and $m \cdot s^{-1}$, respectively. The parameters T_g, T_{ref}, T_P, and T_c represent the temperatures of gas, reference, particle, and activation (activation energy divided by perfect gas constant R), respectively, while R_P is the particle radius in m, A_p is the particle surface area in m^2 and α is an exponential parameter set equal to 0.75 in CFX 11. Other default parameters considered by the solver are T_{ref} (293K), the oxygen diffusivity of reference, D_{ref}, $1.8 \cdot 10^{-5}$ $kg \cdot m^{-1} \cdot s^{-1}$ and the parameter A_c in equation (10), set as 4. The terms $[I]$ and $\alpha_{I,n}$ are the molar concentration of the gas I and the stoichiometric coefficient of the respective gas in each combustion reaction n. The rate of gas phase combustion $r_{comb,n}$ in $mol \cdot m^{-3} s^{-1}$ is taken into account as an instantaneous process, given by the ratio of the local turbulent dissipation energy and turbulent kinetic energy. Transport of particles is considered by applying the second law of Newton:

$$m_P \frac{dU_P}{dt} = F_D + F_S \quad (13)$$

where:

$$F_D = \frac{C_D \rho_f A_P |U_F - U_P|(U_F - U_P)}{2} \quad (14)$$

$$F_B = \frac{\pi d_P{}^3 (\rho_P - \rho_F) g}{6} \quad (15)$$

In equations (13-15), m_p is the particle mass in kg, U_P is the particle velocity vector expressed as $m \cdot s^{-1}$, F_D and F_B are the drag and buoyancy forces in N, respectively. The drag force is considered to admit a constant non-dimensional drag coefficient $C_D = 0.44$, ρ_f is the fluid density in $kg \cdot m^{-3}$, d_P is the particle diameter in m and g is the acceleration of gravity field, 9.8 $m \cdot s^{-2}$. The equations (13-15) are solved numerical and simultaneously with the balance equations of moment, mass, and energy. The operating conditions are given in Table 1 and the corresponding scheme is depicted in Figure 1.

Table 1 - Temperature and flow in the gasifier

Location (see Fig. 1)	Flow ($kg \cdot h^{-1}$)	Temperature (K)
Top	200 (biomass)	673
Burner (2)	90	673
Air box (1) and air tubes (3)	270	303
Ashtray Air (6)	200	303

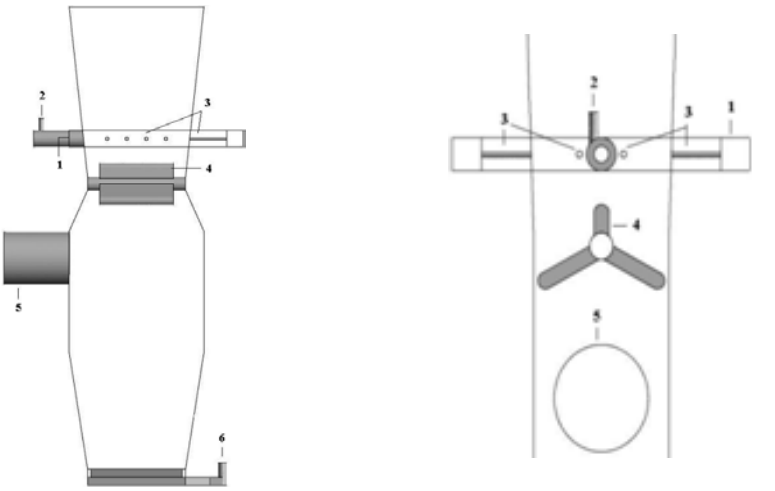

Figure 1 - Scheme of the gasifier.

The parts numbered as 4 and 5 are the metallic grate and the outlet of the reactor, respectively. The grate retains thick particulates (ash and tar), separating the sections of reduction (above) and starting of combustion (below) of the gases formed. The outlet is to be connected to a combustion chamber that is also being simulated apart. Wastes of leather are fed on the top of the gasifier, where devolatilizations occur (still not considered in this step). The remaining particles consist of char and ash, so that the fixed carbon is oxidized to generate heat that maintains the temperature that sustains the gasification reactions. Air is fed through the burner and tubes that redistribute it along the reactor. The ashtray air begins the combustion below the grate and oxidizes the remaining char particles.

4. Results and Conclusions

Estimated molar fractions of the main gases are presented in Table 2, compared with some previous results from the former reactor configuration. In Figure 2 are shown temperature contours and a sample of the three-dimensional vector field of biomass particles with varying char mass fractions.

Table 2 - Mean molar fractions at gasifier outlet

Component	Molar Fraction	Molar Fraction (Godinho, 2006)
CH_4	0,08	0,118
H_2	$2{,}09 \cdot 10^{-6}$	-
CO	0,0648	0,061
CO_2	0,081	0,132
H_2O	0,029	-

The obtained fuel gas has a very low concentration in hydrogen. Larger values may be reached by injecting steam into the gasifier to displace the water-gas shift equilibrium to the right. This approach is intended to further be applied in order to increase the calorific power of the gas.

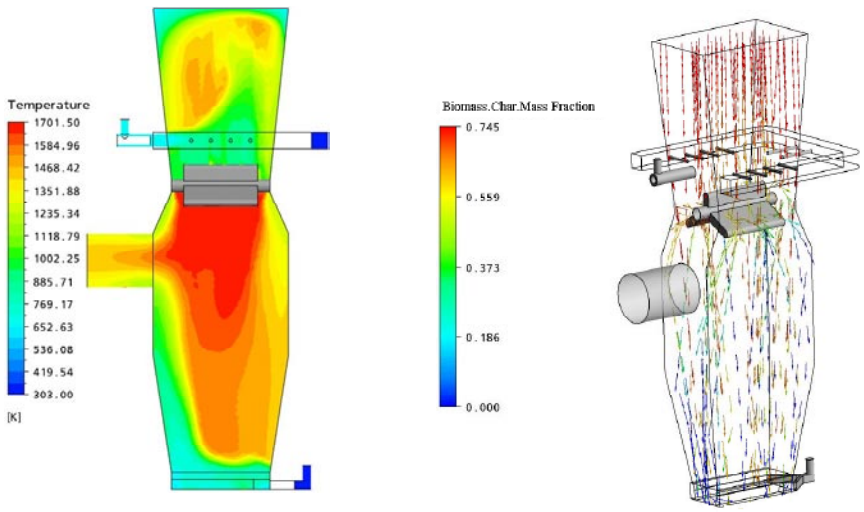

Figure 2 - Temperature profiles and vector field.

According to Figure 2, the largest temperatures occur immediately below the grate, where the homogeneous combustion reactions begin to occur. About the char particles, one verifies the bulk combustion occurs in the upper-half of the reactor. Although some non-burnt particles reach the ashtray, most of them are oxidized with the oxygen fed in that section.

These preliminary results show that gasification of leather wastes seems a very promising energy source due to capability of formation of useful gases for combustion and heat generation (mainly methane and likely hydrogen). The expermental results obtained with the plant operation shortly will be compared with the simulations carried out in this work to design the reactor.

Acknowledgments

The authors are very thankful to profs. Celso Martins, Leonardo Masotti and Marcelo Godinho for their valuable experience and help in the development of this work.

Abstract

Free-radical polymerization of styrene in the presence of trifunctional initiator was investigated to understand the behavior of initiators with functionality greater than two. The trifunctional initiator selected was the TRIGONOX 301 from Akzo Nobel. This study proposes a kinetic mechanism and a mathematical model to free radical polymerization of styrene using a trifunctional initiator. The complexity of the kinetic mechanism increases as the functionality of the initiator increases. The mathematical model was built and predicts results as conversion, molecular weight, radical concentration and polymer concentration. An experimental investigation was also explored to validate the simulations results. The experimental part followed the method of polymerization in ampoules. Experiments were also carried out to verify the effect of temperature and initiator concentration on the polymerization kinetics and molecular weights.

Keywords: multifunctional initiator, polystyrene, polymerization.

1. Introduction

The study of chemical initiators that have functionality superior than two has been explored in the scientific and industrial field. Free-radical polymerization in the presence of multifunctional initiator has been also investigated to understand the behavior of these initiators. The multifunctional initiator is able to increase the reaction rate in a free radical polymerization without decrease the molecular weight of the formed polymer and it can also changes the polymer structure.

Literature shows experimental and simulation studies related to free radical polymerization using bifunctional initiators (Villalobos et al., 1991; Dhib et al., 2000; Machado and Lona 2005 and others). Cerna et al. (2002) and Sheng et al. (2004) present detailed and important experimental studies with trifunctional initiators.

There are very few studies presenting models of free radical polymerization using multifunctional initiators (Scorah, 2005 and Scorah et al., 2007).

To understand the behavior of initiators with functionality greater than two, trifunctional initiators were chosen. The trifunctional initiator selected was the TRIGONOX 301 from Akzo Nobel. It is a cyclic triperoxide and very unstable at temperatures greater than 40ºC. It must be kept at room temperature. This study proposes a kinetic mechanism and a mathematical model to free radical polymerization of styrene using

this trifunctional initiator since there are very few studies presenting models of free radical polymerization using multifunctional initiators. Styrene is chosen because it is a very well known monomer and there are a lot of data about it. The mathematical model was built in Fortran 90, based on the Method of Moments Equations for all species, and predicts results as conversion, molecular weight (Number Average, Mn, and Weight Average, Mw), radical concentration and polymer concentration. An experimental investigation was also explored to validate the simulations results. The experimental part followed the method of polymerization in ampoules. Full-conversion-range experiments were carried out to validate the model and also to verify the effects of the temperature and initiator concentration on the polymerization kinetics and molecular weights. Conversion was calculated based on differences of masses (gravimetry). Gel Permeation Chromatography (GPC) was used to measure the molecular weights of polystyrene. The validation was made to conversion and molecular weights.

2. Experimental Procedure

Styrene was first washed with NaOH solution and deionized water. Then it is dried with $CaCl_2$. The washed styrene is distillate using a vertical rotative evaporator equipped with vacuum pump and a hot bath.

After that determined quantities of the solution initiator-monomer are transferred to ampoules. They are all sealed after the elimination of oxygen and put into a bath of oil at a desirable temperature.

At certain intervals of time, each ampoule is removed from the bath, cooled and weighted. Then the ampoule is broken and the solution polymer + monomer + initiator is dissolved in tetrahydrofuran (THF) and then the polymer is precipitated with ethanol. After ethanol evaporation, the sample of polymer goes to a dryer to guarantee the total evaporation of the solvent. After this, the dried samples are weighted, and conversion is calculated based on differences of masses (gravimetry). Finally, the polymer is dissolved in THF and characterized by GPC analysis, providing molecular weights data. These results bring elements to understand the behavior of trifunctional initiator in the production of polystyrene, since they provide data to validate the mathematical model and to estimate parameters.

3. Results

The simulation results and experimental data are shown in Figures 1, 2, 3 e 4. The experimental data are used to validate the model.

In Figures 1 and 2 it was considered temperature equal to 130°C and initiator concentration of 0.005M.

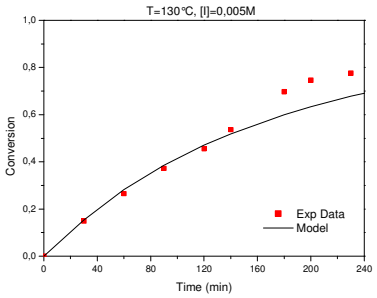

Figure 1. Conversion x Time.

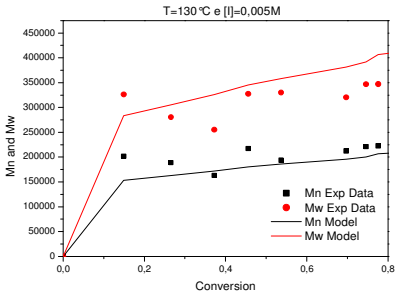

Figure 2. Weight and Number Average Molecular Weights x Conversion.

Figures 4 and 5 show results from a different operating condition; temperature of 125°C and initiator concentration of 0.0029M.

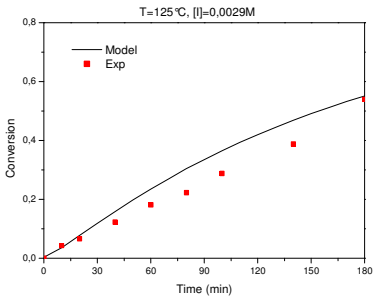

Figure 3. Conversion x Time.

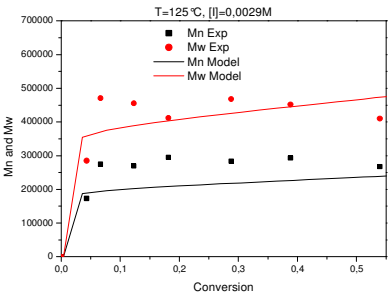

Figure 4. Weight and Number Average Molecular Weights x Conversion.

It is possible to verify from Figures 1 to 4 that the model presents agreement with experimental data. It was possible to explore the model using different operating conditions providing a study of effects of temperature and initiator concentration on the reaction rate and proprieties of the polymer. Figures 5 and 6 show the effect of temperature in conversion and number average molecular weight.

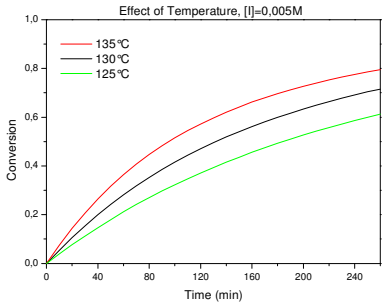

Figure 5. Conversion x Time.

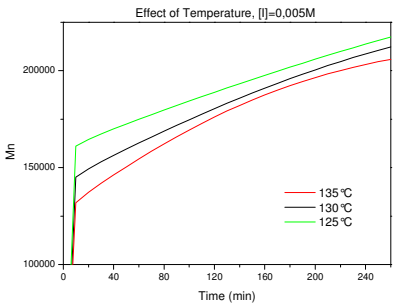

Figure 6. Number Average Molecular Weight x Time.

It is possible to verify in Figure 5 that conversion increases as the temperature increases. That is expected since an increasing in temperature increases the reaction rate generating more radicals to react with the molecules of monomer. Figure 6 shows that Mn decreases as the temperature increases, what was also expected, since a large quantity of radicals implies in a large quantity of chains, but short ones, making the molecular weight decreases.

Figures 7 and 8 show the effect of initiator concentration in conversion and number average molecular weight.

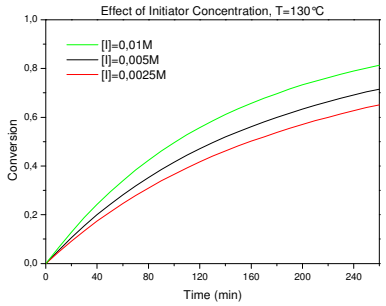

Figure 7. Conversion x Time.

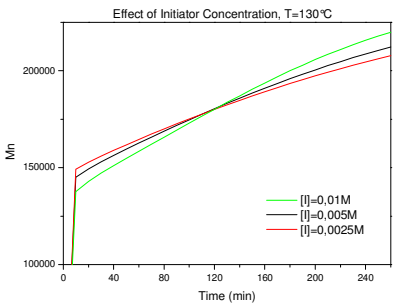

Figure 8. Number Average Molecular Weight x Time.

As expected, Figure 7 shows that an increasing in initiator concentration is also very important to achieve faster conversions, since a large quantity of initiator implies in a large quantity of consumed monomer. Figure 8 shows that, first, Mn decreases as the initiator concentration increases and then this behavior changes and Mn starts to increase with the increasing in the initiator concentration. The first part was expected, since a large quantity of radicals implies in a large quantity of chains, but short ones, making the molecular weight decrease, but the behavior in the second part is really unexpected. Maybe, this can be explained by the fact that with the increase on the initiator concentration, more radicals are formed resulting in the increasing of the number of chains and before 120 minutes, Mn (which depends on the number of chains)

decreases. However, after 120 minutes, as the initiator concentration is smaller (there is less initiator in the reaction), when all initiator is consumed, the polymeric chains that have undecomposed peroxides start to break, making Mn decrease. At this point, the inversion in the behavior begins because the highest initiator concentration has not all initiator consumed, so its chains have not yet their undecomposed peroxide broken, so molecular weights of the highest initiator concentrations keep still growing.

4. Conclusion

Results from model simulation of styrene polymerization using trifunctional initiator TRIGONOX 301 showed agreement with experimental data. These results from simulation are new, since there is no research published about this subject. The existent models are very few and they are not based in the Method of Moments. So far it was possible to verify some aspects of the behavior of a trifunctional initiator through the study of the effects of temperature and initiator concentration and it was possible to see how interest is the behavior of a multifunctional initiator in a polymerization reaction and to verify the benefits of its use.

Abstract

The fabric filter is a pioneering piece of equipment used to reduce the emission of small size particulate matter from industrial sources. It is relatively inexpensive and offers easy operation and high efficiency of collection for a wide range of sizes. Aiming at making the filtration operation more efficient and economical, this work investigated the best position of the feed in the filtration box and, consequently, the best way to clean the fabric filter. The cleaning system used in fabric filters is of great importance for the efficiency and durability of the equipment, and it defines the position of the dirty gas inlet in the filtration box. This work used CFD (Computational Fluid Dynamics) techniques to simulate the pressure drop and the fluid dynamics of the gas as a function of the position of the feed, which was varied from the top to bottom of the filtration box. The simulations were carried out using a new polyester filter for each feed position. According to the results, the fluid should be fed next to the bottom of the filtration box, which produces a smaller pressure drop, a better distribution of the gas and less wear of the bags adjacent to the gas feed.

Keywords: Filtration, Fabric Filter, CFD.

1. Introduction

The increasing concern with the quality of the air, the limits of atmospheric emissions of particulate materials required by the current law, as well as the need to recover raw materials or added value products demand a more effective control of the atmospheric emissions on the part of the industries. The filtration is one of the first and most common operations used to clean gases and capture particles from gaseous flows due to its high collection efficiency, low cost of operation and low sensitivity to the fluctuations of the operating conditions. The fabric filter is the equipment most often used in dry filtration for presenting collection efficiency around 99% (Hinds, 1999).

The satisfactory performance of fabric filter for a particular application requires both the right choice of the material that will be used for the filtration (adequate choice of the fiber), which must be compatible with the particulate material that will be collected, and a project that is appropriate to the geometry of the dust collector and to the cleaning conditions (Rodrigues, 2004).

According to Damian *et al.* (2003), the distribution of the air velocity in the filtration box actually does not occur in a uniform way, presenting problems of premature wear of the bags located in regions of high velocity.

In this context, the objective of this work was to evaluate which position of the gas feed could produce a more uniform distribution of the fluid through the bags, as well as a smaller pressure drop during the operation of the filtration system.

2. Method

This work simulated the fluid dynamics of a representative part of an industrial filtration system with air-cloth ratio of 0.04 $m^3/m^2.s$. Figure 1 shows the details of the filtration box with the 13 bags. Bag number one is closest to the gas feed.

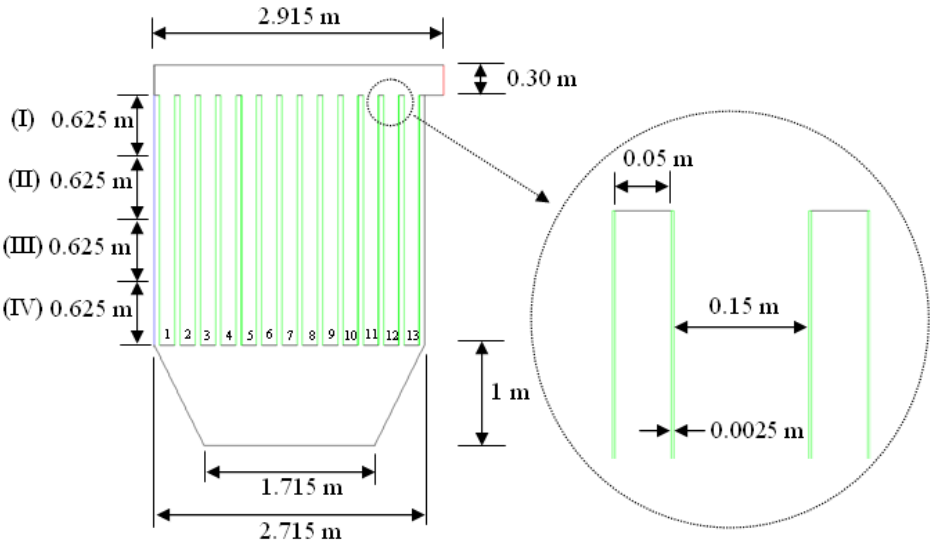

Figure 1 – Dimensions of the filtration system

The was software Fluent was used for the fluid dynamics simulations and the main boundary conditions were: velocity of the air feed 1.56 m/s, permeability $4.69x10^{-10}$ m^2, porosity 82%, thickness $2.5x10^{-3}$ m, relative of humidity of the air 20% and temperature 25ºC, all taken from Rocha *et al*. (2008).

The simulations were carried out bidimensionally with approximately 850,000 computational cells. The turbulence model used was the RSM *(Reynolds Stress Model*). The method *PRESTO*! was used for the interpolation of the pressure, and the algorithm *SIMPLE* was applied for the coupling of the pressure-velocity binomial. *UPWIND* methods of the second order were adopted for the interpolation of the remaining fluid dynamics variables (Vieira *et al*., 2007).

3. Results

The fluid dynamics simulations reveal that the pressure drop in the filtration system studied depends on the position of the gas feed, as shown in Figure 2.

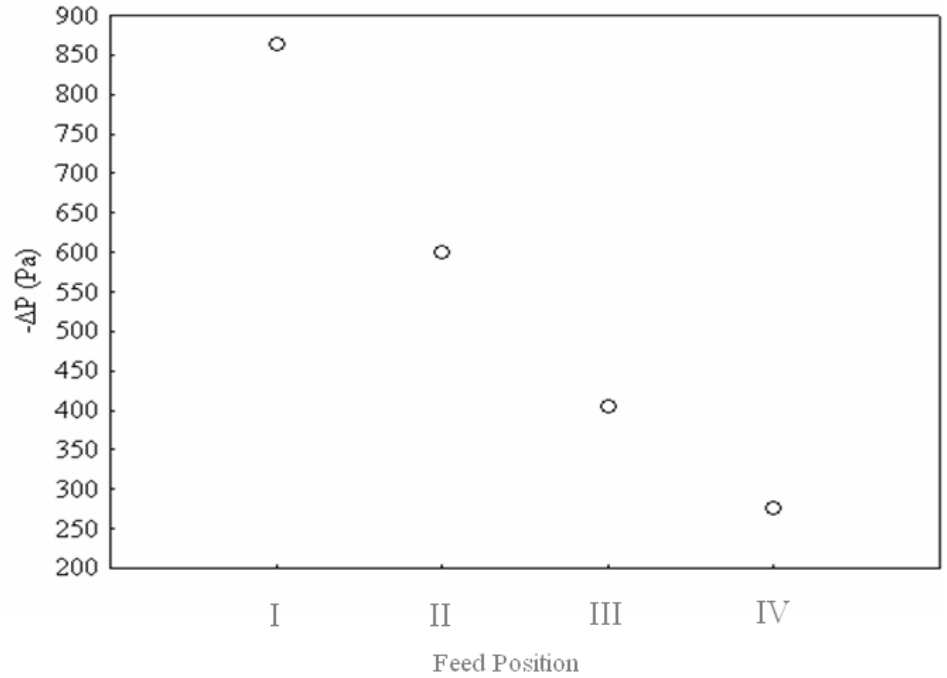

Figure 2 – Influence of the position of the gas feed on the pressure drop

As shown in Figure 2, when the fluid is fed next to the base of the filtration box, the pressure drop in the set of bags tends to diminish. Hence, the position "IV" produced the smallest pressure drop (277 Pa) among the configurations studied. In other words, for a given operational pressure drop (defined by the user), the position "IV" allows a longer filtration time, decreasing the number of cycles. For a given job, the reduction of the number of cycles allows for a smaller number of operations of cleaning of the bags (a procedure more damaging to the structure of the fabric of the filter) and, consequently, a lower wear of the bags. That, in turn, makes the operation more viable, because the bags are the most expensive component of a typical filtration unit.

Figure 3 presents the fluid dynamics profiles for the velocity of the clean air in the interior of the filtration system.

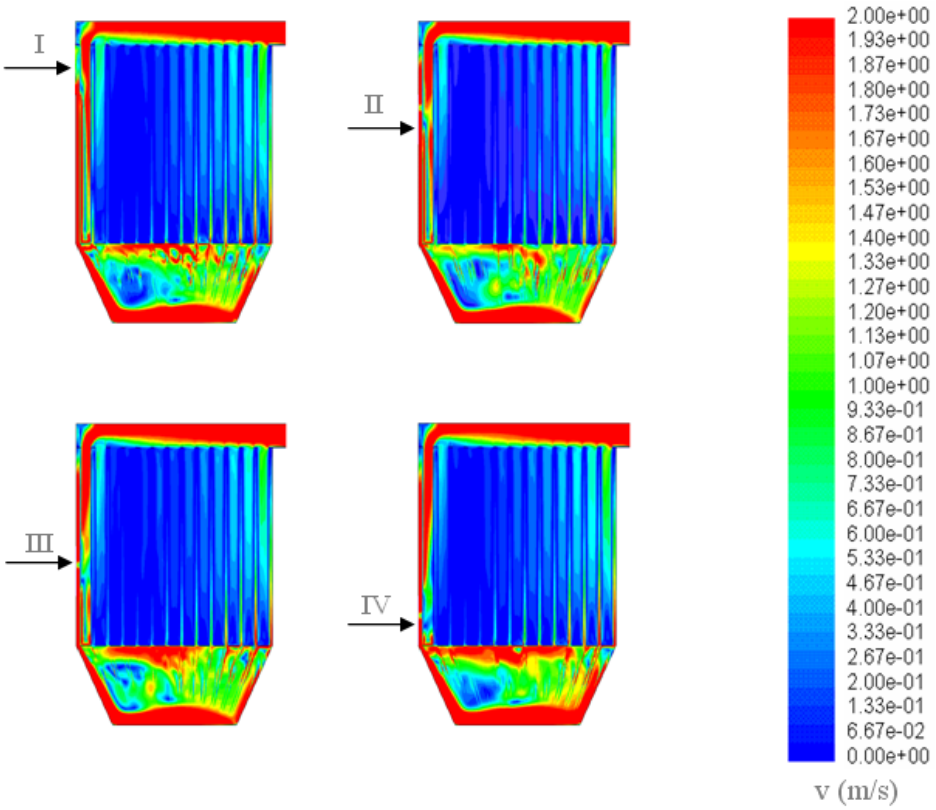

Figure 3 – Fluid dynamics of air in the filtration system.

According to the velocity profiles presented in Figure 3, it was possible to verify that, independently from the position of the air feed, the fluid has a preferential distribution through the bags. The simulations showed that bag "1" is the one that produced the highest rates of filtering amongst all bags. Probably, such behavior is due to the fact that it is subject to the highest gradients of velocity. Consequently, the position of bag "1" will probably make it wear prematurely when compared to the others. The same consideration can be made for bags "2", "12" and "13". On the other hand, it was seen that bags "3", "4" and "5" are those that provided the lowest filtering rates. Finally, the productivity of bags "6" to "11" did not change in the operational conditions used in this work. Figure 4 confirms the previous considerations and presents the rates of filtered mass produced by each one of the bags.

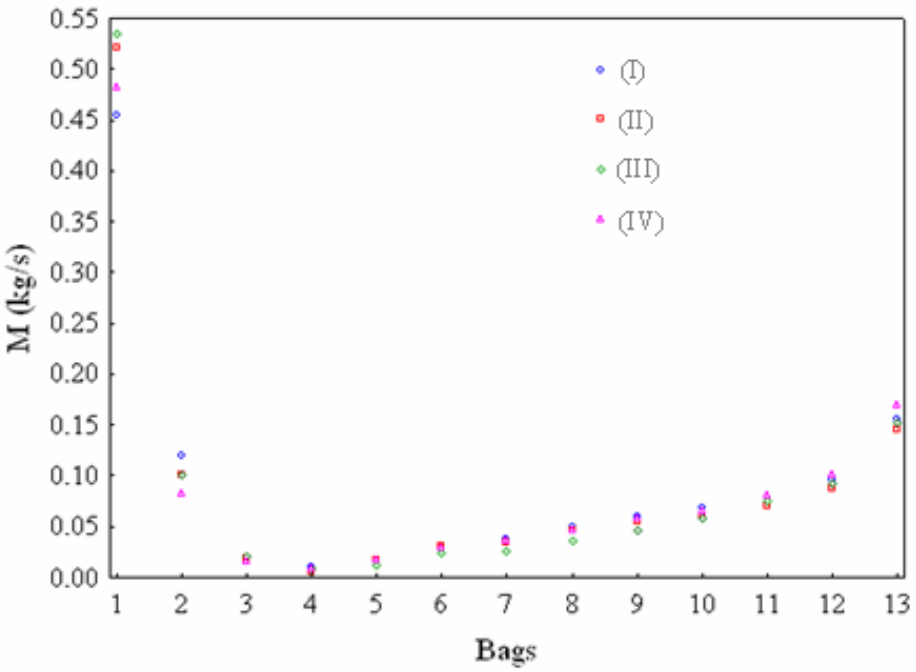

Figure 4 –Distribution of the filtered mass as a function of the positions of the bags and of the gas feed.

As illustrated by Figure 4, the position of the air feed practically did not influence the distribution of the fluid in the bags. Except for position "III", all the others lead to the same rates of filtering. Since the rate of filtered mass in each bag is practically indifferent to the feed positions "I", "II" and "IV", it is convenient to feed the fluids in position "IV", which produces the smallest pressure drop.

4. Conclusions

In the operational and geometric conditions used in this work, and based on the fluid dynamics simulations, the following conclusions can be drawn:

i) The pressure drop in the filtration unit was completely dependent on position of the feed;

ii) Position "IV" (near the base of the unit) provided the smallest pressure drop. This position probably allows longer filtration periods and the need for fewer cleaning operations, increasing the useful life of the bags (the most expensive part of the filtration unit);

iii) The distribution of the fluids through the bags was not uniform. It was seen that the flow showed preference for the bags adjacent to the feed (subject to the highest gradients of velocity, bags 1 and 2);

iv) The non-uniform distribution of the gas through the bags was indifferent to the position of the gas feed in the filtration unit.

Future works are suggested to evaluate the position of the gas feed in the bottom of the equipment, in order to homogenize the distribution of the fluid through bags and to

subject the filter structures to the same rate of wear/deterioration. Another suggestion would be the construction of a prototype to validate the results obtained in this work, both with and without particulate materials.

5**. Simbology**

M – Rate of fluid mass produced in each one of bags (kg/s);
v – Velocity of the fluid (m/s);
-Δp – Pressure drop between the feed and the outlet of the filtration unit (Pa).

Decomposition Techniques for Multi-Scale Structured Product Design: Subspace Optimization

Charles C. Solvason, Nishanth G. Chemmangattuvalappil,
Susilpa Bommareddy, Mario R. Eden
Department of Chemical Engineering, Auburn University, Auburn, AL 36849, USA, edenmar@auburn.edu

Abstract

Recent developments in the area of integrated process and product design have shown that products can be designed in terms of their properties without committing to any specific components a priori. Although current techniques make use of group contribution methods (GCM) to design molecules, there are many properties, atomic arrangements, and structures that cannot be represented using GCM. One approach to expand the capability of GCM to handle a more diverse range of solutions is to combine property clustering with decomposition techniques in a reverse problem formulation. This approach first utilizes multivariate characterization techniques to describe a set of representative samples, and then uses decomposition techniques such as principal component analysis (PCA) and partial least squares (PLS), to find the underlying latent variable models that describe the molecule's properties.

Keywords: Reverse problem formulation, principal component analysis, multi-scale product design, property clustering, molecular design

1. Introduction

One of the most common methods for designing molecules for specific end uses while minimizing computational expense has been group contribution (Gani et al., 2005, Marrero and Gani, 2001). In product design, the associated properties of concern are most often consumer attributes which do not have group contribution parameters (Hill, 2005). One way to address this concern is to map the consumer attribute data from the mega-scale into a set of properties on the macro scale that can be described by group contribution (Solvason et al., 2009a). This step is often performed via chemometrics which defines an empirical relationship through the use of design-of-experiments (DOE) and multivariate-linear-regression (MLR). Any uncertainty in the relationship between the attributes and properties is handled by increasing the size of the feasibility regions in the property domain and validating the enumerated candidate molecules in the attribute domain (Solvason et al., 2009b). Often the attribute-property relationship is poorly defined, which limits the effectiveness of this type of approach. An improvement is to map the attribute information down to a domain subspace that exhibits a stronger attribute-property relationship. The constraints on this new domain are that it must be linear in the constituent space and it must have the ability to be described by a molecular combinatorial technique. A key difference in this method is that the domain subspace is not required to be one of the known properties described by group contribution.

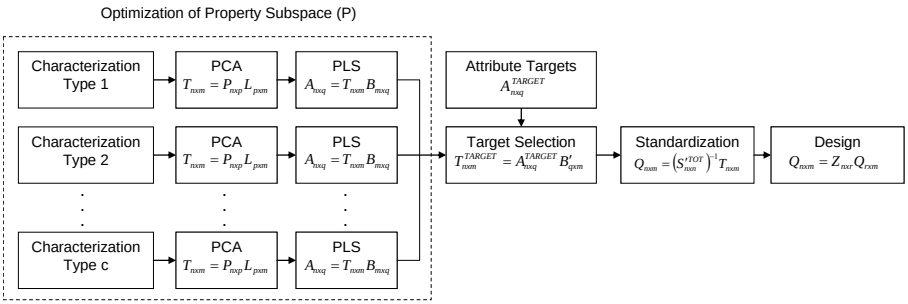

Figure 1: Method Flowchart

2. Methods

The objective of this paper is to enumerate all possible molecules that meet a set of target attributes using a domain subspace mapping function combined with molecular group theory applied to chemometric data. To achieve this objective, a reverse problem formulation is applied where the attributes are mapped down to a domain subspace comprised of properties that have better attribute predictive power than conventional GCM described properties. Several tools, such as characterization and decomposition can be used to find the domain subspace. Molecular combinatorial techniques and property clustering are then applied to find and interpret the solution to the reverse problem formulation. Fig. 1 illustrates the method.

2.1. Characterization Techniques

Characterization is a class of tools associated with the determination of not only chemical constituency or molecular structure, but also of larger structural characteristics describing the orientation and alignment of these molecules often called microstructure at the meso-scale. Some examples of characterization techniques include nuclear magnetic resonance (NMR), x-ray diffraction (XRD), and infrared spectroscopy (IR). The techniques are often applied to a training set of molecules defined by an experimental design used to explore the interesting facets of a set of property attributes. The added structural information available from the characterizations can be used to extend the group contribution method to higher orders as well as discern some orientation specific information. The choice of characterization technique for the specific design can be written into a MINLP, minimizing the predicted variance Q^2_m of the models describing the attribute-property relationships. To significantly reduce experimentation, improve prediction power, and ensure orthogonality of the models decomposition techniques are applied.

2.2. Decomposition Techniques

The most common decomposition is principal component analysis (PCA). By definition, PCA uses the variance-covariance structure to compress the property data to principal component data that contains much of the system variability. This result also improves the interpretation of the data structure by consolidating multiple property effects into single, underlying latent variables which are devoid of colinearity. If the original property data are of the same type, then the eigenvalues can be considered measures of the contrasts, or loadings $\boldsymbol{L_{pxm}}$ of the original variables; and the eigenvectors are referred to as scores $\boldsymbol{T_{nxm}}$ (Johnson and Wichern, 2007).

$$P_{nxp} = T_{nxm} L'_{mxp} \tag{1}$$

In most cases the first 2 or 3 principal components can account for 80% to 90% total variance. The remaining components can be removed without much loss of information (Johnson and Wichern, 2007). The relationship between the principal component scores $\boldsymbol{T_{nxm}}$ and the attribute properties $\boldsymbol{A_{nxq}}$ is then developed using a PLS model of a new DOE factorial design where the scores are varied between their high (+1) and low (-1) levels:

$$A_{nxq} = T_{nxm} B_{mxq} \tag{2}$$

In Eq. 2 $\boldsymbol{B_{mxq}}$ are the regressed coefficients found using PLS. It should be noted that the PLS model uses a separate set of scores and loadings to develop the relationship between $\boldsymbol{A_{nxq}}$ and $\boldsymbol{T_{nxm}}$.. The overall predicted variance of this model is then estimated using the following:

$$R^2_{predM} = \prod_j^q \left(R^2_{predj}\right)^{\frac{1}{q}},\ j \in q \tag{3}$$

Choosing the characterization that maximizes the prediction power in Eqn. 3 for a given number of experiments is a procedure that can be written as a MINLP. Care must be taken to ensure that an appropriate model fitness, as measured by R^2, is not sacrificed to improve the prediction power, R^2_{predM}. Also, although this method can select the appropriate characterization, it is experimentally costly since it requires that each design point be tested by each characterization technique until the appropriate one for the molecular design is chosen. To reduce the required experimentation, molecular design techniques are applied.

2.3. Molecular Design

In order to use characterization to extend GCM to handle complex structures and orientations in molecular design, the dissemination of characterization data must follow a set of rules designed to shadow those developed by Marrero and Gani (2001). First, the characterization must be able to completely quantify each individual molecular group used in the design. Second, in some characterizations, progressively larger groups completely contain the information of the smaller groups, but also contain corrections for 2nd order, 3rd order, structural, and orientation effects. This hierarchal nature is handled by specifying that all groups should be combined such that the largest functional group is specified first, then the second largest, and so on. Third, in some situations only partial overlaps may occur, for which the method will fail to specify any corrections to the first order combination at the overlap interface. To minimize this impact, it is specified that the groups be built such that the combinations occur across the C-C bond which carries the smallest amount of information (Marrero and Gani, 2001). Unlike conventional GCM, the molecular group specific variables are case specific. For instance, in many places in literature, typical absorbance wavelengths are published for IR and NMR spectroscopy. In order to convert these spectra to the underlying molecular group scores $\boldsymbol{T_{rxm}}$, a case specific set of loadings $\boldsymbol{L_{pxm}}$ are needed, which are derived from the original DOE. The full molecule scores $\boldsymbol{T_{nxm}}$ are then estimated as shown in Eq. 4.

$$T_{nxm} = Z_{nxr} T_{rxm} \tag{4}$$

where $\boldsymbol{Z}_{nxr}$ are the number of structure and orientation specific groups in the molecules being designed.

2.4. Property Clustering

Property clustering is a tool used to improve the interpretation of the subspace properties by deconstructing the design problem into a Euclidean vector in the cluster domain and a scalar called the Augmented Property Index *AUP*. The clusters themselves are conserved surrogate properties described by property operators, which have linear mixing rules, even if the operators themselves are nonlinear. Methods for the application of group contribution methods for molecular design have previously been developed using property clustering by Eljack *et al.* (2007, 2008). To utilize the latent variables in the property clustering algorithm, it is important to recognize that the data structure of Eq. 5 follows a linear mixing rule:

$$T_{nxm} = P_{nxp} L_{pxm} \tag{5}$$

$$\psi^{mix}_{nxm} = X_{nxp} \psi_{pxm} \tag{6}$$

The pure properties $\boldsymbol{\psi}_{\text{pxm}}$ have the same structure as the loadings $\boldsymbol{L}_{\text{pxm}}$, thus the loadings can be thought of as the pure values of the principal components. Likewise, the response $\boldsymbol{\psi}^{\boldsymbol{mix}}{}_{\text{nxm}}$ data are predicted mixture properties and have the same structure as the score $\boldsymbol{T}_{\text{nxm}}$ data. That means that the mixture fraction $\boldsymbol{X}_{\text{nxp}}$ in the property models is related to the multivariate data in $\boldsymbol{P}_{\text{nxp}}$. However, there is a concerning difference between the two methods: the mixture fractions sum to 1 across the properties for each sample and the multivariate data $\boldsymbol{P}_{\text{nxp}}$ do not. In order for latent variable models to be utilized in property clustering, it is necessary to standardize the latent variable structure by dividing $\boldsymbol{X}_{\text{nxp}}$ and $\boldsymbol{T}_{\text{nxm}}$ by $\boldsymbol{S}^{\boldsymbol{T}}{}_{\boldsymbol{nxn}}$, resulting in Eqn. 8.

$$S_k = \sum_{i}^{p} X_{ik} \ , \ k \in n \tag{7}$$

$$Q_{nxm} = R_{nxp} L_{pxm} \tag{8}$$

The new $\boldsymbol{Q}_{\text{nxm}}$ matrix now represents standardized scores or mixtures. The loadings matrix $\boldsymbol{L}_{\text{pxm}}$ remains unchanged and the $\boldsymbol{R}_{\text{nxp}}$ matrix now represents fractions of loadings whose cumulative sum is one for each run. Unfortunately, although the components sum to one, they are sometimes negative due to the mean-centering of the multivariate property data prior to PCA. The constraint that the fractions must be between 0 and 1 is removed with no effect on the associated mathematics, only on their interpretation. At this point, the loadings $\boldsymbol{L}_{\text{pxm}}$ are the underlying latent variable domain subspace. Both full molecules and molecular group subspace properties $\boldsymbol{Q}_{\text{nxm}}$ or $\boldsymbol{Q}_{\text{rxm}}$ can be found by multiplying the latent variables $\boldsymbol{L}_{\text{pxm}}$ by the associated fractions $\boldsymbol{R}_{\text{nxp}}$ or $\boldsymbol{R}_{\text{rxp.}}$ Since the molecular and group subspace property relationships in Eqs. 2 and 4 were derived using a decomposition technique, the constraints imposed by decomposition should also be observed for any new molecules or mixtures created.

$$Q_{nxm} = Z_{nxr} Q_{rxm} \tag{9}$$

The molecular design of Eq. 9 is a representation of a linear mixture of the underlying latent variable subspace properties, all of which are linear in nature; it is essentially a *linear mixture of linear mixtures*. This observation assumes that any nonlinearity in the attribute system is handled by the attribute-latent property relationship and not the molecule-group subspace property relationship (Muteki and MacGregor, 2006).

3. Case Study – Acetaminophen Tablet Design

Three attributes that are important to direct compression tablet manufacturing are disintegration time, crushing strength, and ejection force. These attributes have been notoriously difficult to analyze based on traditional mixing design because of the complex and highly nonlinear nature of pharmaceutical excipients. In order to better control these attributes, they are mapped down to a domain subspace where they can be approximated as linear combinations of molecular group parameters. The domain subspace was found to be characterized by three properties using a training set of 24 excipients $\boldsymbol{P}_{\mathbf{nxp}}$ (Gabrielsson *et al.,* 2003). To reduce the number of parameters in the subspace, decomposition was performed using PCA. Although the number of parameters could be reduced, it was decided to keep all of them for illustrative purposes. Using PLS models developed from the training set, consumer specific set of targets $\boldsymbol{A}_{nxq}$ were mapped to the domain subspace $\boldsymbol{Q}_{\mathbf{nxm}}$ as shown in Table 1.

Table 1. Design Targets

Subspace Targets	Q1	Q2	Q3
UL	2.00	2.00	1.00
LL	1.00	0.00	0.00

The molecular groups identified by the characterization were identified as CH, CH_2, OH, CHO, O, CH_2-O, CHOH, CH_2OH, $CHCH_2OH$, CHCHO, Ocyc, α-pyranose, β-pyranose, and cellulose. Using the molecular design procedure outlined in Fig. 1, the molecular groups $\boldsymbol{Q}_{\mathrm{rxm}}$ were combined to build a complete set of molecules $\boldsymbol{Q}_{\mathrm{nxm}}$ matching the domain targets as shown in Fig. 2 and Table 2. Of note was the selection of α-pyranose over β-pyranose compounds as candidates, effectively removing the traditional microcrystalline cellulose excipient from consideration. Other candidate excipients are also shown in Table 2.

Table 2. Designed Molecules

Candidate Molecules	Q1	Q2	Q3
CH2OH-CH2OH	1.22	1.20	0.61
CH2OH-(α)pyranose-CH2OH	1.85	1.08	0.90
CH2OH-CH(OH)-CH2OH	1.79	1.07	0.43
CH2OH-CH2-O-CH2OH	1.75	1.06	0.15
CH2OH-O-CH2OH	1.75	1.03	0.14
CH2OH-CH(CH2OH)-CH2OH	1.80	1.45	0.57
OH-CH2-OH	1.17	0.47	0.13
OH-(α)pyranose-CH2OH	1.80	0.35	0.42
OH-CH(CH2OH)-CH2OH	1.75	0.72	0.09
OH-CH2-CH2-CH2-OH	1.75	1.29	0.23

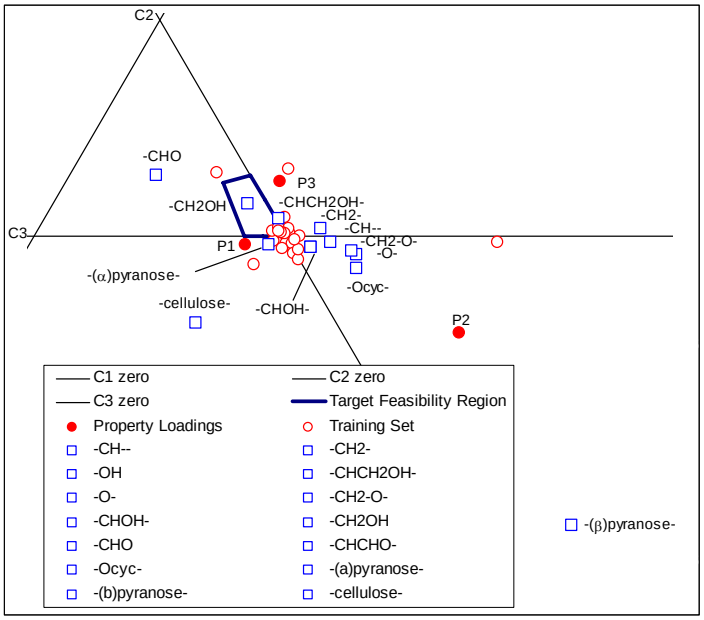

Figure 2: Molecular Design Cluster Diagram

4. Conclusions

In summary, the combination of property clustering and principal component analysis offers many insights and advantages for structured product design. In particular CAMD problems are no longer hindered by a lack of structure information in the molecular design. Rather, the uncertainty in predicting large molecular structures has now been removed from the models and replaced solely with the experimenter's ability to choose appropriate training sets, for which many proven techniques exist. This represents a useful addition to the existing CAMD methodology. Furthermore, the method is universal in nature and can be extended to include many characterization techniques.

Simultaneous Solution of Process and Molecular Design Problems using an Algebraic Approach

Susilpa Bommareddy, Nishanth G. Chemmangattuvalappil, Charles C. Solvason and Mario R. Eden

Department of Chemical Engineering, Auburn University, AL 36849, USA

Abstract

The property integration framework has allowed for simultaneous representation of processes and products and established a link between molecular and process design from a properties perspective. The simultaneous approach involves solving two reverse problems. The first reverse problem identifies the property targets corresponding to the desired process performance. The second reverse problem is the reverse of a property prediction problem, which identifies the molecular structures that match the targets identified in the first problem. Therefore, successful tracking of properties is the key in applying reverse problem formulation for integrated process and product design problems. In this contribution, an algebraic technique has been developed for solving process and molecular design problems simultaneously. The molecules are identified to meet the process performance defined in terms of properties. Since, both process and molecular property operators target the same optimum process performance, the set of inequality expressions can be solved simultaneously to identify the molecules that meet the desired process performance. Since this approach is based on an algebraic algorithm, any number of properties can be tracked simultaneously.

Keywords: Property Operators, Reverse problem formulation, Molecular Design

1. Introduction

The identification of optimal molecule(s) corresponding to optimum process performance is a challenging issue. To achieve this goal, it is necessary to consider the aspects of both process and product design simultaneously. The concept of reverse problem formulation (RPF) has helped to formulate the integrated process-product design problems without leading to MINLP formulations (Eden *et al.*, 2003a). Techniques have been developed by Eden *et al.* (2003a, 2003b) for the identification of property targets corresponding to the optimum process performance using a visual approach. Algorithms to identify the molecules that meet the process targets have been developed by Eljack *et al.* (2007) and Chemmangattuvalappil *et al.* (2009). However, there is a need for a simultaneous algorithm that can be used to identify the suitable molecules corresponding to specific process performance. Since the process performance may depend upon several properties, the algorithm should be able to solve for any number of properties.

2. Normalized Process Property Operators

Property operators are functions of the original properties tailored to obey linear mixing rules (Shelley and El-Halwagi, 2000) so that they can be used to add the property

contributions from different streams linearly to obtain the property operator corresponding to the product stream:

$$\psi_j(P_{jm}) = \sum_{s=1}^{N_s} x_s \psi_j(P_{js}) \tag{1}$$

Where $\psi_j(P_{js})$ is the property operator of the j^{th} property P_{js} of stream s, x_s is the fractional contribution and N_s is the total number of streams. To allow comparison of different property values on a single platform, property operators are made dimensionless by dividing it by an appropriately chosen property reference. The general dimensionless property operator mixing rule can be estimated as follows:

$$\Omega_j(P_{jm}) = \sum_{s=1}^{N_s} x_s \Omega_j(P_{js}) \tag{2}$$

3. Group Contribution Method for Property Estimation

The group contribution method (GCM) provides a convenient way to relate molecular structures to properties. In GCM, the property function $f(Y)$ of a compound is estimated as the sum of the property contributions of all the molecular groups present in the structure (Marrero and Gani, 2001):

$$f(Y) = \sum_i N_i C_i + \sum_s N_s C_s + \sum_t N_t C_t \tag{3}$$

N_i, N_s and N_t are the numbers of first, second and third order groups and C_i, C_s, C_t are their respective property contributions.

4. Molecular Property Operators

The property models in GCM can be used for molecular design. Molecular property operator ψ^M is defined as (Eljack *et al.*, 2007):

$$\psi_j^M(P_{jm}) = \sum_{g=1}^{N_g} n_g P_{jg} \tag{4}$$

Where, P_{jg} is the contribution of property j from group g, n_g is the total number of that group in the molecule.

5. Simultaneous Process and Molecular Design

Since, both process and molecular property operators target the same optimum process performance, the set of inequality expressions can be solved simultaneously to identify the molecules that meet the ideal process performance. Since the approach is based on an algebraic algorithm, any number of properties can be tracked.

5.1. Estimation of number of first order groups

The mathematical expression for the Free Bond Number (*FBN*), which is the number of free bonds in each molecular string, is (Eljack *et al.*, 2007):

$$FBN = \sum_{g=1}^{N_g} n_g FBN_g - 2\left(\sum_{g=1}^{N_g} n_g FBN_g - 1\right) - 2N_r \tag{5}$$

Where, N_r is the number of rings in the final molecule and FBN_g is the number of free bonds in each group. The following expressions can be developed to ensure the existence of a meaningful molecule.

$$n_g \geq 0 \quad , \quad \sum n_{gr} \geq 3 \text{ or } 0 \quad , \quad FBN = 0 \tag{6}$$

The property targets to be satisfied by the sink can be stated as:

$$P_j^{lower} \leq P_j \leq P_j^{upper} \tag{7}$$

The normalized property operators corresponding to these targets can be written as:

$$\Omega_j^{lower} \leq \Omega_j \leq \Omega_j^{upper} \tag{8}$$

It is evident that, for each property, there will be two inequality expressions; one for the minimum value and the other for the maximum value for a given sink (Qin *et al.*, 2004). The Normalized process property operator is expressed as a function of normalized molecular property operators to allow the integration of process and molecular design problems. Equations 4-9 are solved simultaneously to find the maximum values of n_g.

$$\Omega_j = f(\psi_j^M) \tag{9}$$

5.2. Molecular Design

In order to increase the accuracy of property based molecular design techniques, the effects of higher order molecular groups are to be considered while designing molecules. The following methodology has been developed to estimate the contributions of higher order groups (Chemmangattuvalappil *et al,* 2008):

Rule 1. Higher order groups can only be formed from complete molecular fragments.
Rule 2. If any of the higher order groups completely overlap some other higher order group, only the larger group must be chosen in order to prevent redundant description of the same molecular fragment.

So, if (k: n) is the set of first order groups that are the building blocks of one second order group, s, (n_{gk}:n_{gn}) is the number of those first order groups present in the molecule, η is the number of occurrences of one particular first order group in a selected second order group, n_{gs} is the number of possible second order groups from those first order groups, then:

$$n_{gs} = Min\left(\frac{n_{gk}}{\eta_k} : \frac{n_{gn}}{\eta_n}\right) \tag{10}$$

n_{gs} must be rounded down to the nearest integer number according to Rule 1. If Ω_{jg2} is the property contribution from the second order groups, the normalized property operator for the property contributions from second order groups, Ω_{ijs} is calculated as:

$$\Omega_{ijs} = \sum_{s=1}^{N_S} n_{gs}\Omega_{jg2} \tag{11}$$

If (n_{gk}:n_{gn}) has subsets of smaller second order groups (n_{gl}:n_{gm}), the number of those small second order groups, n^*_{gs} is found by:

$$n_{gs}^{*} = Min\left(\frac{n_{gl}}{\eta_l} : \frac{n_{gm}}{\eta_m}\right) - Min\left(\frac{n_{gk}}{\eta_k} : \frac{n_{gn}}{\eta_n}\right) \quad (12)$$

According to Rule 1, this must be rounded down to the nearest integer. The third order effects can be calculated using the same approach. The normalized property operator for molecule *i* can now be estimated as (Chemmangattuvalappil *et al,* 2009):

$$\Omega_{ij} = \Omega_{ijf} + \Omega_{ijs} + \Omega_{ijs}^{*} + \Omega_{ijt} + \Omega_{ijt}^{*} \quad (13)$$

Where Ω^{*}_{ij} corresponds to the property value from overlapped small groups. Now, utilizing the above rules the maximum number of second and third order groups are found for each first order group combination without invoking Rule 2. All possible combinations of the numbers $[0,n_g]$, $[0,n_{gs}]$ and $[0,n_{gt}]$ are generated subject to following constraints based on Rule 2.

$$n_{ga}^{x} + n_{ga}^{y} \leq \max(n_{ga}^{x}) \quad (14)$$

Where *a* is *s* or *t* indicating second or third order group and *x* is a group that is completely overlapped by *y*. The above method of generation enables the identification of isomers as the possibility of nonexistence of each second and third order groups is considered. The possible molecules are screened out by checking if the combination of all the groups satisfies Eqs. 4 and 7.

6. Case Study

A current gas treatment process uses fresh methyl diethanol amine, MDEA, ($HO-(CH_2)_4-CH_3N-OH$) and two other recycled process sources (*S*1, and *S*2) as a feed into the acid gas removal unit. Another process stream, *S*3, currently a waste stream could be recycled as a feed if mixed with a fresh source to allow the mixed stream properties to match the sink (Kazantzi *et al.*, 2007). Design objectives and requirements are to find a solvent that will replace MDEA as a fresh source and that will maximize the flow rate of all available sources (*S*1, *S*2 and *S*3). The following three properties are considered: critical volume (V_c), heat of vaporization (H_v) and heat of fusion (H_{fus}). Additionally, two thermal constraints are imposed on the synthesized molecules to make sure that the designed molecule will remain in liquid state at the process conditions and to prevent excessive solvent losses via evaporation. The process property targets and flow rate data for all streams (*S*1, *S*2 and S3) and the sink along with the property operators corresponding to each property are summarized in Table 1.

Table 1. Property data for gas purification

Pj	Property Operators	Property Bounds on Sink	S1	S2	S3
V_c	$V_{cM} = \sum_{s=1}^{Ns} x_s \cdot V_{cs}$	530-610	754	730	790
H_v	$H_{vM} = \sum_{s=1}^{Ns} x_s \cdot H_{vs}$	100-115	113	125	70
H_{fus}	$H_{fusM} = \sum_{s=1}^{Ns} x_s \cdot H_{fuss}$	20-40	15	15	20
Flowrate		300	50	70	30

The property operators for the target properties are given in table 2 and the property contributions of all the candidate groups are obtained from Marrero and Gani (2001).

Table 2. Property targets

P_j	ψ_j	Adjustable Parameter	Property Bounds
T_b	$\exp\left(\frac{T}{t_{b0}}\right)$	222.543	532-547
T_m	$\exp\left(\frac{T}{t_{m0}}\right)$	147.45	<380
V_c	$V_c - V_{c0}$	7.95	
H_v	$H_v - h_{v0}$	11.733	
H_{fus}	$H_{fus} - h_{fus0}$	-2.806	

Fourteen first order groups have been considered for molecular design. To insure water solubility and to reduce vapor pressure, the amine must have two or more –OH groups. To limit the extent of corrosion, only one amino group is allowed to be in the amine (N in the amino group either connects to H or C). Finally, to limit detrimental effects of direct exposure to the solvent, tertiary amines are ruled out in this case study.

The functions to link property operators found on process and molecular side are formed based on Eqs. 1, 2, 4 and 9. The combined property operator (Eq. 13) of the preselected first order groups in terms of unknown maximum number of each first order group and their molecular property data (Marrero and Gani, 2001) is found. For example, the generated expressions for critical volume are shown below:

$$V_{CM} = x_f * V_{Cf} + x_{S1} * 754 + x_{S2} * 730 + x_{S3} * 790$$

$$V_{CM} = x_f * (V_C + 7.95) + x_{S1} * 754 + x_{S2} * 730 + x_{S3} * 790$$

$$V_C - 7.95 = n_1 * 68.35 + n_2 * 56.28 + n_3 * 37.5 + n_4 * 30.61 + n_5 * 88.2 + n_6 * 74.03 + n_7 * 60.06$$
$$+ n_8 * 117.62 + n_9 * 76.36 + n_{10} * 77.04 + n_{11} * 95.15 + n_{12} * 99.16 + n_{13} * 16.01 + n_{14} * 52.96$$

Similar equations are written for all properties and the maximum number of each first order group is then found solving the equations subject to constraints given by Eqs. 5-8.

CH_3:2 CH_2:1 CH:1 C:1 OH:3 CH_3O:2 CH_2O:1 CHO:1 CH_2NH_2:1 $CHNH_2$:1 CH_3NH:1 CH_2NH:1 CHNH:1 CO:1

Now, different combinations of these first order groups are generated. Possible second and third order groups are screened out and their maximum number is calculated using Eq. 10 and their various possible combinations are generated for each combination of first order groups subject to Eq. 14. Equations 4 and 7 along with the thermal constraints are used to screen the molecules and the structural feasibility of the designed molecules is checked using Eqs. 5 and 6. The final solution is given in Table 3 below.

The generated molecular structures have the properties consistent with the property limits of the sink and also since the second step of the simultaneous design considers the elimination of each possible second and third order groups, successful detection of isomers is reached.

7. Conclusions

In this work, an algorithm has been developed that solves process and molecular design problems simultaneously to find the molecules that would fit the process. Here, an algebraic approach has been followed which ensured that any number of properties can be tracked. In future works, the algorithm will be extended to identify the best molecule considering cost and environmental impact while also concentrating on optimizing the fractional recycle of different feeds.

Abstract

The design of batch plants necessary involves how equipment may be utilized, which means that plant scheduling and production must form an integral part of the design problem. The market demand for such products is usually changeable, and at the stage of conceptual design of a batch plant, it is almost impossible to obtain the precise information on the future product demand over the lifetime of the plant. This paper addresses the problem of the optimal design of batch plants with imprecise demands and proposes an alternative treatment of the imprecision by using concepts of fuzzy logic. For this purpose, we extended a Multi-Objective Genetic Algorithm (MOGA) developed in previous works, taking into account simultaneously three criteria, i.e. minimization of the investment cost, the operation cost and the total production time. The case of study is a multiproduct batch plant for the production of proteins taken from the literature. The methodology provides a set of scenarios that are helpful to the decision's maker and constitutes a very promising framework for taken imprecision into account in new product development stage.

Keywords: Multi-objective optimization, genetic algorithm, fuzzy arithmetic.

1. Introduction

In recent years, there has been an increased interest in the design of batch processes due to the growth of specialty chemical, pharmaceutical, and related industries, because they are a preferred operating method for manufacturing small volumes of high-value products. The market demand for such products is usually changeable, and at the stage of conceptual design of a batch plant, it is almost impossible to obtain the precise information on the future product demand over the lifetime of the plant. However, decisions must be made on the plant capacity. This capacity should be able to balance the product demand satisfaction and extra plant capacity in order to reduce the loss on the excessive investment cost or that on market share due to the varying demands on products. Consequently, the mission of the designer, assisted by traditional tools, may prove to be hazardous and makes essential the resort to a more robust approach.
The design of multiproduct batch plants has been an active area of research over the past decade. Most of the work has been yet limited to deterministic approaches, wherein the problem parameters are assumed to be known with certainty. However, in reality

there can be uncertainty in a number of factors such as processing times, costs, demands, and not all the requirements placed by the technology of the process and the properties of the substances are defined. To cope with this, there has been increased interest in the development of different types of probabilistic models that explicitly take into account the various uncertainties (Sahinidis, 2003). For instance, Wellons and Reklaitis proposed an MINLP model for the design of batch plants under uncertainty with staged capacity expansions. Based on the structure of multiproduct batch plants, Straub and Grossmann (1992) developed an efficient procedure to evaluate the expected stochastic flexibility, embedded within an optimization framework for selecting the design (size and number of parallel equipment). Two-stage stochastic programming approaches have also been applied for design under uncertainty (Ierapetritou and Pistikopolous (1996); Harding and Floudas (1997); Petkov and Maranas (1998); Cao and Yuan (2002).

The key point in the optimal design of batch plants under imprecision concerns modeling of demand variations. The most common approaches treated in the dedicated literature represent the demand uncertainty with a probabilistic frame by means of Gaussian distributions. Yet, this assumption does not seem to be a reliable representation of the reality, since in practice the parameters are interdependent, leading to very hard computations of conditional probabilities, and do not follow symmetric distribution rules. In this work, fuzzy concepts and arithmetic constitute an alternative to describe the imprecise nature on product demands.

For this purpose, we extended a multi-objective genetic algorithm, developed in previous works (Dietz et al. 2005). For instance, the optimal design of a multiproduct batch chemical plant is not only to minimize the investment, but also to minimize the operation cost and to minimize the total production time, simultaneously. The paper is organized as follows. Section 2 is devoted to process description and problem formulation. Section 3 presents a brief overview of fuzzy set theory involved in the fuzzy framework within a multi-objective genetic algorithm. The presentation is then illustrated by some typical results in Section 4.

2. Process description and problem formulation

In previous works (Dietz et al., 2005, 2006), batch plant design was carried out minimizing the investment cost and the production system was represented using discrete event simulation techniques in order to take into account different production policies. Two strategies for campaign policies were tested, either monoproduct or multiproduct. In this work, only the monoproduct campaign policy was considered, so that the computation of cycle time can be easily implemented using the classical formulation proposed in (Montagna et al., 2000), involving size and time equations as well as constraints. The model uses the formulation presented in (Modi and Karimi, 1989), then modified in (Xu et al., 1993), for multiproduct batch plant design formulation. It considers not only treatment in batch stages, which usually appears in all kinds of formulation, but also represents semi-continuous units that are part of the whole process (pumps, heat exchangers…). Let us recall that a semi-continuous unit is defined as a continuous unit working by alternating low-activity and normal activity periods. Besides, this formulation takes into account short-term or mid-term intermediate storage tanks. They are used to divide the whole process into sub-processes, in order to store materials corresponding to the difference of each sub-process productivity. This representation mode confers to the plant a major flexibility for numerical resolution, by preventing the whole process production from being

paralysed by one bottleneck stage. Therefore, a batch plant is finally represented by series of batch stages (B), semi-continuous stages (SC) and storage tanks (T).
The model considers the synthesis of I products treated in J batch stages and K semi-continuous stages. Each batch stage consists of m_j out-of-phase parallel items of same size V_j. Each semi-continuous stage consists of n_k out-of-phase parallel items of same processing rate R_k. The item size (continuous variables) and equipment number per stage (discrete variables) are bounded. The *S-1* storage tanks, of size V_s*, divide the whole process into S sub-processes.
For instance, the optimal design of a multiproduct batch chemical plant is not only to minimize the investment, but also to minimize the operation cost and to minimize the total production time, simultaneously. Then, an optimal design problem becomes a MOOP as following:

$$Min\ (Cost) = \sum_{j=1}^{J} (m_j a_j V_j^{\alpha_j}) + \sum_{k=1}^{K} (n_k b_k R_k^{\beta_k}) + \sum_{s=1}^{S} (c_s V_s^{\gamma_s}) \tag{1}$$

$$Min\ (D_p) = \sum_{i=1}^{N} \sum_{j=1}^{M} C_{E_j} \frac{Q_i}{B_{is}} + C_{O_i} Q_i \tag{2}$$

$$Min\ (H) = \sum_{i=1}^{I} \frac{Q_i}{B_{is}} T_{is}^{L} \tag{3}$$

The problem statement involves four forms of different constraints as reported in literature: (i) Dimension constraints: every units has to restrict to its allowable range. (ii) Time constraint: the summation of available production time for all products is inferior to the total production time. (iii) Limiting cycle time for product i. (iv) Volume constraints: the volume V_j has to be able to process all the products i.

3. Overview of fuzzy multiobjective genetic algorithm approach

3.1. Representation of fuzzy demands and time horizon due-date
In the context of engineering design, an imprecise variable is a variable that may potentially assume any value within a possible range because the designer does not know *a priori* the final value that will emerge from the design process. The fuzzy set theory was introduced by Zadeh to deal with problems in which a source of vagueness is involved. The proposed approach involves arithmetic operations on fuzzy numbers and quantifies the imprecision of the demand by means of fuzzy sets (trapezoidal). In this case, the flat line over the interval (q_2,q_3) represents the precise demands with an interval of confidence at level α=1, while the intervals (q_1,q_2) and (q_3,q_4) represent the "more or less possible values" of the demand. The result of the *total production time* $\widetilde{H}_i$ and the operation cost are treated and analyzed through fuzzy numbers. The time horizon $\widetilde{H}$ represented by a fuzzy expression (rectangle) and the production time $\widetilde{H}_i$ (trapezoidal) are fuzzy quantities, three different cases for determination of the criterion may occur, as shown in figure 1. The temporal criterion selected is called "common surface", representing the intersection between the sum of the production time (trapezoid) and the horizon of time to respect (rectangle). The calculation of the criterion depends on each case: for instance, case1 illustrate the solutions which arrive just in time.

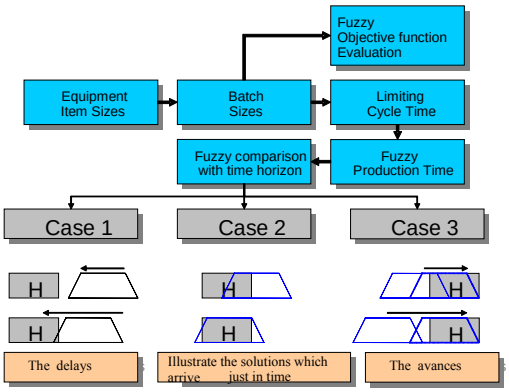

Figure 1 – Fuzzy evaluation procedure in the GA

3.2. Overview of multi-objective genetic algorithm approach

The multi-objective genetic algorithm presented elsewhere (Dietz et al., 2005) was then extended to take into account the fuzzy nature of both demand and horizon time. Let us mention that that the same encoding procedure was adopted since no fuzzy parameter is involved at that stage. The originality of this proposed research is that fuzziness is maintained throughout the computation procedure and no defuzzification is operated so that fuzzy results are proposed to the decision's maker. The tunable parameters of the GA will also not be discussed here. More detail can be found in (Dietz et al., 2006). They involve addition, subtraction, taking the maximum of two fuzzy numbers (mainly at the selection stage and at the Pareto sort procedure), through the extension principle of (Zadeh, 1975). Although there is a large body of literature that deals with the comparison of fuzzy numbers, the approach proposed by (Liou and Wang, 1992) was finally adopted here.

3.3. Treatment of an illustrative example

The case of study is a multiproduct batch plant for the production of proteins taken from the literature (Montagna et al., 2000), (Pinto et al., 2001). The batch plant involves eight stages for producing three recombinant proteins, on one hand two therapeutic proteins, Human insulin (I) and Vaccine for Hepatitis B (V) and, on the other hand, a food grade protein, Chymosin (C). This example is used as a benchmark since short-cut models describing the unit operations involved in the process are available.

The GA parameters are the following ones: Population size 200 individuals, number of generations 400 iterations, crossover probability 40%, mutation probability 30% and the stop criterion considered in this study concerns a maximum number of generations to reach. For the considered example, table 1 shows the values for processing times, size factor for the units, cost data, and the production requirement for each product quantifying the imprecision of the demand by means of fuzzy numbers representing the "more or less possible values".

4. Typical results

The method proposes a sufficiently large range of compromise solutions making it possible to the decision's maker to tackle the problem of the final choice, with relevant

information for his final choice. The result obtained of the multi-objective optimization problem involves 200 non-dominated solutions: among them, 4 represent the case 2, where the production time H_i (trapezoidal) is within of time horizon H (rectangle), 2 represent the first case (the delay) and 194 represent the case 3(the advance).
This study leads to three different scenarios as a fuzzy decision-making approach to preliminary design. Table 2 shows the solution that minimizes the investment cost for case 2. Tables 3 and 4 present the results that minimize the total production time and minimize the investment cost (cases 1 and 3), respectively.

5. Conclusions

In this paper, we have proposed a fuzzy approach to the treatment of imprecise demands in the batch design problem. In real application, designers not only require to minimize

investment, but also to minimize the operation cost and horizon time, simultaneously. An example was used to show the significance of the proposed approach. The results show that a set of compromise solutions is generated to the decision's maker, with an acceptable degree of imprecision affecting the defined criteria, which seems more realistic than a classical crisp approach. This approach will reduce the risk of making design decisions incorrectly. The results obtained on the treated example have shown that three different scenarios were obtained as a fuzzy decision-making approach. Finally, this framework provides an interesting decision-making approach to design multiproduct batch plants under conflicting goals.

Abstract

In recent years, numerical simulation and optimization of chemical reactors in general, and polymerization reactors in particular, have become increasingly popular as a means of understanding the behavior of reactors and improving their performance. The commercial importance of Nylon 6 has stimulated a considerable amount of research directed towards the modeling and simulation of its polymerization through the hydrolytic route in various industrial reactors. Computer simulations based on the mathematical modeling of the polymerization process are of paramount importance for quality control and operational optimization of the existing plant, as well as in the design of similar new plants. The major objective in this work will be to apply modeling and simulation tools for development of new application for Nylon 6. The intention is to be able to correlate reaction parameters and operational parameters (as monomer concentration, water and additives, operational temperature), to final desired properties of the obtained polymer – especially to molecular weight (aiming the polymer production matching specifications to a desired application). In addition, that correlation analysis allows evaluating the variation on polymers production rate – (higher production that minimizes production costs). To make possible to meet such objectives its coupled experimental design procedure together with the nylon reactor mathematical modeling and literature information. The developed procedure showed to be an interesting and important tool to develop products with the required specification whereas keeping lower production costs.

Keywords: simulation, hydrolytic polymerization, Nylon 6

1. Introduction

With the recent trend of building small flexible plants that are close to the market of consumption, there has been renewed interest in batch processes. Since commonly the production volumes are low, batch plants are often multiproduct facilities in which the various products share the same pieces of equipment. This requires that the production in these plants be scheduled.

Considering the economic scale of Nylon 6 production, it is not surprising that a number of polymerization models based on first principles have appeared [1-4]. These models attempt to apply knowledge of kinetics, physical and thermodynamic properties, mass and energy transport, and phase equilibrium to simulate a manufacturing process.

Several examples may be mentioned in which the use of an accurate model allows to improve the product quality, increase the production rate, and reduce production costs. The hydrolytic polymerization of ε-caprolactam is an important commercial process and has drawn the attention of many researches. It will be considered in this work as step required for the development of nylon as an engineering plastic.

1.1. Commercial Nylon 6 Manufacturing Process

The reactor feed typically contains fresh caprolactam monomer, recycled monomer, water and desired additives [5], such as chain-terminating agents (monofunctional amines and carboxylic acids). The process covers the monomer hydrolyzes, the conversion to a polymer, and the building up the polymer molecular weight as a function of the polymer application.

Because the molten polymer is in equilibrium with water and monomer, the byproduct water must be removed by vaporization to increase the molecular weight. However, vaporization of the water may also remove a significant amount of caprolactam, which is recovered and recycled.

In conventional processes, the polymer is then pelletized and leached with hot water to remove low-molecular-weight extractables, such as residual monomer and cyclic oligomers. The polymer is then dried and shipped elsewhere. Figure 1 depicts a conventional Nylon 6 production scheme.

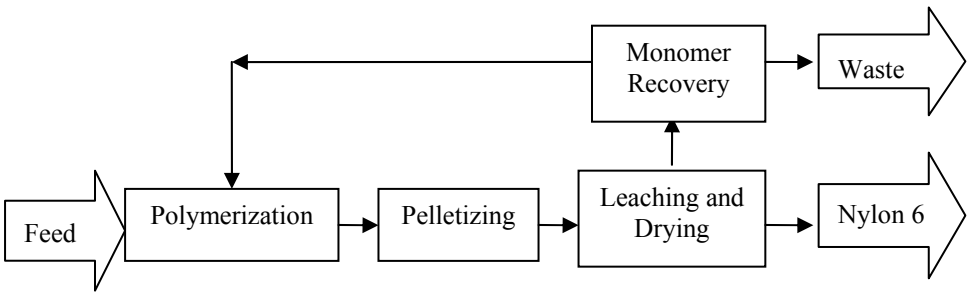

Figure 1 – Block diagram of a conventional Nylon 6 polymerization process.

1.2. Nylon 6 polymerization kinetics

The initial stage for the kinetic model development of reaction consists of the definition of chemical species that will be considered. In general, and also in this work, these species include water (W), ε-caprolactam (CL), cyclic dimmer (CD), monofunctional acid termination, such as acetic acid (AA), monofunctional amin (cyclohexilamin) and polymer.

For all equilibrium reactions considered here that do not involve chain terminator, it were adopted scheme and kinetic proposed by Arai *et al.* (1981), largely utilized in the majority of Nylon 6 kinetic studies published. For the monofunctional acid termination reaction, the scheme proposed by Gupta and Kumar (1987) was adopted. For the termination reaction scheme of the monofunctional amin, a similar behavior to the amino terminal groups was assumed (two reactions, without considering the reactions with oligomers).

The main studies of polymerization reaction modeling of Nylon 6 that exist in literature ignore the formation of superior cyclic oligomers, only considering the dimmers formation. These studies are according to the assumption that the majority of cyclic oligomers exists as dimmer.

Arai *et al.*[6] have presented the accepted standard regarding the chemistry and kinetics of the hydrolytic polymerization of ε-caprolactam. Their reaction mechanism includes

the ring opening of caprolactam (CL), polycondensation, polyaddition of CL, ring opening of a cyclic dimmer (CD), and polyaddition of a CD, as given in Table I.

Table I –Nylon 6 hydrolytic polymerization reaction mechanisms[a]

Reaction name	Equilibrium reaction
Ring opening of caprolactam	$W + CL \underset{k_1'}{\overset{k_1}{\leftrightarrow}} P_1$
Polycondensation	$P_m + P_n \underset{k_2'}{\overset{k_2}{\leftrightarrow}} P_{m+n} + W$
Polyaddition of caprolactam	$CL + P_n \underset{k_3'}{\overset{k_3}{\leftrightarrow}} P_{n+1}$
Ring opening of cyclic dimmer	$W + CD \underset{k_4'}{\overset{k_4}{\leftrightarrow}} P_2$
Polyaddition of cyclic dimmer	$CD + P_n \underset{k_5'}{\overset{k_5}{\leftrightarrow}} P_{n+2}$

[a]P_1 is aminocaproic acid. P_n is a Nylon 6 molecule with a degree of polymerization *n*.

In this work, one more equilibrium reaction to this kinetic scheme was added: the termination reaction with a monofunctional acid, such as acetic acid:

$$AA + P_n \underset{k_2}{\overset{k_2'}{\leftrightarrow}} P_{nx} + W$$

It was assumed that this reaction follows the same kinetics as the polycondensation reaction, as in reference 2.
The analysis of cyclic oligomers higher then dimers was ignored for the sake of simplicity. Experimental data are required to identify the kinetic parameters are shown in the next section.

2. Experimental

The theoretical objective of this work is studying an Experimental Unit of batch polymerization, that comprehends a polymerization reactor (autoclave), a nitrogen supplement system (cylinders), a vacuum system (vacuum pump), a water supplement system for refrigeration and cleaning, a polymer granulation system (granulator), and a drying system to polymer (vacuum greenhouse). The processing recipe is described below.

Researches for development of new applications for Nylon 6 intend to correlate reaction parameters and operational parameters to final properties of the obtained polymer. To make possible that analysis was made an experimental design, after an ample literature examination. As a result, the selected variables to be controlled (since they have a considerable influence on the molecular weight of the obtained polymer and also on its production rate) were: monomer concentration (CL), water concentration (W), acetic acid concentration (AA) and temperature (T).
Table II presents the controlled variables (factors) and their variation levels used in the experimental design. This experimental design made possible an analysis of controlled

variables influence on polymer characteristics, in special on molecular weight, as well as on polymerization reaction rate.

Table II- Experimental design 2^4 with central point

Factor	**Levels**		
	-1	**0**	**+1**
CL	1700g	2000g	2300g
W	19,6g	37,1g	54,6g
AA	1,87g	3,57g	5,27g
T	240°C	260°C	280°C

3. Results and Discussion

In the experimental design obtained, the confidence limit chosen was 95%. Tables III and IV depict the variance analysis (ANOVA) for production rate and molecular weight, obtained through experimental design and simulations made with deterministic software of polymerization process modeling studied here.

Figures 2 and 4 show Pareto charts of the controlled variables effects. Analyzing these diagrams, the effect of the manipulated operational variables on production rate and polymer molecular weight can be evaluated. On the other hand, in Figures 3 and 5, the deviations between observed values and predicted values (calculated by models obtained through experimental design) can be observed.

3.1. Polymerization Rate

Through Figure 2, it can be observed that the production rate is strongly influenced by temperature and variation of water concentration. Production rate increases as temperature and water concentration increase. There is a synergic effect between these controlled variables. The variation effect of monomer (CL) and acetic acid (AA) concentrations were not significant on values range utilized. Figure 3 shows the diagram of predict values (by model) versus observed values. Through ANOVA and Figure 3, it can be observed that the model is satisfactory.

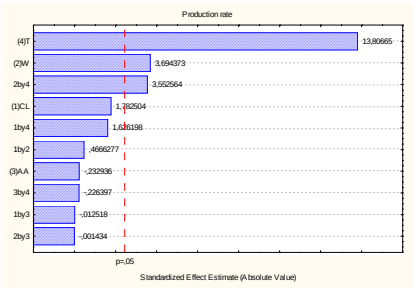

Figure 2 – Pareto chart for production rate

Table III – ANOVA in the form to analyze of the production rate model

	SS	**Freedom Degree**	**MS**	**$F_{calc.}$**	**$F_{tab.}$**	**$F_{calc./tab.}$**
Regression	0,000163	10	0,0000163	24,44	4,06	6,02
Residue	0,000004	6	$6,67*10^{-7}$			
Total	0,000167	16				

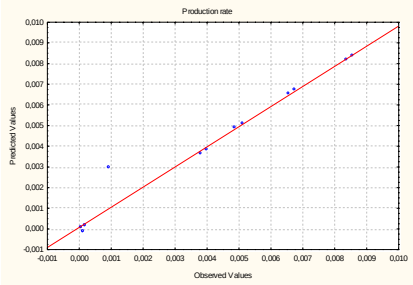

Figure 3 – Predicted values x observed values for production rate.

3.2. Molecular Weight

Through Figure 4, it can be seen that molecular weight is influenced by all controlled variables. This property decreases as water and acetic acid concentrations increase and it increases as the monomer concentration and temperature increase. There is a weak antagonist effect between water and monomer concentration. Figure 5 shows the diagram of predict values (by model) versus observed values. Through ANOVA and Figure 5, it can be concluded that the model is satisfactory.

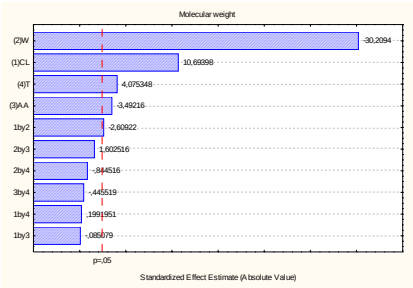

Figure 4 – Pareto chart for molecular weight.

Table IV – ANOVA in the form to analyze of the molecular weight model

	SS	**Freedom Degree**	**MS**	**$F_{calc.}$**	**$F_{tab.}$**	**$F_{calc./tab.}$**

Residue	3136709	6	522784,83			
Total	560480959	16				

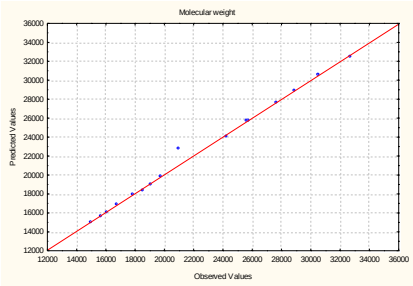

Figure 4 – Predicted values x observed values for molecular weight.

Figure 5 shows the response surfaces for production rate and molecular weight, considering the controlled variables more significant.

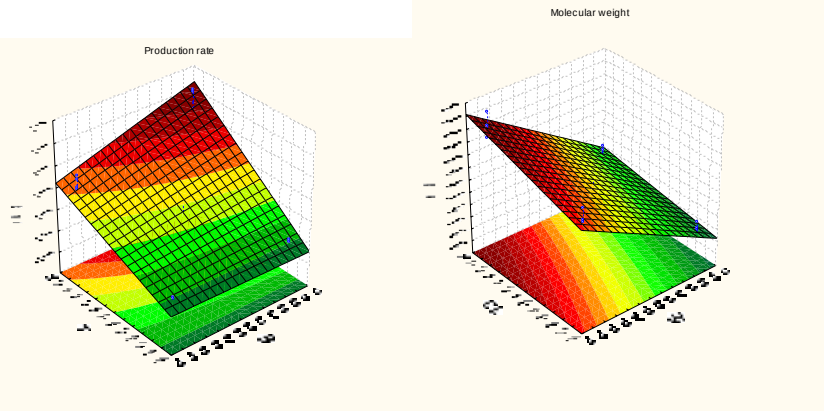

Figure 5 – Response surfaces for production rate and molecular weight.

4. Conclusions

A deterministic mathematic model was developed, enabling an influence analysis (of some controlled variables) on polymerization rate and on molecular weight of obtained polymers. This model can be used to propose optimization strategies aiming high conversions, assuming as restrictions the desired polymer properties for specific applications. This is specially required when rapid prototyping process are considered. The use of desired properties as restrictions is an interesting approach in the formulation of the optimization problem that, together a reliable mathematical model, allow the production of polymers with very tight specific properties.

Abstract

In this paper, a mathematical model of CO_2 chemical absorption system using MDEA (MethylDiEthanolAmine) and PZ (Piperazine) aqueous solutions is investigated. Precisely, the complex reactive absorption behavior is modeled by an NLP mathematical model. The resulting mathematical model is implemented in GAMS and CONOPT is used as NLP solver. The proposed model will allow to optimize the operating conditions to maximize the CO_2 capture. The model is successfully validated using data from the literature.

Keywords: CO_2 Alkaline Absorption, Optimization of Chemical Absorption Process.

1. Introduction

In recent years, the removal of CO_2 from industrial gas streams has become important. This has resulted from the environmental concern for reduction of greenhouse gas emissions from industrial sources. CO_2 is considered to be the largest contributor to the global warning problem, and is thus the major target for reduction.
Recent studies on the costs of different processes for CO_2 capture from power plants show that post-combustion CO_2 removal by absorption with chemical solvents has the potential to remain the most important process also in the future.
Extensive research activities are directed towards the optimization of the process and also the search for new environmentally friendly and energy efficient absorbents. Several models are available to analyze the solubility of CO_2 in aqueous solutions of alkanolamines and to correlate the equilibrium CO_2 loading. The electrolyte-NRTL, Deshmukh-Mather and the Kent-Eisenberg models are widely used.
Benamor et al. (2005) measured the CO_2 solubility and carbamate concentration in MDEA, DEA and their mixtures at various temperatures (303-323 K) and CO_2 partial pressure (0.09-100 kPa). The experimental equilibrium data for the absorption the CO_2 was analyzed using Deshmukh- Mather model.
Liu et al. (1999) measured the CO_2 solubility in aqueous mixtures of MDEA and PZ for temperatures and CO_2 partial pressures ranging from 303 to 363 K and 13.16 to 935.3 kPa. Experimental data were correlated using a modified Deshmukh–Mather thermodynamic model, in which the effect of salts on Henry's constant, is taken into consideration. They not consider PZ - carbamate formation because they have worked at high loading CO_2, so only protonation amine is considered.
Bishnoi et al. (2002) studied vapor-liquid equilibrium, speciation and amine solubility for the PZ/ MDEA/ H2O/ CO_2 system and modeled their results with electrolyte NRTL model. They take into account the formation of PZ - carbamate and the protonation of

PZ.
Kundu et al. (2006a, 2006b) presented experimental results about solubility of CO_2 in DEA/AMP/H_2O system and DEA/MDEA/H_2O. A modified Clegg-Pitzzer equation to develop a model for both quaternary systems was used by the authors.
In this paper, the complex behavior of the CO_2 absorption CO_2 chemical absorption into MDEA (MethylDiEthanolAmine) and PZ (Piperazine) aqueous solutions is modeled by using mathematical programming. The modeling of the system leads to a Non Linear NLP model. The resulting mathematical model is implemented in GAMS and CONOPT is used as NLP solver.

2. Thermodynamic model

The CO_2-MDEA-PZ-H_2O system includes the chemical reaction equilibria in the liquid phase, and also the gas-liquid equilibrium between two phases.
The modified Deshmukh- Mather thermodynamic model (Deshmukh et al.) is used for the liquid phase and the Peng-Robinson equation of state to describe the vapor phase (Peng et al. 1976).

The following main chemical reactions take place in the aqueous phase for the CO_2-MDEA-PZ-H_2O system:

$$PZH^+ \overset{K_1}{\rightleftarrows} PZ + H^+ \tag{1}$$

$$MDEAH^+ + \overset{K_2}{\rightleftarrows} MDEA + H^+ \tag{2}$$

$$H_2O + CO_2 \overset{K_3}{\rightleftarrows} H^+ + HCO_3^- \tag{3}$$

$$H_2O \overset{K_4}{\rightleftarrows} H^+ + OH^- \tag{4}$$

$$HCO_3^- \overset{K_5}{\rightleftarrows} H^+ + CO_3^{2-} \tag{5}$$

Due to the chemical reactions in the amine-acid-gases-water systems, there is a strong deviation from the ideality in the liquid phase. This behavior is included in the equilibrium constants expressions by activity coefficients (γ_i), which are calculated with the extended Debye-Huckel equation (E. Guggenheim et al). Interaction parameters (β_{ij}) are obtained from Liu et al (1999).

$$\ln(\gamma_i) = -\left(\frac{A \times z_i^2 \times I^{0.5}}{1 + I^{0.5}} \right) + 2 \times \beta_{ij} \times m_j \tag{6}$$

The corresponding thermodynamic equilibrium constants expressions are computed as follows:

$$K_1 = \left(\frac{m_{PZ} m_{H^+}}{m_{PZH^+}} \right) \left(\frac{g_{PZ} g_{H^+}}{g_{PZH^+}} \right) \tag{7}$$

$$K_2 = \left(\frac{m_{MDEA} m_{H^+}}{m_{MDEAH^+}} \right) \left(\frac{g_{MDEA} g_{H^+}}{g_{MDEAH^+}} \right) \tag{8}$$

$$K_3 = \left(\frac{m_{HCO_3^-} m_{H^+}}{m_{CO_2}} \right) \left(\frac{g_{HCO_3^-} g_{H^+}}{g_{CO_2}} \right) \left(\frac{1}{a_w} \right) \tag{9}$$

$$K_4 = \left(m_{H^+} m_{OH^-} \right) \left(g_{H^+} g_{OH^-} \right) \left(\frac{1}{a_w} \right) \tag{10}$$

$$K_5 = \left(\frac{m_{CO_3^{2-}} m_{H^+}}{m_{HCO_3^-}} \right) \left(\frac{g_{CO_3^{2-}} g_{H^+}}{g_{HCO_3^-}} \right) \tag{11}$$

The condition of electro-neutrality is given by:

$$m_{PZ} + m_{PZH^+} = \frac{c_1}{r} \tag{12}$$

$$m_{MDEA} + m_{MDEAH^+} = \frac{c_2}{r} \tag{13}$$

$$m_{CO_2} + m_{HCO_3^{2-}} + m_{CO_3^{2-}} = \frac{\left(c_1 + c_2 \right) a}{r} \tag{14}$$

$$m_{H^+} + m_{PZH^+} + m_{MDEAH^+} = m_{OH^-} + m_{HCO_3^-} + 2m_{CO_3^{2-}} \tag{15}$$

The equilibrium constants and Henry's constant used in the calculation are listed in Table 1.

The resulting mathematical model involves 69 variables and 60 constraints. The model was implemented in General Algebraic Modeling System GAMS. CONOPT was used as the solver for the resulting NLP model.

Finally, it is important to notice that the mathematical model can lead to multiple and/or local optimal solutions due to the non-convex constraints involved in the mathematical model.

$a_3 = -813702 - 295623\left(\frac{c_2}{r}\right) + 414660\left(\frac{c_2}{r}\right)^2 - 79674.6\left(\frac{c_2}{r}\right)^3$	

3. Study case, results and discussions

In this section, the proposed model is validated with the literature data and computational performance is presented. The following parameter set was used for the model validation: free PZ concentration: 0.7 mol/m^3, free MDEA concentration: 2.8 mol/m^3, temperature: 323 K.

Design data reported by Liu et al. (1999) are used for comparison purposes. For model testing, the proposed model was used as a "simulator" than an optimizer.

Figure 1 compares the model outputs with data taken from the literature. From the results shown in Fig. 1 it can be concluded that the values of all chemical species obtained from the model agree satisfactorily with those reported by Liu et al. (1999).

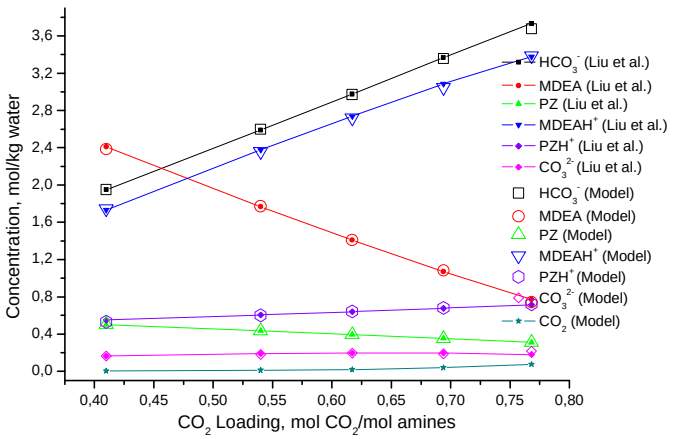

Figure 1. Model outputs vs. data taken from Liu et al (1999)

Computational aspects of the proposed model

Despite the simplicity of the model, the non-convex constraints involved by the mathematical model such as logarithms to compute the activity coefficients and bilinear terms can lead to computational problems and local solutions as well.

The convergence of the proposed model depends strongly on the initial values.

In order to guarantee the convergence of the proposed model, solutions from the simpler model are used as initial values to solve the detailed model. Thus, this initialization procedure improves the model convergence considerably.

The simplified model is based on the following assumptions:

- Effects on the mass and charge balance equations of the concentrations of H^+ and OH^- are neglected. This assumption is reasonable since the concentrations are low.
- All forms of the absorbed carbon dioxide are regarded as bicarbonate since the contents of CO_3 and CO_2 are also very low.

Figure 2 compares the values obtained from the simplified and detailed models.

As is shown in Fig. 2 it is possible to conclude that the simplified model can be effectively used to initialize the detailed model because the first model approximates well to the second one.

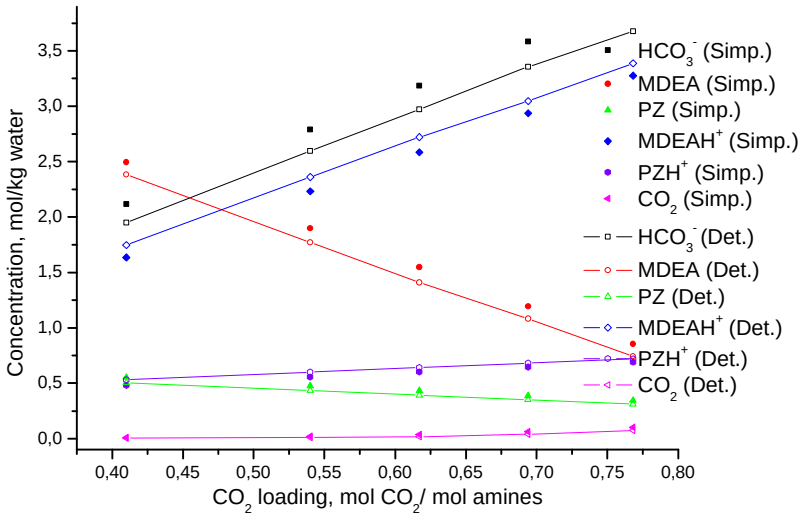

Figure 2. Comparison between simplied and detailed models

Conclusions and Future Work

A thermodynamic mathematical model for the CO_2 Capture with amines was developed. The model is successfully validated using data from the literature. The model proposed in this paper will be properly extended in order to develop a more detailed mathematical model which includes for example the energy balance.

The aim is to develop a model which allows to optimize the configuration and operating conditions of absorption and desorption columns. The assumption of simultaneous chemical and phase equilibria is not good enough for realistic process designs. Therefore, it is necessary the development of detailed and rate based models for packed or plate columns which allow to determine temperature and composition profiles along the columns. Those aspects will be addressed in future works and will be introduced gradually into the model here presented.

Abstract

A summary about our experiences in the introduction of heterogeneous entrainers in azeotropic and extractive batch distillation is presented in this work. Essential advantages of the application of heterogeneous entrainers are showed by rigorous simulation and experimental verification in a bench batch distillation column for separating several azeotropic mixtures such as acetonitrile – water, n hexane – ethyl acetate and chloroform – methanol, commonly found in pharmaceutical industry.

Keywords: heterogeneous entrainer, batch column, azeotropic and extractive distillation

1. Introduction

Batch distillation is widely used in pharmaceutical and specialty chemical industry to recover valuable components from waste of solvent mixtures. The regular presence of azeotropes restricts severely the number of feasible separations. Azeotropic and extractive distillations are the most common alternatives encountered in the industry, requiring the addition of a third component to enhance the volatility of the components.
Synthesis and design of a new batch distillation process is done in two steps: (1) selection of an adequate entrainer along with the column configuration and the corresponding product cut sequence. It can be done using a recent computer tool RegSolExpert® (ProSim SA) including an exhaustive set of rules for selecting both, homogeneous and heterogeneous entrainers and (2) the process design for determining the main operating parameters by using a batch process simulator such as ProSim Batch (ProSim SA). In general, heterogeneous entrainers have a more privileged position than homogeneous because a higher number of ternary diagrams are suitable. Indeed, more than 70% of the feasibility rules included in RegSolExpert® match up to heterogeneous entrainers. In this paper, we present a general procedure to systematize the search for an appropriate azeotropic or extractive distillation process enabling the separation of non-ideal binary mixtures by introducing heterogeneous entrainers.
Primary criteria for selecting feasible heterogeneous entrainer comprise the non pollutant component and the market availability. For the separation of aqueous-organic mixtures, many feasible entrainers could be found among those inducing a liquid-liquid phase split with water and vice versa, water seems to be a promising candidate for organic wastes. Essential features of the application of heterogeneous entrainers are showed by rigorous simulation and experimental verification in a bench batch distillation column for separating three commonly found mixtures: acetonitrile – water, n hexane – ethyl acetate and chloroform – methanol.

2. Heterogeneous entrainers in batch azeotropic distillation (HABD)

Azeotropic distillation in a batch rectifying column is based on the complete addition of an adequate amount of entrainer together with the azeotropic mixture as initial charge in the boiler. One unstable node given by a component or mixture can be drawn as a top product. The general feasibility criterion for selecting a heterogeneous entrainer can be summarized as follows: choose a low, intermediate or high boiling entrainer (E) giving rise to a ternary system in which the heterogeneous azeotrope is an unstable node of the residue curve map. The separation of all components is better if: (a) the heterogeneous azeotrope is binary instead of ternary, (b) the heteroazeotrope composition defines an approx. equal liquid phase split in the decanter and (c) the immiscibility gap is large leading to a high purity of the distillate and the entrainer-rich phase. These features will be analyzed considering two azeotropic mixtures: acetonitrile – water and n hexane – ethyl acetate in a batch rectifier and a quaternary mixture in a middle vessel column.

2.1. Rectifying column configuration

The mixture acetonitrile - water displays a minimum boiling azeotrope with $x_{acetonitrile}$ = 0.676 at 76.8°C. The initial entrainer candidate list included 91 entrainers spanning a wide spectrum of chemical families. According to RegSolExpert®, only 21 entrainers matched with some feasibility criterion (Gerbaud et al., 2006). Four homogeneous entrainers were rejected because the separation was possible due to the curvature of the distillation boundaries and led to complex sequences of operating tasks. From the 17 remains heterogeneous compounds only three light entrainers did not form ternary azeotrope: dichloromethane (39.4°C), chloroform (61°C) and acrylonitrile (77.3°C). Only chloroform and acrylonitrile were tested. Acrylonitrile has been found earlier by manual search (Rodriguez et al. 2002) in an experimental database (Gmehling, J., 1994). Figure 1a and 1b display the residue curve map for chloroform and acrylonitrile, respectively.

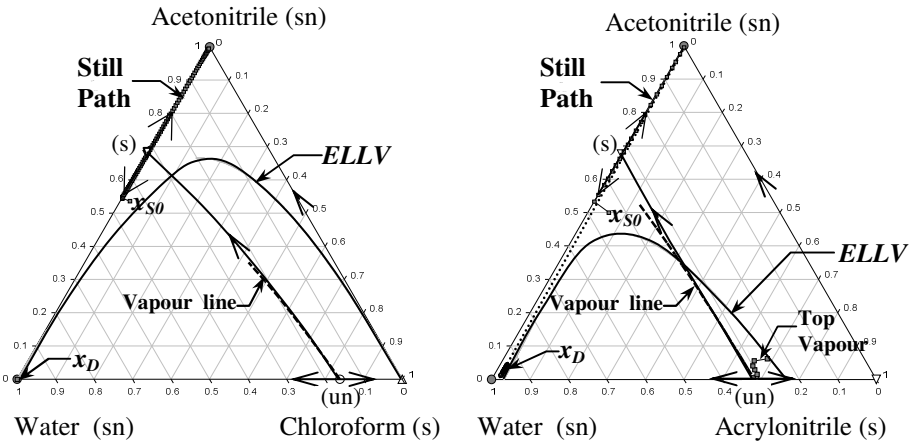

Figure 1. Residue curve map and simulation results of HABD.

Simulation results for both heterogeneous entrainers are reported in Table 1 considering only the reflux of the entrainer-rich phase and showing the superiority of chloroform in recovery and purity of all components. However, the operating times were very similar (about 6.5 hours) because both entrainers lead to a similar phase split ratio into the decanter from the condensed top vapour (about 0.16 in water-rich phase).

Table 1. Simulation results chloroform vs acrylonitrile

	Chloroform	Acrylonitrile (* experimental values)	
Aqueous	x_{Water}=0.9996	x_{Water}=0.947	*x_{Water}=0.946
Phase	$R_{ecovery}$=97.8%	$R_{ecovery}$=92.6%	*$R_{ecovery}$=89.0%
Entrainer	x_E=0.9990	x_E=0.712	*x_E=0.6916
Phase	$R_{ecovery}$=81.0%	$R_{ecovery}$=72.0%	*$R_{ecovery}$=69.0%
Final	$x_{acetonitrile}$= 0.9945	$x_{acetonitrile}$= 0.992	*$x_{acetonitrile}$= 0.995
Still	$R_{ecovery}$= 99.2%	$R_{ecovery}$= 95.6%	*$R_{ecovery}$= 91.8%

Experimental validation of HABD with acrylonitrile were carried out in a SHOTT batch distillation column available in a bench scale (Rodriguez et al., 2002; 2005) considering two reflux policies: case (1) only the reflux of acrylonitrile-rich phase from the decanter for the mixture acetonitrile – water and case (2) an additional reflux given by a portion of the condensed vapour by manipulating the open/close time of the solenoid valve for the separation of n hexane – ethyl acetate using acetonitrile. Experimental values are shown in Figure 1b and Table 1 for case (1) and Figure 2 displays the simulation and experimental results for the case (2) demonstrating the acceptable performance of the HABD process.

	simulation vs experiments	
n hexane phase	x_1=0.951 $R_{ecovery}$=95.0%	x_2=0.968 $R_{ecovery}$=94.5 %
entrainer phase	x_E=0.736 $R_{ecovery}$=54.5%	x_E=0.728 $R_{ecovery}$=48.4%
final still	x_2= 0.992 $R_{ecovery}$= 81.0%	x_2= 0.991 $R_{ecovery}$= 75.1%

Figure 2. Simulation and experimental results for n hexane – ethyl acetate – acetonitrile.

Those two examples bring important insights on HABD:

(a) less entrainer amount is required in the initial charge, compared to azeotropic distillation with a homogeneous entrainer.

(b) the liquid – liquid splitting of the top condensed vapour allows the straightforward withdrawal of one component (water or n hexane) as distillate,

(c) reflux policy can be versatile given by only the reflux of the entrainer-rich phase or by a combined reflux of both decanted phases (Rodriguez-Donis et al., 2002, Skouras et al., 2005),

(d) the adequate reflux policy displaces the typical distillation boundary of the residue curve map close to the binary side of azeotropic components. Therefore, the feasible region is not limited by the typical distillation boundary of the residue curve map anymore (Lang, 2006).

In HABD, the still path moves in a bigger region wherein it is connected to the binary heterogeneous vapour at the column top and the boiler can reach the stable node of acetonitrile at the end of the process (see still path in Figure 1 and 2 starting in x_{S0}). In the case of the sole reflux of the decanted entrainer-rich phase, the boundary of HABD is given by a hypothetical line joining the homogeneous azeotrope to be separated and the composition of the product-rich phase (dotted line in Figure 1b and 2). Although in both cases good agreement was obtained between simulation and experimental results, the reflux policy established in case (2) provided a more stable amount proportion of both liquid phases inside the decanter during the whole process. Theoretically as computed by simulation in Figure 1b and Figure 2, the composition of the top vapour stayed closer to the binary heteroazeotrope composition for case (2). As in continuous heterogeneous azeotropic distillation, liquid – liquid splitting occurred inside the top section in the SCHOTT column and experimental validations went well.

2.2. Middle vessel column configuration (MVC) with light or intermediate entrainer

Analysis of the heterogeneous azeotropic distillation in this column configuration has been made only by using rigorous simulation with ProSim Batch. MVC enable to split quaternary mixtures by a single task like the ternary mixtures using a batch rectifier. The separation of acrylonitrile (light entrainer) – acetonitrile – water – acetic acid mixture was studied elsewhere involving a single basic distillation region in the quaternary composition space (Rodriguez et al., 2001). The binary heteroazeotrope reaches the column top and a suitable reflux policy keep acetonitrile and acetic acid stay into the middle vessel and the boiler at the end of the process, respectively. Now, the use of an intermediate boiling heterogeneous entrainer (isobutyl acetate) is viable for separating a methanol – water – propanoic acid mixture (residue curve map in figure 3).

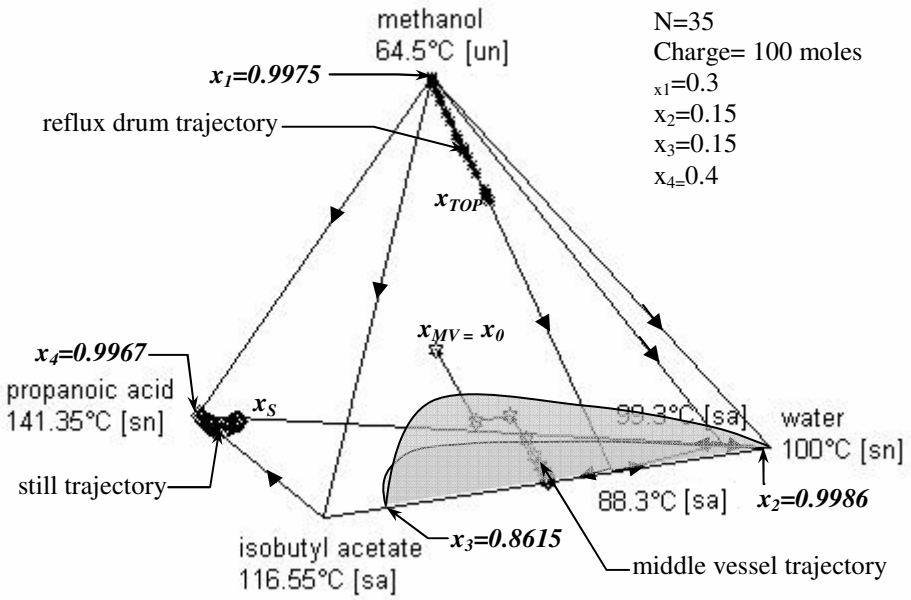

Figure 3. Separation of a quaternary mixture for HABD in a middle vessel column.

The homogeneous mixture methanol – water – propanoic acid exhibits a saddle azeotropic point and it can not be separated by conventional distillation process.

However, separation is feasible in a MVC by HABD with isobutyl acetate. Two binary azeotropes occur but in this case, both are saddle points and the composition space is divided by an unstable distillation boundary in two basic distillation regions. Methanol is the sole unstable node while water and propanoic acid are the stable nodes of their respective regions. The still initial charge into the still and the middle vessel (x_0) has to be located inside the region wherein propanoic acid is the stable node. Figure 3 displays the composition into the boiler (x_S) and the reflux drum (x_{top}) after the heat and liquid filling operation of the whole column. An adequate definition of the liquid holdup inside the reflux drum and the middle vessel allows the separation of four components by one single operating step under infinite reflux ratio. Methanol goes to the top reflux drum (x_1), propanoic acid concentrates into the boiler (x_4) and the saddle binary heteroazeotrope water (x_2) - isobutyl acetate (x_3) is kept into the middle vessel at the end of the process. Figure 3 shows the final composition and the composition path inside the still, the condenser and the middle vessel along with the column specifications operated under reflux total conditions until steady state is reached (after about 2 hours). Distillate removal or closed operation can start afterwards.

3. Heterogeneous entrainers in batch extractive distillation (HBED)

Extractive distillation is the most used process in the industry due to its operating simplicity. But, the selection of the entrainer is based mainly on a criterion: High boiling homogeneous entrainer forming no additional azeotropes. Despite the criterion simplicity, designing a new extractive distillation process is often complicated. Indeed, many suitable entrainers enhancing significantly the relative volatility of azeotropic components usually give rise to new binary and even ternary heterogeneous azeotropes, that are often saddles. Therefore, these entrainers were always considered as unfeasible although it is not the case using HEBD process (Rodriguez et al., 2003) because a more general criterion rules extractive distillation process feasibility (Rodriguez-Donis et al., 2009a, 2009b). Unlike to azeotropic distillation, the entrainer is fed continuously at some column position, leading to different column sections.

Our precedent works concerned three ternary mixtures: acetonitrile – water with butyl acetate, ethanol – water with ethyl acetate and chloroform – methanol with water (Rodriguez et al., 2003, Van Kaam et al. 2008). HEBD brings a few more advantages:

(1) HEBD in a batch rectifier is simpler than extractive batch distillation using a homogeneous entrainer fed at some intermediate tray, as is usual. Indeed, the heterogeneous entrainer can be fed at the column top leading only to an extractive column section and allowing the withdrawal of the saddle binary heteroazeotrope as top vapor. The further condensation of the top vapor generates two liquid phases similar to the heteroazeotropic distillation process,
(2) Water is often a suitable non pollutant heterogeneous entrainer for organic wastes treatment. And, organic compounds are suited for aqueous-organic wastes split.
(3) HEBD offers more ternary diagrams alternatives than the numerous HABD ones.

Experimental validation in the SCHOTT distillation column was recently performed for the separation of chloroform – methanol – water waste using the inner component, water, as heterogeneous entrainer. Figure 4 displays the simulation results (x_S) and the experimental verification (x_{exp}) of the process. Even if the performance of the process was good and adequate agreement between experiments and prediction was also obtained, extreme care must be taken with the regulation of the heat duty in the boiler. Accumulation of water into the boiler required a continuous increasing of the oil bath

temperature wherein the boiler was immersed. However, pollution of methanol in the chloroform-rich phase occurs rapidly if the correct ratio of the water flow rate and the vapor overflow inside the column is surpassed. Indeed, a significant amount of heterogeneous entrainer was required for the separation of all studied ternary system by HEBD given by the interception of the univolatility line α_{12} in the heterogeneous edge close to the entrainer vertex. A better column configuration must be considered such as middle vessel column or those having two boilers as proposed by Hua et al. (2007).

	Simulation Results		Experimental Results	
Products	Mol	x_{MOLAR}	Mol	x_{MOLAR}

4. Conclusions

Application of heterogeneous entrainer for separating non-ideal mixtures using azeotropic and extractive batch distillation demonstrated important advantages having a straight effect over the economy of the process: more potential candidates reducing the time of the preliminary process synthesis, less amount of entrainer is usually required, heterogeneous entrainer neutralizes the effect of the distillation boundaries of the residue curve map giving a bigger feasible region and allowing the separation of all components in one single operating task. For the separation of aqueous-organic mixtures, many feasible entrainers could be found among those inducing a liquid-liquid phase split with water and vice versa, water seems to be a promising candidate for separating organic wastes. Possibility of the use of non pollutant entrainers is increased.

In Situ Incorporation of Recycled Polymer in Suspension Polymerizations

Caio K. Melo, Matheus Soares, Príamo A. Melo and José Carlos Pinto

Programa de Engenharia Química / COPPE – Universidade Federal do Rio de Janeiro Cidade Universitária, CP: 68502, Rio de Janeiro, 21941-914 RJ, Brazil.

Abstract

Polymer materials find widespread use because of their characteristic low costs and wide range of end-use properties. However, the continuous accumulation of polymer materials in the environment constitutes a significant environmental problem. In order to promote the reutilization of used polymer materials, it is shown in this work that the *in situ* incorporation of recycled polystyrene into virgin polystyrene beads can be performed successfully during suspension polymerizations. The influence of increasing recycled polystyrene contents on the course of the polymerization is investigated. It is shown that the recycled polystyrene content does not affect the kinetics of the polymerization significantly, indicating that operation policies can be adapted to increasing amounts of recycled material with the help of common suspension polymerization models.

Keywords: Recycling, polymer, polystyrene, styrene, suspension polymerization.

1. Introduction

Polymer materials find widespread use because of their characteristic low costs and wide range of end-use properties. However, the continuous accumulation of polymer materials in the environment constitutes a significant environmental problem. However, polymer wastes should be regarded as raw materials for the manufacture of new products through recycling processes. Several techniques can be applied to reintroduce recycled products into the market with competitive performance, such as mechanical recycling, chemical recycling and energy production. Mechanical recycling usually requires the combination of high temperatures and shear stresses (energy consumption) in order to mix used polymers with other materials. Typical operation conditions can cause the thermo-oxidation and the degradation of the polymer product, hindering the final properties of the material (Luzuriaga, 2005). Chemical recycling usually requires depolymerization of the recycled material through solvolysis (e.g. hydrolysis and alcoholysis) or themal-catalytic methods (e.g. pyrolysis). In both cases, the obtained product is normally a complex mixture of monomer, oligomers and residues, requiring complex posterior purification. Energy production is usually achieved through combustion, producing toxic gases that must be removed from the gas exhaust before its final release in the atmosphere (Spinace, 2005).

Polystyrene is among the most popular polymer materials, used mainly for packing and production of disposable materials because of its low cost and good processability. However, final pieces are produced in large scale and most times present short lifecycle. For this reason, the waste management of polystyrene pieces constitutes an important environmental problem. Waste management procedures should certainly consider the

development of new technologies for waste reuse and recycle, instead of enhancement of polymer degradation in landfills (Vilaplana, 2008).
In order to promote the reutilization of used polymer materials, it is shown in this work that the *in situ* incorporation of recycled polystyrene into virgin polystyrene beads can be performed successfully during suspension polymerizations. The influence of increasing recycled polystyrene contents on the course of the polymerization is investigated. It is shown that the recycled polystyrene content does not affect the kinetics of the polymerization significantly, indicating that operation policies can be adapted to increasing amounts of recycled material with the help of common suspension polymerization models

2. In situ incorporation of additives during suspension polymerizations

It is known that additives can be incorporated *in situ* during suspension polymerizations in order to modify the final properties of the final material and develop specific applications. For example, x-ray contrast has been incorporated *in situ* into poly(methyl methacrylate) resins used for production of bone cements (Lemos, 2006). High impact polystyrene (HIPS) can also be produced through *in situ* incorporation of polybutadiene during the styrene suspension polymerization (Casis, 2005). The incorporation of additives during the polymerization process is advantageous, because improved homogeneity (and, consequently, enhanced mechanical properties) can be obtained. Despite that, recycling of used polymer materials through suspension polymerizations have seldomly been reported.

3. Experiments

3.1 Chemicals and Experimental Procedures

Styrene was provided by Nitriflex Resinas S/A, with a minimum purity of 99%. The suspending agent [poly(vinyl alcohol), PVA] and the initiator (benzoyl peroxide, BPO) with a minimum purity of 75% and moisture content of 25%, was supplied by Vetec Química Fina. Hydroquinone was supplied by Vetec Química Fina and used as a polymerization inhibitor to interrupt the polymerization of collected samples. Tetrahydrofuran (THF), used for GPC analyses, was supplied by Tedia Brasil with a minimum purity of 99.9%. Recycled polystyrene materials were obtained as clean disposable cups.

Table 1 – Basic polymerization recipe.

Component	*Mass*
Initiator BPO	4g
Stabilizer PVA	2.2g
Styrene	100g
Water	400g

Suspension polymerizations were carried out in a 1-L jacketed glass reactor (FGG Equipamentos Científicos Ltda) at 80 °C, with a total organic hold up of 20 wt %, unless stated otherwise. Initially, the reactor was fed with distilled water, containing the specified amount of suspending agent (PVA). When the desired temperature was

reached, the reagents and the initiator (BPO) were added. The system was kept under isothermal conditions with a constant agitation of 1000 rpm. The experimental setup is presented in Figure 1. The basic polymerization recipe is presented in Table 1. The specified amount of recycled polymer was dissolved in fresh monomer before monomer feeding.

The reactor was equipped with a reflux condenser, which was fed by a refrigeration bath (3). A heating bath (2) was used to keep the temperature of the reaction medium at the desired setpoint value. The mechanical agitator (5) was equipped with a helix-type impeller. The reactor temperature was monitored in-line with the help of a J-type thermocouple connected to a microcomputer (4).

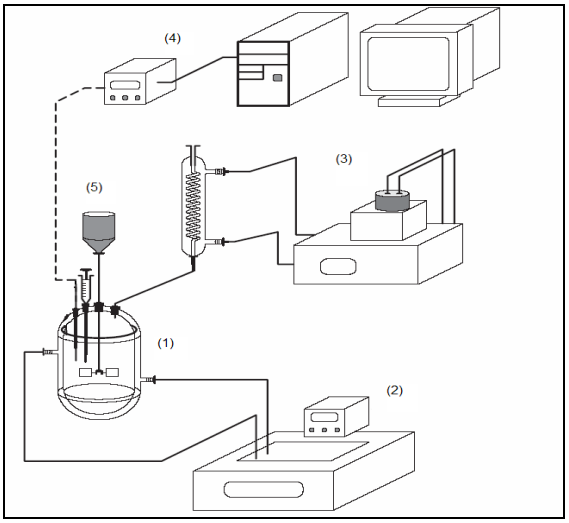

Figure 1 - Experimental Module.

4. Characterization

Samples of approximately 5.0 mL were withdrawn from the system at regular intervals of time for analyses. About 100 ppm of hydroquinone was used to halt the reaction just after the withdrawal of the samples. The total monomer conversion was determined through gravimetry by drying polymer samples until constant weight in a vacuum oven at 40 °C.

The weight-average molecular weight was measured through gel permeation chromatography (GPC). The system was composed of three linear columns with gel porosities ranging from 10^3 to 10^6 Å. A refractometer was used as the detector. The refractometer and the pumping system were connected to a personal computer for data acquisition and data handling. The calibration curve was built using samples of polystyrene with known molecular weight and a polydispersity index smaller than 1.05. Approximately 10-15 mg of dry polymer were dissolved into 2 mL of solvent and filtered through porous membrane filters prior to analysis. After filtration, 200 µL of the polymer solution was injected into the GPC system. Analyses were performed at 35 °C.

5. Model

5.1 Kinetic Model

The kinetic mechanism used to describe the styrene suspension polymerization comprises the usual initiation, propagation, transfer to monomer, inhibition and termination by combination steps, as shown in Table 2. Assuming that the long-chain and quasi-steady-state hypotheses are valid for the polymer radicals, it is possible to develop the following set of mass balance equations for the styrene polymerization process, as shown in Table 3. The well-known method of moments (Ray, 1972) was used for computation of molecular weight data. The kinetic parameters used on the model are presented in Table 4.

Table 2 – Kinetic mechanism.

Initiation by initiator decomposition	Chain transfer to monomer
$I \xrightarrow{K_d} 2R_1$	$R_i + M \xrightarrow{K_{tm}} \Theta_i + R_1$
Spontaneous thermal initiation	Termination by combination
$3M \xrightarrow{K_{th}} R_1(+D)$	$R_m + R_n \xrightarrow{K_{tc}} \Theta_{m+n}$
Monomer propagation	Inhibition
$R_i + M \xrightarrow{K_p} R_{i+1}$	$R_i + H \xrightarrow{K_{tS}} \Theta_i$

Table 3 – Mass balance equations for polymerization.

Initiator Mass Balance

$$\frac{dI}{dt} = -K_d I$$

Inhibitor Mass Balance

$$\frac{dH}{dt} = F_H - K_{tS}\left(\frac{H}{V_O}\right)\left(\frac{m_0}{V_O}\right)V_O$$

Monomer Mass Balance

$$\frac{dM}{dt} = -K_{th}\left(\frac{M}{V_O}\right)^3 V_O - (K_P + K_{tM})\left(\frac{M}{V_O}\right)\left(\frac{m_0}{V_O}\right)V_O$$

Live Chain Mass Balance

$$\frac{dR_i}{dt} = K_P\left(\frac{M}{V_O}\right)\left(\frac{R_{i-1}}{V_O}\right) - K_P\left(\frac{M}{V_O}\right)\left(\frac{R_i}{V_O}\right) - K_{tM}\left(\frac{M}{V_O}\right)\left(\frac{R_i}{V_O}\right) - K_{tS}\left(\frac{H}{V_O}\right)\left(\frac{R_i}{V_O}\right) - K_{tc}\left(\frac{m_0}{V_O}\right)\left(\frac{R_i}{V_O}\right)$$

Dead Chain Mass Balance

$$\frac{d\Theta_i}{dt} = K_{tM}\left(\frac{M}{V_O}\right)\left(\frac{R_i}{V_O}\right)V_O + K_{tS}\left(\frac{H}{V_O}\right)\left(\frac{R_i}{V_O}\right)V_O + \frac{K_{tc}}{2}\sum_{j=1}^{i-1}\left(\frac{R_{i-j}}{V_O}\right)\left(\frac{R_j}{V_O}\right)V_O$$

Moments and Molecular Weights

$$m_k = \sum i^k R_i \quad , \quad x_k = \sum i^k \Theta_i \quad , \quad M_n = \frac{x_1 + m_1}{x_0 + m_0} PM \quad , \quad M_w = \frac{x_2 + m_2}{x_1 + m_1} PM$$

6. Results

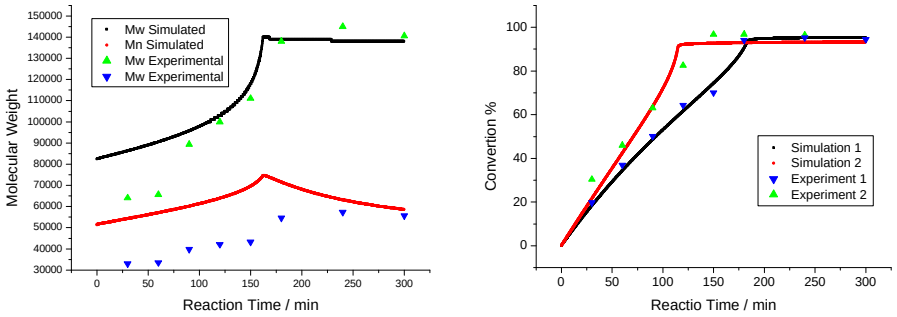

Figure 2 – Validation of model simulation with experimental data.

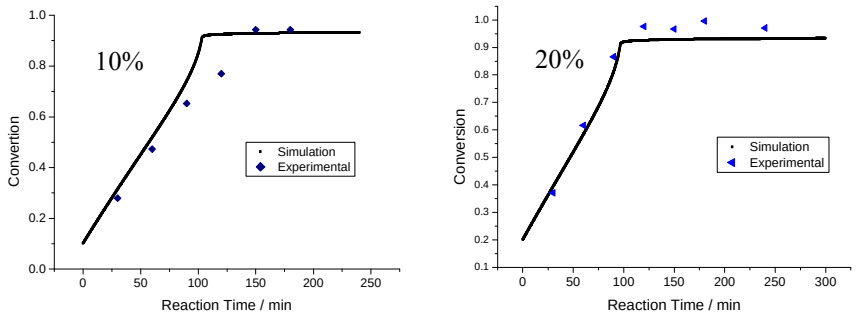

Figure 3 – Simulation and experimental results for reactions containing 10 and 20% of recycled PS.

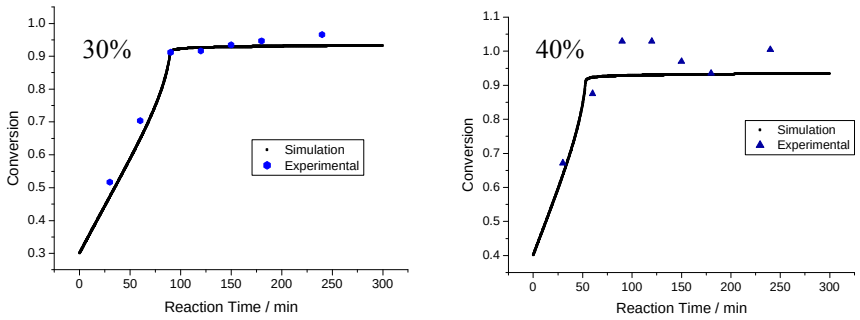

Figure 4 – Simulation and experimental results for reactions containing 30 and 40% of recycled PS.

The model was validated for different polymerization runs. Results can be seen in Figure 2. When recycled polystyrene is incorporated into virgin polystyrene beads, it can be assumed that the initial monomer conversion is equal to the recycled polystyrene content (as a mass fraction). As it can be seen in Figures 2 to 4, the model describes the course of monomer conversion very well. This is very interesting because it shows that the gel-effect does not depend on the polymer quality significantly, as one might expect. (As observed experimentally, the average molecular weights of recycled polymer materials were much larger than the ones produced through suspension polymerizations

and approximately equal to $3.0x10^5$ g/mol.) Additionally, as the recycled polymer material certainly contained unknown additives, it was shown that possible inhibitory effects (Rabelo, 2000) might be disregarded. Despite that, Table 5 shows that the obtained molecular weight averages (M_n and M_w) were smaller than predicted by the model (M_n^{cal} and M_w^{cal}), indicating that additives might promote chain transfer reactions. (Results not shown here for lack of space confirmed this hypothesis.)

Table 5 – Comparison between experimental and calculated average molecular weights.

	M_n	M_w	M_n^{cal}	M_w^{cal}
Experiment - 10% PS incorporated	11347	23753	20708	82637
Experiment - 20% PS incorporated	15278	67481	19551	102923
Experiment - 30% PS incorporated	13731	85439	19392	109153
Experiment - 40% PS incorporated	11550	93153	18855	123479

7. Conclusion

The influence of increasing recycled polystyrene contents on the course of suspension styrene polymerizations was investigated. It was shown that the recycled polystyrene content does not affect the kinetics of the polymerization significantly, indicating that operation policies can be adapted to increasing amounts of recycled material with the help of common suspension polymerization models. It was also shown that unknown additives of recycled materials do not cause any significant inhibitory effects, but can promote chain transfer reactions.

Abstract

In the present work, a previous superstructure model developed for simultaneous optimization of the process configuration and equipment dimensions- i.e., process synthesis and design- and the operation conditions of activated sludge wastewater treatment plants (Alasino et al., 2007) will be extended to account for phosphorus as well as nitrogen removal. Continuous operation is supposed, and the influent wastewater flowrate and composition are assumed known. The performance criterion selected is to minimize the net present value including investment and operating costs while verifying compliance with the effluent permitted limits.
The Activated Sludge Model No. 3 extended with the Bio-P module for computing biological phosphorus removal is used to model the reaction compartments, and the Takàcs model for representing the secondary settler. In the present work, new variables and equations for components accounting for phosphorus removal processes are incorporated and the superstructure is also enlarged to embed the most widely used combined N and P removal process configurations. Therefore, the complexity of the problem has been increased. The problem is posed as a NLP problem, specifically a nonlinear programming problem with discontinuous derivatives -DNLP-, as it results in a highly nonlinear system with non-smooth functions. The model is implemented and solved using General Algebraic Modelling System (GAMS), and proved to be robust and flexible. Results for case studies are presented and discussed.

Keywords: activated sludge process, combined N and P removal, optimal synthesis and design, ASM3+Bio-P.

1. Introduction

The activated sludge (AS) system is the most used biological process for municipal wastewater treatment (WWT) plants. Along the activated sludge treatment process, the wastewater stream can be exposed to different environmental conditions (anaerobic, anoxic, and aerated zones) in order to facilitate the different microbiological processes such as the release or uptake of phosphorus and the nitrification/denitrification processes.
In Alasino et al. (2007) the simultaneous optimization of the process configuration and equipment dimensions -i.e. process synthesis and design- and the operation conditions of activated sludge wastewater treatment plants for nitrogen (N) removal based on a superstructure model was presented. That work was one of the first for synthesis and design based on a superstructure model for the wastewater treatment process, using rigorous models for biochemical and settling processes, and aiming at costs minimization. Then, in Alasino et al. (2008), the optimal operation conditions resulting

from a superstructure model that embeds the most widely used configurations for combined N and phosphorus (P) removal, aiming at minimizing operating annual costs was investigated for given wastewater specifications. In that work the plant equipment was supposed given, and no investments costs were computed. The plant lay-out used as the departing model was that proposed by Gernaey and Jorgensen (2004), which corresponds to the A2/O process. The other configurations embedded were the UCT process (VIP process), the modified UCT process and the Bardenpho process.
In the present work, a superstructure model for simultaneous optimization of both the process configuration and equipment dimensions- i.e., process synthesis and design- and the operation conditions of activated sludge wastewater treatment plants in continuous operation, and for given wastewater specification and flow rate, is developed to account for P as well as for N removal. Here, the model embeds up to seven reaction compartments and a secondary settler, and allows for flow distribution of the main process streams (i.e. nitrate recycle, sludge recycle and fresh liquid), bypasses and external carbon source dosage along the reaction zone. The objective function is to minimize the Net Present Value -NPV- considering investment and operating costs. The compartments volumes and the operating conditions are to be optimized, while the decanter (with fixed dimensions) is supposed given. Each compartment will operate in aerobic, anoxic, or anaerobic conditions according to the aeration flowrate computed and the streams fed to it. As explained in the previous work (Alasino et al., 2007), all the decision variables are modeled as continuous, and some small lower bounds were used when necessary to avoid numerical problems. When a continuous variable (e.g. reaction compartment volume and flowrate of aeration, fresh wastewater, recycles, bypasses, and external carbon source to each reaction compartment) take a zero value at a solution point, the corresponding unit and/or stream is removed from the superstructure, meaning that it is not part of the final process configuration (flowsheet), and not in the sense that the mathematical representation of this unit and/or stream is eliminated in the mathematical model. In future works, new mathematical models based on MINLP or Generalized Disjunctive Programming –GDP– methodologies will be presented.

2. Problem Definition

The problem addressed is the simultaneous optimization of the process configuration (process synthesis), equipment dimensions (design) and the operating conditions (flow rates of aeration, recycles and fresh feed to each reaction compartment and external carbon source dosage) of ASWWTPs for combined biological N and P removal, aiming at minimizing the net present value. The influent wastewater specifications, effluent permitted limits, and the cost model computing operation and investment costs, are assumed given.

3. Process Description

In ASPs, the WW stream is exposed to different environmental conditions (anaerobic, anoxic and aerated zones) to facilitate the different microbiological processes such as the release or uptake of P, nitrification and denitrification. Reduction of carbonaceous matter and nitrification (ammonium is converted to nitrate by autotrophs) are favored by aerobic conditions; while denitrification (nitrate is converted to N gas by heterotrophs) is favored by anoxic ones, if readily biodegradable C is available. Biological P removal relies on P uptake by aerobic heterotrophs (known as phosphate-accumulating organisms PAOs) capable of storing orthophosphate in excess of their biological growth

requirements. Under anaerobic conditions, PAOs convert readily available C (e.g., VFAs) to C compounds called polyhydroxyalkanoates PHAs. PAOs use energy generated through the breakdown of polyphosphate molecules to create PHAs. This breakdown results in P release. Under subsequent aerobic or anoxic conditions, PAOs use the stored PHAs as energy to take up the P that was released in the anaerobic zone, as well as any additional phosphate present in the WW.

4. Process Optimization Model

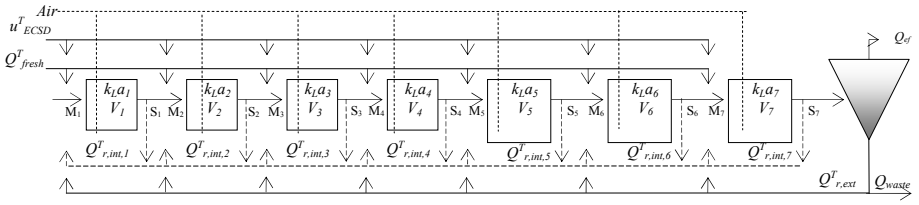

Figure 1. Representation of the WWTP Superstructure.

The considered process superstructure is shown in Fig. 1. The superstructure embeds the more widely used process alternatives for combined N and P removal. More specifically, the model embeds a chain of up to seven reaction compartments followed by a secondary settler (the latter with fixed dimensions), and allows for flow distribution of the main process streams i.e. nitrate and sludge recycle, bypasses and fresh feed streams, and external carbon source dosage along the reaction zone. The compartments volumes are to be optimized. Each compartment operates in aerobic, anoxic, or anaerobic conditions according to the aeration flow rate computed and the streams fed to it.

4.1. *Reactor model*

For the aeration tanks, steady state CSTR model is considered. The ASM3 model (Gujer et al, 1999) extended with the Bio-P module (Rieger et al., 2001) is chosen to model the biological processes. The stoichiometric coefficients and kinetic constants are interpolated to 15 ^oC as proposed by Alasino et al. (2008). The volumes of the reaction compartments and their k_La values are to be optimized using upper and (very small) lower bounds as proposed in Alasino et al. (2007).

4.2. Secondary settler model

The secondary settler is modeled as a non-reactive settling tank subdivided into 10 layers of equal thickness, using the double-exponential settling velocity model (Takács et al., 1991). A fixed settler depth of 4 m and a cross area of 1500m^2 are adopted.

4.3. Splitter and mixer mass balances.

Splitters and mixers models are also needed to represent the proposed superstructure.

4.4. Effluent quality limits

These effluent thresholds values were used as specification constraints (Copp, 2002; Gernaey and Jorgensen, 2004): $S_{NH,ef}$: 4 gN m^{-3}; $P_{tot\ ef}$: 1.5 gP m^{-3}; $N_{TOT,ef}$: 8 gN m^{-3}; BOD_{ef}: 10 gCOD m^{-3}; COD_{ef}: 100 gCOD m^{-3}; $X_{SS,ef}$: 30 gSS m^{-3}.

4.5. Maximum values for operation variables

The maximum values for the operation variables taken from Copp (2002) are: $Q_{r,ext}$: 36892m^3d^{-1}; $Q_{r,int}$: 92230m^3d^{-1}; Q_{waste}:1844.6m^3d^{-1}; u_{ECSD}: 2*10^3 kgCODd^{-1}; k_La_i:360 d^{-1}.

4.6. Objective Function

Here, the Net Present Value (NPV) is adopted as the objective function to be minimized, computing the investment (IC) and operating (OC) costs, as in Alasino et al. (2007).

The investment cost includes reaction tanks, aeration systems, secondary settler, influent pumping station, and sludge pump costs. The operation cost computes the cost for pumping and aeration, dosage of an external carbon source, excess sludge treatment for disposal, and fines according to contaminating units discharged.

The investment cost of the plant is computed as follows (Alasino et al., 2007):

$$IC = IC_t + IC_a + IC_{sett} + IC_{ips} + IC_{sr}$$

The investment cost functions used IC_p have the basic structure $IC_Z = b_Z Z^{\alpha_Z}$, where b and α are parameters and Z is an equipment characteristic dimension; for instance, the volume V_i of each reaction compartment R_i; the Oxygen Capacities $OxCa_i$ ($OxCa_i = B\ k_L a_i\ V_i$) for the aeration system. and the cross area $A_{settler}$ for the secondary settler. For this case, two different investment costs are computed: cost for tank construction and electromechanical system. Finally, the influent pumping station (concrete, screws and screening) and the sludge pump cost are considered. For these items, the characteristic dimension are the influent wastewater flow rate (Q_{FreshT}) and the recycled sludge flow rate (Q_{rext}).

The annual operating cost is computed as follows (Vanrolleghem and Gillot, 2002):

$$OC^{T,Annual} = OC_a + OC_{pump} + OC_{EQ} + OC_{SLDGD} + OC_{ECSD}$$

where OC_p is the annual operating cost of unit p. EQ, E_a, E_{pump}, u_{SLDGD} and u_{ECSD} are the effluent quality index, aeration energy demand, pumping energy demand, waste sludge production rate, and external carbon source dosage rate, respectively, whose expressions are given in detail in Alasino et al. (2007) and Gernaey and Jorgensen (2004). The annual unitary operation costs are (Vanrolleghem and Gillot, 2002; Mussati et al., 2002; Gernaey and Jorgensen 2004): α_{EQ}: 50 Euro day (kgPU year)$^{-1}$; α_E: 25 Euro day kWh year)$^{-1}$; α_{SLDGD}: 75 Euro day (kgS_S year)$^{-1}$; α_{ECSD}: 109.5 Euro day (kgCOD year)$^{-1}$. The effluent quality index EQ (kg contaminating unit d^{-1}), which is related to the fines paid due to contaminant discharge, is computed by weighting the compounds loads having influence on the water quality that are usually included in the legislation. Finally, the total operating cost is computed as follows:

$$OC = \Gamma\ OC^{T,Annual}$$

where Γ is used to update costs to the present value. The updating term is:

$$\Gamma = \sum_{j=1}^{n} \frac{1}{(1+i_d)^j} = \frac{1-(1+i_d)^{-n}}{i_d}$$

where i_d is the interest rate (discount rate) and n is the life span of the WWTP. A discount rate (i_d) of 0.05 and a life span (n) of 20 years are used.

4.7. Influent Wastewater Specifications

The influent WW flow rate is set at 18446 m^3 d^{-1}. The influent WW composition used consists of the original flow-weighted average dry weather influent composition for ASM1 proposed in COST, modified to make it compatible with the ASM3+BioP model. The influent $PO4^{=}$ concentration (S_{PO}) has been taken from Gernaey and Jorgensen (2004). The nonzero input concentrations for compounds are: S_I: 30 gCOD

m^{-3}; S_S: 69.5 gCOD m^{-3}; X_I: 51.2 gCOD m^{-3}; X_S: 202.32 gCOD m^{-3}; X_H: 28.17 gCOD m^{-3}; X_{SS}: 215.493 gSS m^{-3}; S_{NH}: 40.60 gN m^{-3}; S_{ALK}: 7 gCOD m^{-3}; S_{PO4}: 9.01 gP m^{-3}.

5. Results and Discussion

A multiple starting point strategy was adopted for model initialization, and several locally optimal solutions were found depending on the initial value set as in the previous work (Alasino et al., 2007). The WWTP configuration showing the minimal NPV value is represented in Figure 2. Table 1 shows the effluent concentrations and costs.

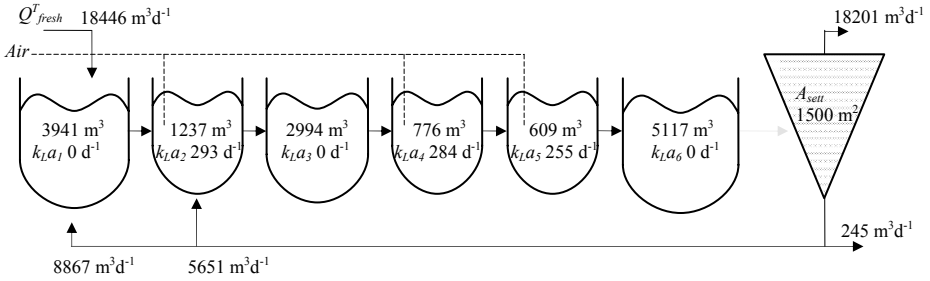

Figure 2. Optimal configuration and main process variable values.

Table 1. Main variables optimal values and costs.

Effluent Contaminant	**Value**	**Effluent Contaminant**	**Value**
$S_{NH,ef}$, g N m^{-3}	3.34	BOD_{ef}, g m^{-3}	1.67
$N_{TOT,ef}$, g N m^{-3}	5.37	COD_{ef}, g CODm^{-3}	45.00
$P_{TOT,ef}$, g P m^{-3}	1.50	$X_{SS,ef}$, g SS m^{-3}	15.05
Costs (Euros)			
OC_{EQ}	196397	IC_t	2382674
OC_{pump}	14763	IC_a	181764
OC_a	156959	IC_{set}	442671
OC_{SLDGD}	193860	IC_{ips}	268985
OC_{ECSD}	0	IC_{sr}	35310
$OC^{T,Annual}$	***561979.8***		
OC	***7002268***	***IC***	***3311404***
NPV	**10313672.3**		

As shown in Fig. 1, the optimization resulted in six reaction compartments with volumes of 3941, 1237, 2994, 776, 609 and 5117 m^3, respectively. That is, the optimal configuration includes six of the seven available reaction compartments. The volumen of the seventh (last) compartment achieves the lower bound, which is sufficiently small and insignificant from a practical point of view; so, that compartment is eliminated and is not represented in the figure. The second, fourth and fifth compartment are aerated;

thus, the WWTP consists of a sequence of compartments with the following characteristics: Ana-Ae-Anox-Ae-Ae-Anox. The optimal solution considers external recycle distribution: around 61% of the external recycle flowrate (8867 m^3 d^{-1}) is fed to the first compartment and the rest to the second one. No feed distribution is necessary and no external carbon source is dosed. As can be appreciated in Table 2.a, only the $P_{TOT,ef}$ concentration achieves the effluent threshold value.

In the previous work for N removal (Alasino et al., 2007), the synthesis and design for the same wastewater specification concentration and flowrate (except for the P content), with a superstructure consisting on 5 reaction compartments, resulted in three reaction compartments with volumes of 1083 m^3 (moderately aerated, k_La: 218 d^{-1}), 9096 m^3 (slightly aerated, k_La: 36 d^{-1}) and 6099 m^3 (slightly aerated, k_La: 27 d^{-1}), respectively, with fresh feed distribution (around 56% of the influent flowrate -10360 m^3 d^{-1}-, fed to the first compartment and the rest to the second one), and an external sludge recycle of 11841 m^3d^{-1} conducted to the first reaction compartment. The total reaction volume (sum of the reaction compartments volume) computed for that case is similar to this, but as P compounds and the organisms for P removal (X_{PAO}) were not considered, only 3 reaction compartments for developing conditions to N removal were needed. When phosphorous removal is targeted, an anaerobic compartment is essential to develop conditions for phosphorous release process, which is a biological step needed for phosphorous removal. As carbonaceous matter is consumed for P as well as for N removal processes, i.e. for P release and uptake process and for the nitrification/denitrification process, there is a shortage of carbonaceous matter and the effluent quality reached is not as good as in the previous work. Taken in conjunction with the fact that the effluent S_{NH} is higher in this case and that the P compounds are here computed, it results in a worse EQ (effluent quality) and in a higher cost due to fines. In addition, the higher amount of sludge for disposal produces higher sludge treatment cost. This results in an increment in the net present value, which is 10313672 Euros against 7473917 Euros in the previous work.

Abstract

In this work, the use of the ionic liquid 1-methyl-3-methylimidazolium dimethylphosphate or ethylene glycol as an separation agent was evaluated in a two-column or three-column configuration extractive distillation for the production of anhydrous ethanol (99.8% weight, 99.5% mol) from diluted solutions (11% weight). The extractive distillation process was simulated and optimized with the HYSYS® software. The vapor liquid equilibrium for the system was calculated by the NRTL thermodynamic model, whose interactions parameters were previously published. Experimental design was used in combination with modeling and simulation to determine the operational conditions that minimize reboiler duty. Simulation results showed that both separating agents present similar reboiler duty to produce high-purity ethanol.

Keywords: anhydrous ethanol, ionic liquids, extractive distillation, simulation.

1. Introduction

The growing demand for anhydrous ethanol and the preservation of the environment need a safe, inexpensive and green process. Many industrial techniques have been proposed to separate of ethanol/water azeotropic mixture, such as crystallization, liquid-liquid extraction, adsorption and azeotropic or extractive distillation (Huang et al. 2008). We have focused our attention on the extractive distillation. Extractive distillation is a partial vaporization process, in the presence of a non-volatile and high boiling point compound, usually called solvent or separating agent, which is added to prevent the azeotrope formation (Perry et al., 1992). In most commercial extractive distillation process, there are three-column or two-column configurations to obtain pure ethanol from a dilute aqueous ethanol solution. The separating agent is fed in the upper part of the extractive column, above the feed stream (Pinto et al., 2000; Ligero and Ravagnani, 2003). In the three-column configuration, the concentrator and stripper are in different columns. In the two-column configuration, both columns could be joined together and the last column is used to recuperate the separation agent, recycling it to the extractive column. Usually, the separating agent is the benzene, but this compound is toxic and shows operating unstable control. Another solvent, as reported by Meirelles et al. (1992), is the ethylene glycol (EG). On other hand, ionic liquids have emerged as possible "green" solvents because they are not volatile and, therefore, do not have

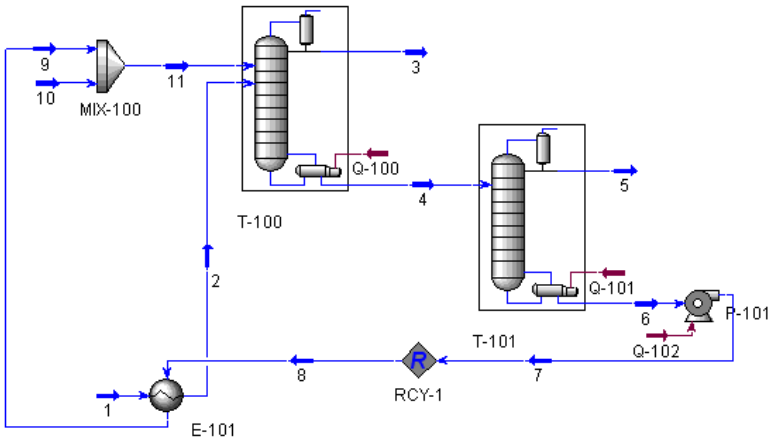
pollutant gas emissions. Ionic liquids are organic salts which are liquid at room temperature, with melting points below 373 K (Marsh et al., 2004). Zhao et al. (2006) reported vapor pressure data for the ionic liquids 1-methyl-3-methylimidazolium dimethylphosphate ([mmim][DMP]) in systems containing ethanol/water at several temperatures and compositions.

The main objective of this work is to model and optimize the two-column and three-column configurations using EG or [mmim][DMP] in order to produce 99.8% weight ethanol from an 11% weight ethanol solution. The results are compared in terms of heat duties and impurities contained in the ethanol product stream.

2. Methodology

The flowsheet of the extractive distillation process for modeling and optimization can be seen in Figure 1. This figures show the recycle point for the simulation (RCY-1).

(a)



(b)

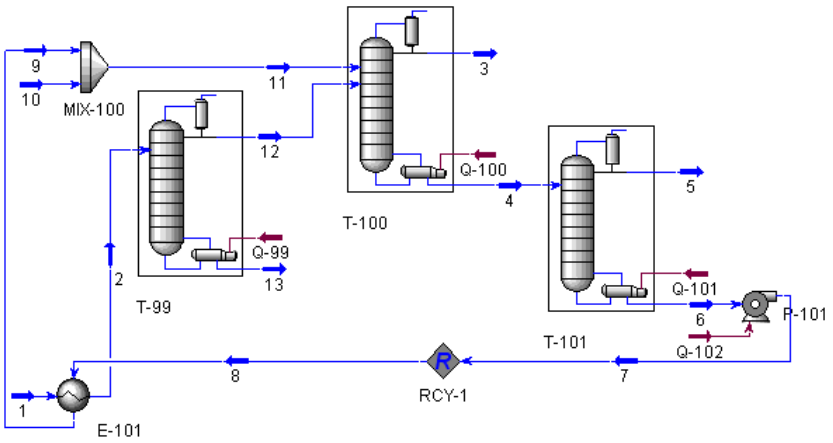


Figure 1. (a) Two-column configuration. (b) Three-column configuration.

2.1. Thermodynamic Model

The ionic liquid was created as a hypothetical component in the HYSYS® software using the liquid density from NIST (2008), pseudo critical properties calculated with the method of Valderrama and Robles (2007) and other properties estimated within HYSYS®. The activity coefficient was described using the NRTL (Renon and Prausnitz, 1968) thermodynamic model. The binary interaction parameters were taken from Zhao et al. (2006) for [mmim][DMP] systems, and from Meirelles et al. (1992) for EG systems. Table 1 displays these NRTL binary interaction parameters. Activity coefficient calculations for the mixture were validated with experimental data reported in previous works (Zhao et al., 2006; Meirelles et al., 1992) using HYSYS® simulator.

Table 1: NRTL binary interaction parameters.

Compound (1) + (2)	α_{12}	Δg_{12o} (J/mol)	Δg_{12t} (J/molK)	Δg_{21o} (J/mol)	Δg_{21t} (J/molK)
water + [mmim][DMP]	0.4116	5065.44	-	-9565.9	-
ethanol + [mmim][DMP]	0.5927	13172.16	-	-6426.83	-
water + EG	0.1859	1383.43	8.0409	-1445.97	-9.1506

ethanol + water	0.3008	5612.08	-	-510.81	-

$\Delta g_{12} = \Delta g_{12o} + T\Delta g_{12t}$

2.2. Experimental design

In distillation process with new chemical components, the first step is to know the main operational variables. The second step is selecting the correct interval of work of these main operational variables and, finally their optimization. The software Statistica (Statsoft, v. 7.0) was used to analyze the results for all experimental design.

2.2.1. Finding the main operational variables

Experiments are very time-consuming when many factors have to be considered. In contrast, Plackett–Burman designs (Plackett and Burman, 1946) are very useful for picking up the most important factors from a long list of factors (operational variables) with the less number of experimental trials. In order to perform these steps, the EG separating agent was arbitrarily selected. There were considered as the most important variables those listed in Table 2. Then, the influences of these variables on separation agent loss (X) and energy consumption (Y) was investigated.

2.2.2. Selecting the correct interval of operational variables

In order to select the interval of operational variables, a sensibility analysis was performed, where the column theoretical stage, the separation agent molar flow, and the separation agent feed stage were analyzed. Also, several variables are maintained constants, such as the fermentation broth temperature feed (298 K), the operational pressure of concentrator and extractive column (101.3 kPa), the ethanol molar fraction in the concentrator or extractive column bottom (10^{-6}), the ethanol molar fraction in distillate extractive column (0.995), the water molar fraction in the recovery column bottom (10^{-6}), and the separation agent molar fraction in the distillate recovery column (10^{-6}). Then, the analyzed variables were varied up to obtain constant values of reboiler duty or ethanol molar fraction. The optimal stage for the stream feeds are into the coalescence between the rectification and stripping sections of the distillation column (Walas, 1990). Then, the feed stage was selected as the lowest reboiler duty was obtained for a column.

2.2.3. Optimization of the operational variables:
This step found the operational variables optimal value for the lowest energy consumption (Y). The operational variables selected by Plackett–Burman analysis with limits chosen by the sensibility analysis and the other factor used as constants are the input variables in this optimization. The optimization could be done by either on gradients or complex methods based on local optimization or by direct variation of variables as Taguchi method (Taguchi et al., 1990). In this work, Taguchi method was chosen as it gives a faster, more reliable and more stable solution. Once the interval values of relevant variables were selected, experiments were designed by the Taguchi method with energy consumption as response. The L_9 orthogonal array was selected in the Taguchi method to analyze the variables at different levels.

3. Results

Since the value range of the variables is unknown, a sensibility analysis was performed to estimate it. Thereby, (1) the reboiler duty is maintained constant over 40, 30 and 12 theoretical stages for the concentrator, extractive and recovery columns, respectively, (2) the separation agent molar flow should be over 3 kmol/h to obtain 0.998% w ethanol, (3) lower separation agent molar flow results in a lower reboiler duty, (4) in order to prevent contamination of the distillate, the separation agent feed stage should be 2 and 5 for [mmim][DMP] and EG, respectively, (5) the separating agent temperature feed can be equal to the boiling point of ethanol. In order to know the main operational variables in the process, each operational variable was tested at two levels, as shown in Table 2. The interval values used are in agreement with the previously sensibility analysis.

Table 2. Variables process using ethylene glycol.

N	Variable name	-1	+1
	Two-column configuration		
1	Molar flow of separation agent (kmol/h)	3.00	9.00
2	Number of theoretical stages in extractive column	35.00	55.00
3	Separation agent feed stage	2.00	5.00
4	Pressure in recovery column (kPa)	20.26	101.3
5	Number of theoretical stages in recovery column	15.00	30.00
6	Separation agent temperature (K)	341.44	361.44
	Three-column configuration		
1	Molar flow of separation agent (kmol/h)	3.00	9.00
2	Number of theoretical stages in concentrator column	25.00	50.00
3	Ethanol molar fraction in distillate of concentrator column	0.50	0.90
4	Number of theoretical stages in extractive column	25.00	45.00
5	Separation agent feed stage	2.00	5.00
6	Pressure in recovery column (kPa)	20.26	101.3
7	Number of theoretical stages in recovery column	15.00	30.00
8	Separation agent temperature (K)	341.44	361.44

The Plackett–Burman results are shown as Pareto charts of effects on separation agent lost in distillated (X) and energy consumption (Y) at 95% confidence level. The variables near to the statistical p–value equal 0.05 are significant. The results for the two-column configuration are shown in Figure 2. The energy consumption was mainly affected by the separation agent molar flow (N1), the separation agent feed stage (N3), and the pressure in recovery column (N4), while for solvent loss, the separation agent molar flow (N1), and the separation agent feed stage (N5) are the significant variables.

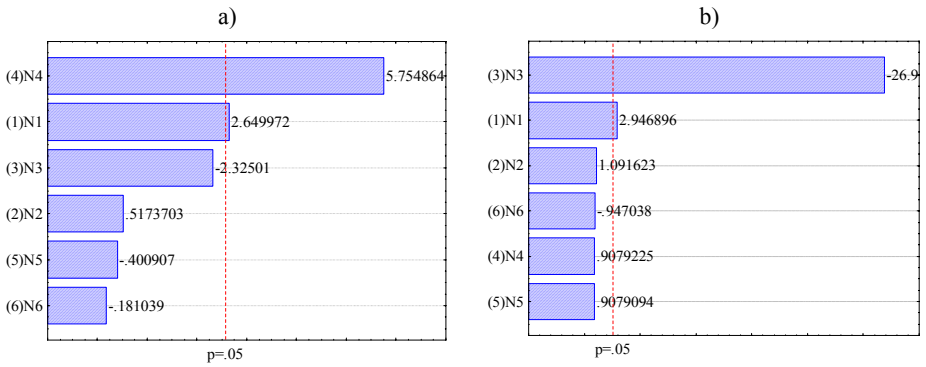

Figure 2. Pareto chart of variables effects at 95% of confidence level for two-column configuration. a) energy consumption, b) agent separation loss.

The results for the three-column configuration are shown in Figure 3. The energy consumption was mainly affected by the separation agent molar flow (N1), the number of theoretical stages in concentrator column (N2), the ethanol molar fraction in distillate concentrator column (N3), the separation agent feed stage (N5), and the separation agent temperature (N8), while for solvent loss, the separation agent molar flow (N1), the number of theoretical stages in concentrator column (N2) and the separation agent feed stage (N5) are the significant variables.

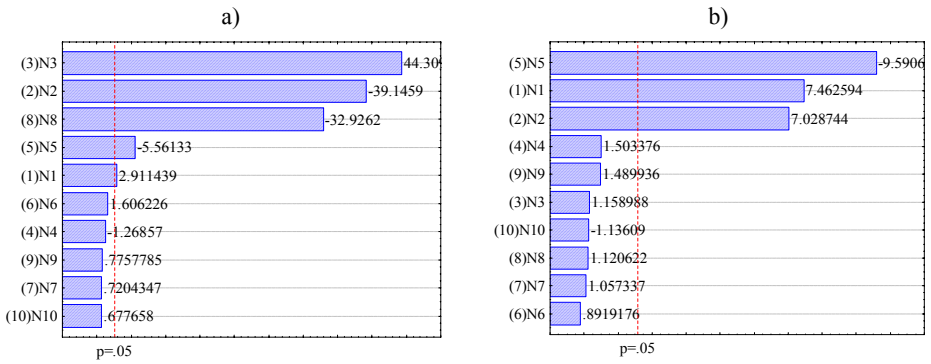

Figure 3. Pareto chart of variables effects at 95% of confidence level for three-column configuration. a) energy consumption, b) agent separation loss.

According the results, the two-column configuration does not need variable optimization, because all variables can be fixed using values from sensibility analysis. The pressure in recovery column and the separation agent molar flow should be the lowest in order to obtain the lowest reboiler duty, 20.26 kPa and 3 kmol/h, respectively. The optimal values for the two-column configuration are displayed in Table 3.

Table 3. Optimum conditions and performance for the two-column configuration.

Separation agent	N1	N2	N3	N4	N5	N6	Energy consumption (kJ/kg ethanol)	Separation agent loss (kmol/h)
[mmim][DMP]	3	40	2	20.26	12	351.44	25819.5	$9 \cdot 10^{-11}$
EG	3	40	5	20.26	18	351.44	25515.5	$1 \cdot 10^{-4}$

The Taguchi method was applied for the three-column configuration variables with significant effect. The factors not marked as statistically important by the Plackett–Burman analysis were fixed as constant (N4=35, N5=5, N6=20.26, N7=18 for EG and N4=35, N5=2, N6=20.26, N7=12 for [mmim][DMP]). Table 4 shows the factors and levels, while the optimal values for operational variables are displayed in Table 5.

Table 4. Factors and their levels for the three-columns configuration.

Level	N1	N2	N3	N8
1	3	25	0.7	341.44
2	6	40	0.8	351.44
3	9	55	0.9	361.44

Table 5. Optimal conditions and performance for the three-column configuration

Separation agent	N1	N2	N3	N8	Energy consumption (kJ/kg ethanol)	Separation agent loss (kmol/h)
[mmim][DMP]	3	55	0.8	361.44	6987.2	$1 \cdot 10^{-6}$
EG	3	55	0.8	361.44	6909.0	$3 \cdot 10^{-5}$

Table 5 shows simulation results obtained using the Taguchi method that, for an efficient use of the energy, the concentrator column should produce an ethanol molar fraction equal to 0.8, a variable not well studied in dehydration ethanol works. The ionic liquid is the separating agent with less contamination of the distillated ethanol.

4. Conclusions

The energy consumption of dehydration of aqueous ethanol by an extractive distillation method was compared for two different configurations and two different separating agents. The calculated results showed that ethylene glycol is more contaminant than [mmim][DMP], but the energy consumption is similar. On the other hand, the three-column configuration process has lower energy consumption than the two-column configuration process.

Abstract

Bioethanol is produced from fermentation of sugars, what produces a dilute solution (around 10 wt% ethanol). Because water and ethanol form an azeotrope with concentration of 95.6 wt% ethanol at 1 atm, an alternative separation process such as azeotropic distillation must be employed to produce anhydrous bioethanol, which can be used in a mixture with gasoline. In this work, simulations of three different configurations of the azeotropic distillation process with cyclohexane for anhydrous bioethanol production were carried out using software Aspen Plus. Process parameters were optimized in order to decrease the formation of a second liquid phase inside the column. Ethanol and entrainer losses as well as energy demand were evaluated.

Keywords: bioethanol, azeotropic distillation, simulation.

1. Introduction

Climate change and the consequent need to diminish greenhouse gases emissions have encouraged the use of bioethanol in a mixture with or as a replacement of gasoline. In order to be used in a mixture with gasoline, ethanol produced from fermentation of sugars, obtained at a concentration of about 10 wt% ethanol, must be concentrated to at least 99.3 %. Since ethanol and water form an azeotrope with 95.6 wt% ethanol at 1 atm, conventional distillation can not achieve the necessary separation that meets product specification. The main processes employed for anhydrous bioethanol production are azeotropic and extractive distillation and adsorption on molecular sieves.
In the conventional configuration of the heterogeneous azeotropic distillation process for anhydrous bioethanol production, two distillation columns are used: the azeotropic one and the recovery unit. Hydrous ethanol and entrainer are fed in the azeotropic column, where anhydrous ethanol is produced on the bottom and a minimum boiling ternary azeotrope formed between ethanol, water and entrainer is produced on the top. The ternary azeotrope is heterogeneous, and the two liquid phases are separated in a decanter. The light phase contains most of the entrainer and is recycled to the azeotropic column, while the aqueous phase is fed to the recovery column where ethanol and eventually entrainer are recovered. The stream containing ethanol recovered may be recycled to the azeotropic column, in order to reduce ethanol losses.
Benzene was the most common entrainer employed in anhydrous bioethanol production, but due to its carcinogenic characteristics cyclohexane is most frequently used

nowadays. The azeotropic distillation process with cyclohexane is the most common method for anhydrous bioethanol production employed in Brazil, which is the second largest ethanol producer in the world. This process is characterized by high steam consumption on column reboilers, as well as high entrainer losses on the product. In other words, the separation step for obtaining anhydrous ethanol has a significant impact on the final product price, so that it is worthwhile to investigate procedures and alternatives to improve the process economy and performance. Simulation is an attractive tool to evaluate the process since it is not suitable to use large scale units to do so.

Simulation of the azeotropic distillation process is often complex and extremely sensitive to project parameters and specifications, mainly because of the formation of a second liquid phase inside the azeotropic column, which influences the mass transfer behaviour: column efficiencies between 25 and 50% are not uncommon when a second liquid phase is present (Higler et al., 2004).

In this work simulations of the azeotropic distillation process with cyclohexane for anhydrous bioethanol production were carried out using software Aspen Plus. Simulation of different process configurations were carried out, and the main parameters evaluated were the formation of the second liquid phase inside the column, the separation of the ternary azeotrope during settling, entrainer losses on the anhydrous bioethanol and energy consumption on column reboilers.

2. Heterogeneous azeotropic distillation

Heterogeneous azeotropic distillation is widely employed in industry as a separation process for azeotropic or close-boiling mixtures, for which conventional distillation can not achieve the necessary separation. In this process, a third component, called entrainer, is added to the binary mixture, producing a heterogeneous azeotrope with one or both components of the original mixture. In the separation of a binary azeotropic mixture, the new azeotrope produces a more favorable azeotropic pattern for the desired separation. Even though the formation of a second liquid phase simplifies entrainer recovery and the recycle process, it may affect column performance and, consequently, decrease efficiency. Different process configurations can lead to a decreased formation of a second liquid phase, without compromising anhydrous bioethanol production.

3. Simulation of the azeotropic distillation process

Three different configurations of the azeotropic distillation process with cyclohexane for anhydrous bioethanol production were simulated using software Aspen Plus. NRTL was the model used for calculation of the activity coefficient on the liquid phase. Approximately 500 m^3/day of anhydrous bioethanol (99.5 wt% ethanol) are produced on each case, from 16,100 kg/h (521 m^3/day) of hydrous bioethanol (93 wt% ethanol).

3.1. Configuration 1

The first configuration of the process is depicted in Figure 1. In this case, hydrous bioethanol is mixed with the recycle stream of the recovery column and fed to the azeotropic column. Entrainer is comprised by the organic phase obtained in the decanter and a solvent make-up stream. Anhydrous bioethanol is produced on the bottom of the azeotropic column, and the ternary azeotrope in the top. After cooling, the ternary azeotrope splits into two liquid phases in the decanter. The aqueous phase is fed to the recovery column, producing pure water on the bottom.

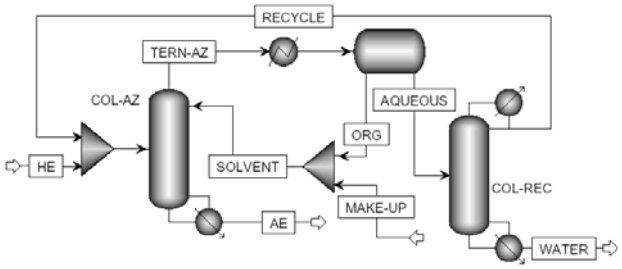

Figure 1. First configuration of the azeotropic distillation process.

3.2. Configuration 2

The main difference between this configuration and the first one is the withdrawn of a fraction of the aqueous phase obtained in the decanter and its mixture with the hydrous ethanol and recycle stream, which are fed to the azeotropic column (Mortaheb and Kosuge, 2004). Configuration 2 of the azeotropic distillation process is displayed in Figure 2.

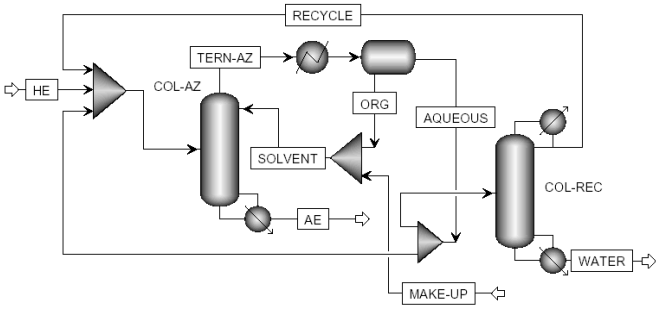

Figure 2. Second configuration of the azeotropic distillation process.

3.3. Configuration 3

In the third configuration part of the ternary azeotrope is condensed and mixed with hydrous ethanol, being subsequently fed to the azeotropic column. In this configuration the top product of the recovery column is not recycled to the azeotropic column, but to the decanter. This configuration is depicted in Figure 3.

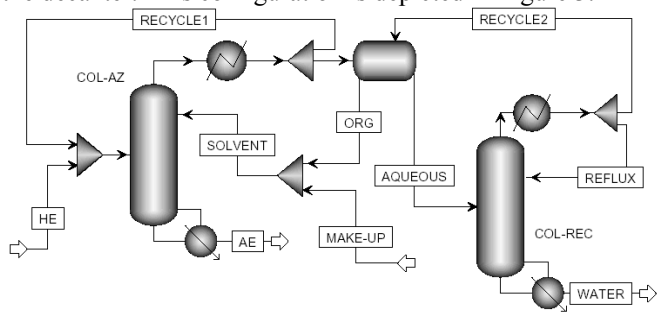

Figure 3. Third configuration of the azeotropic distillation process.

3.4. Simulation parameters

Columns parameters are displayed in Table 1. Stage numbering initiates in the top stage or attached condenser and reboiler is considered the last stage.

Table 1. Process parameters for each configuration.

	Configuration 1	Configuration 2	Configuration 3
COL-AZ number of stages	31	31	31
Feed inlet stage – COL-AZ	18	20	20
Solvent inlet stage	1	1	1
COL-REC number of stages	25	22	17
Feed inlet stage – COL-REC	13	13	13
Decanter temperature (°C)	50	50	50

4. Simulation results and discussion

4.1. Main streams results

The characteristics of process stream differ for each configuration. Results are presented in Tables 2 through 4.

Table 2. Composition of the main streams for the first configuration.

Stream	AE	MAKE-UP	ORG	AQUEOUS	WATER
Temperature (ºC)	78.2	50.0	50.0	50.0	100.0
Flow (kg/h)	15063.6	16.8	42501.6	19524.1	1053.5
Ethanol (wt%)	99.5	0.0	4.7	71.2	0.0
Water (wt%)	0.4	0.0	0.1	10.8	100.0
Cyclohexane (wt%)	0.1	100.0	95.2	18.0	0.0

Table 3. Composition of the main streams for the second configuration.

Stream	AE	MAKE-UP	ORG	AQUEOUS	WATER
Temperature (ºC)	78.2	50.0	50.0	50.0	100.0
Flow (kg/h)	15064.4	21.0	50274.1	22813.3	1057.3
Ethanol (wt%)	99.5	0.0	4.6	71.5	0.0
Water (wt%)	0.4	0.0	0.1	11.3	100.0
Cyclohexane (wt%)	0.1	100.0	95.3	17.2	0.0

Table 4. Composition of the main streams for the third configuration.

Stream	AE	MAKE-UP	ORG	AQUEOUS	WATER
Temperature (ºC)	78.1	50.0	50.0	50.0	78.6
Flow (kg/h)	8395.4	16.8	22877.5	31880.6	7722.0
Ethanol (wt%)	99.5	0.0	5.2	67.6	85.9
Water (wt%)	0.3	0.0	0.1	7.5	14.1
Cyclohexane (wt%)	0.2	100.0	94.7	24.9	0.0

Streams obtained in the decanter (AQUEOUS and ORG) have different compositions on each studied configuration. Configurations 1 and 2 showed similar results, while configuration 3 had a higher concentration of solvent in the aqueous phase. Due to this contamination, recovery column behaviour was significantly affected and "WATER" stream has a high concentration of ethanol (85.9 wt%), so it must be recycled to the previous distillation stage, where hydrous bioethanol is produced.

4.2. Energy consumption and entrainer and ethanol losses

Different process parameters affect ethanol and entrainer losses, as well as energy consumption on column reboilers. The results for these parameters are given in Table 5.

Table 5. Ethanol and entrainer losses and energy consumption on column reboilers for each configuration.

	Configuration 1	Configuration 2	Configuration 3
Ethanol losses (%)*	0.00	0.00	44.26
Entrainer losses (%)**	0.04	0.03	0.07
Reboilers energy (kJ/kg AE)	5588	5828	7235

* Considering the amount of ethanol in the "HE" stream

** Considering the amount of cyclohexane that is fed to the azeotropic column

The "WATER" stream on the third configuration has a very high concentration of ethanol, thus ethanol losses on this configuration are significant. The recycle of this stream to the conventional distillation column would allow ethanol recovery at the expense of an increase in energy consumption of the process, which already has the largest energy consumption on column reboilers. Configurations 1 and 2, on the other hand, present low ethanol and entrainer losses, as well as a relatively low energy consumption.

4.3. Formation of the second liquid phase inside the azeotropic column

Similar liquid flow profiles were observed in the azeotropic column. The profiles for each configuration are represented in Figures 4 through 6.

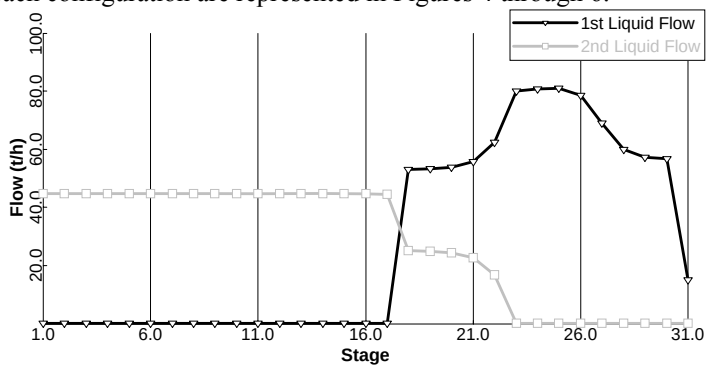

Figure 4. Liquid flow profile in the azeotropic column for configuration 1.

Changes in column parameters, such as feed inlet position in the azeotropic column, greatly influence the formation of a second liquid phase. For the first configuration, the feed inlet stage in the azeotropic column (18) is the one that first presents two liquid phases. The same occurs for the other configurations. The feed inlet stage is the last one that allows column convergence; on the other hand, if the feed stage is located near the

top of the column, two liquid phases are present in this region too. This means that the feed inlet stage in the azeotropic column has to be defined with caution, since it impacts unit behavior and performance.

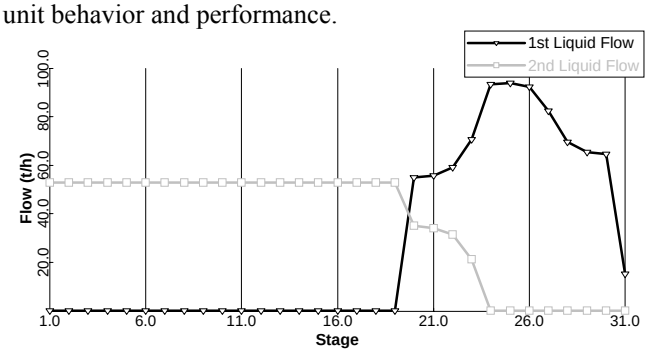

Figure 5. Liquid flow profile in the azeotropic column for configuration 2.

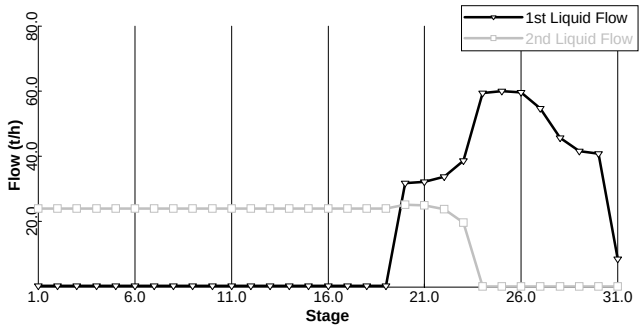

Figure 6. Liquid flow profile in the azeotropic column for configuration 3.

5. Conclusions

Simulations of the azeotropic distillation process with cyclohexane for anhydrous bioethanol production were carried out for three different process configurations. Simulations focus was on decrease of the formation of a second liquid phase inside the azeotropic column, what has significant impacts on process performance. It was observed that changes in process parameters, such as feed inlet stage, greatly influence the formation of the second liquid phase. Configuration 1 presented the best results, considering energy consumption on columns reboilers, ethanol and entrainer losses and product contamination with entrainer.

Abstract

Water is a vital natural resource for human life and to the maintaining of natural cycles, but its scarceness is already a reality in some countries. On the other hand, the disposal of wastewater has also been an apprehension, because environmental laws are becoming increasingly rigorous. As a consequence, in case of chemical industries, they are developing campaigns to reduce this consumption, in which the goal is to minimize the use of industrial water and disposal in many segments such as pulp and paper, food (citrus juice), textile, petroleum refinery and petrochemical. So, in order to promote and implement this reduction a method called Water Source Diagram (WSD) is presented in this work. This is an heuristic algorithmic methodology, of simple application, which takes into account the plant restrictions and doesn't make major changes in the existing process, besides it allows manual calculations. The procedure is applied under the same conditions as other existing technologies and also to propose other scenarios not previously discussed. Several flowcharts were developed using WSD procedure which has proved efficiency in the reduction of consumption of this natural resource. In the pulp and paper industry, it was achieved a reduction of water around 89.5% for maximum reuse and 100% for regeneration with reuse, resulting an economy in the total annual costs of 80% (maximum reuse) and 91.6% (regeneration with reuse). In the citric juice and textile industries, the reduction reached 24.5% and 17.9% for maximum reuse respectively, and for regeneration with reuse, the reduction was 31.4% and 50.8% (with reuse and recycle), respectively. In the petrochemical industry, for a simple contaminant, the reduction was 15.7% and 20.4% for maximum reuse and regeneration with reuse, respectively; for multiple contaminants the reduction was 22.1%. Thus, these results show that the presented methodology has an extreme importance in all studied cases, dealing with good signs of economic viability.

Keywords: water source diagram, algorithm, reuse, regeneration.

1. Introduction

Water is a natural resource vital for the maintenance of life on the Planet and to the functioning of other natural cycles, but its scarcity is already a reality in some countries. Industrial segments such as pulp and paper, food (citrus juice), textile, petroleum refinery and petrochemical consume large volume of water and one of its latest trends is the water and wastewater minimization. Several methodologies have been developed to propose mass exchange networks focusing in water and wastewater reuse. Since reuse

causes problems of accumulation of non process elements, the use of regeneration processes becomes necessary in order to reduce contaminants concentration.
Wang and Smith (1994) used the limiting water profile to minimize the water flow rate in systems with single and multiple contaminants, considering only reuse and reuse with regeneration of effluents. In order to overcome the problems concerned with the method proposed by Wang and Smith (1995), Castro *et al*. (1999) developed a procedure in which the water consumption and the synthesis of mass exchange network were respected simultaneously. This procedure was used in systems with single contaminants and considered only the reuse of effluent streams to reduce fresh water consumption. The Water Source Diagram Procedure presented by Gomes *et al.* (2007) and complemented in this work can be considered as an improvement of Castro *et al*. (1999) and Gomez *et al*. (2000) procedures. It is able to take into account a variety of situations, such as (i) reuse, (ii) multiple water sources, (iii) water losses along the process, (iv) flow rate constraints, (v) regeneration with reuse and (vi) regeneration and recycling. Mirre (2007) was the first one to apply this methodology in an industrial case, in which this procedure was used to define the target of minimum consumption of water for an oil refinery process. The study involved the simultaneous consideration of three contaminants in the aqueous streams, where different scenarios were generated using reuse and/or recycle, including regeneration. A scenario was proposed to reuse every effluent stream as a make-up in a cooling tower after its treatment, but with the quality not allowed to disposal directly into the river. Other scenarios considered the presence and absence of an osmosis system to treat the effluent, which led an elevated economic cost to the process. In addition, it was included the scenario involving the possibility of making the effluent distributed treatment, presenting the best cost reduction. The results showed that a reduction about 20% in total costs was achieved. Different studies involving WSD were developed by the Chemicals Processes Integration Group (GIPQ/EQ/UFRJ), but were applied in examples of literature, so remaining a hole in the WSD application in other segments. In this work the Water Source Diagram procedure (WSD) is applied to some industrial processes which have a high consumption of water to generate mass exchange networks with minimum water consumption through reuse, regeneration with reuse and regeneration and recycle. In order to explain the method, one case-segment is completely described and the results of other studies are shortly presented.

2. Methodology - The Water Source Diagram (WSD)

The Water Source Diagram divides the process in concentration intervals and water is allowed to be reused along these intervals. The concentration limits of each interval are considered sources of water and supplied or regenerated water is considered an external water source. These concentrations are ordered and represented into a grid of concentrations. Then, the amount of mass transferred ($\Delta m_{k,i}$) in each operation (k) in each interval of concentration (i) is calculated and indicated between parenthesis.

After this initial construction, heuristics rules are followed: i) external water sources are allowed to be used only when internal water sources are not available, ii) the greatest amount of mass must be transferred into the interval of concentration, iii) when an operation is present in several intervals, its water flow must remain along these intervals until its end. The advantage of this procedure is that the network structure is obtained simultaneously with the minimum fresh water consumption target. The amount of mass transferred in g/h (Δm_{ki}) in each operation k and each interval i is calculated through eq.

(1), where C_{fi} is the final concentration of interval i in ppm, C_{ii} is the initial concentration of this interval in ppm and f_k is the mass flow rate in t/h through operation k (k = 1..., N_{op}). The concentration intervals are identified by the index i (i = 1..., N_{int}), where N_{int} is the total number of intervals.

$$\Delta m_{ki} = f_k (C_{fi} - C_{ii}) \tag{1}$$

The flow rate required from the water source p for operation k, in the interval of concentration i, can be determined by equations (2) and (3), where C_{ij} is the concentration in which internal source j is used in interval i, C^e_p the concentration of the external source p, C_{fi} the final concentration of interval i and $N_{fia,i}$ is the number of available internal sources in interval i.

- External water sources:
$$f^e_{pki} = \frac{\Delta m_{ki} - \sum_{j=1}^{N_{fia},i} (f^i_{jki} x[C_{fi} - C_{ij}])}{C_{fi} - C^e_p} \tag{2}$$

- Internal water sources:
$$f^i_{pki} = \frac{\Delta m_{ki} - \sum_{j=p-1}^{p} (f^i_{jki} x[C_{fi} - C_{ij}])}{C_{fi} - C^i_p} \tag{3}$$

First, the internal source must be used in the interval, and the respective values of f^i_{jki} are calculated before f^e_{pki}. The sum in the eq. (3) represents the amount of contaminant removed by internal sources, in operation k in interval i, which has preference for external sources. The minimum external water source flow rate at 0 ppm can be calculated by eq. (4).

$$f^e_p = \sum_{k=1}^{N_{op}} \sum_{i=1}^{N_i} f^e_{pki} \tag{4}$$

3. Results and Discussions

In order to validate this methodology a petrochemical complex is analyzed. The data were extracted from Mann and Liu (1999), who applied the pinch technology to minimize the water consumption. The initial water consumption for the studied operations was 3037 t/d. Only suspended solids were considered as a single contaminant and it was involved the maximum reuse. Table 1 presents the operational data for the major operations concerning water consumption. For WSD application, operations which present water gain or loss were divided in two parts: one having fixed flow rate and the other representing the water gain or loss, as shown in Table 2. For example, operation 1.2 represents water gain and 2.2 and 3.2 water loss. Table 1 and 2 also illustrate the results for the amount of mass transferred ($\Delta m_{k,i}$) in each operation, assuming operational conditions.

In Table 2, all maximum inlet ($C_{in,max}$) and outlet ($C_{out,max}$) contaminant concentrations are presented, which are directly related to limits of corrosion, plugging, scale, deposit formation etc. From these concentrations, using eq. (1) and also considering that the amount of mass transferred was maintained in each operation, the limit flow rates (f_l) of each operation were recalculated.

Table 1. Petrochemical complex operational data [Mann e Liu (1999)].

Operations	f_{in} (t/h)	f_{out} (t/h)	C_{in} (ppm)	C_{out} (ppm)	Δm^* (kg/h)
1 - Dewatering Filters	360	630	0	200	126
2 - Cooling Tower A	1201	188	0	9.2	1.73
3 - Cooling Tower B	1374	261	0	8.7	2.27
4 - Scrubber	60	60	9	207	11.88
5 - Forward Washing	42	42	0	3	0.13

* $\Delta m = f_{out}C_{out} - f_{in}C_{in}$.

Table 2. Original operational data from the petrochemical complex with water gain and loss and the limiting data (in gray).

Operations	f (t/h)	C_{in} (ppm)	C_{out} (ppm)	Δm (kg/h)	f_l (t/h)	$C_{in,max.}$ (ppm)	$C_{out,max.}$ (ppm)
1.1 - Dewatering Filters	360	0	200	72	227.34	6	322.7
1.2 - Dewatering Filters	270	0	-	54	170.51	6	-
2.1 - Cooling Tower A	188	0	9.2	1.73	196.59	6.4	15.2
2.2 - Cooling Tower A	1013	0	-	9.32	1059.1	6.4	-
3.1 - Cooling Tower B	261	0	8.7	2.27	260.92	2.1	10.8
3.2 - Cooling Tower B	1113	0	-	9.68	1112.64	2.1	-
4 - Scrubber	60	9	207	11.88	60	9	207
5 - Forward Washing	42	0	3	0.13	42	0	3

Figure 1 presents the WSD considering maximum reuse obtained and related to the data of Table 2 and Figure 2 shows the mass exchange network corresponding to this WSD of Figure 1. The minimum of water consumption was obtained by the sum of all quantities of fresh water used and showed a reduction from 3037 to 2561 t/d (15.7 %). The same calculations were followed when the WSD procedure was applied for the situation of regeneration with reuse. The only difference is that the concentration of the regenerated stream was assumed as a new limit of concentration and inserted in WSD as a new source of water.

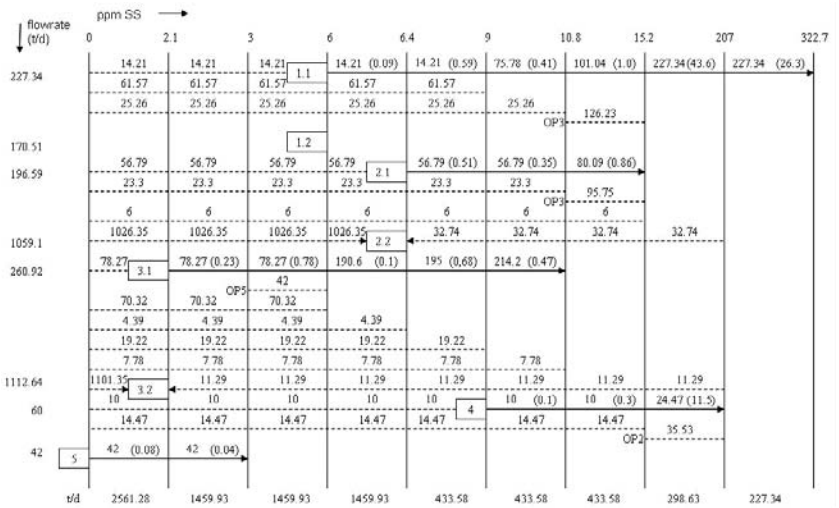

Figure 1. Petrochemical complex WSD with maximum reuse.

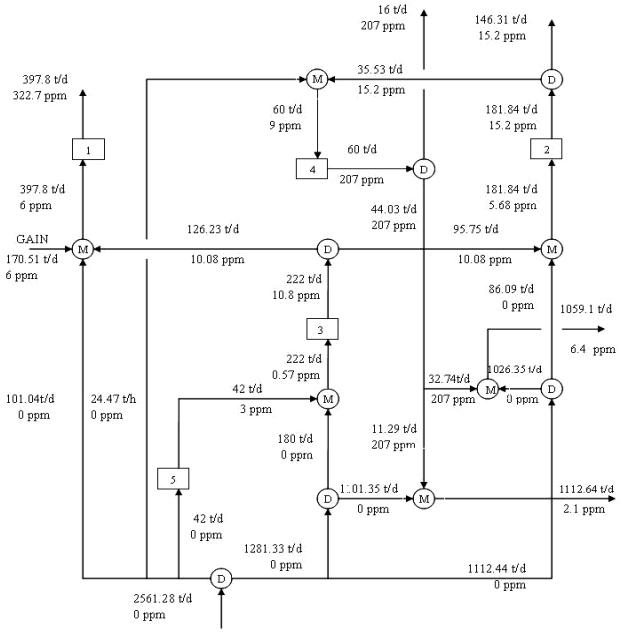

Figure 2. Mass exchange network for maximum reuse.

By the same way, the Water Source Diagram was applied to others industrial segments and it was achieved satisfactory water reduce as observed in the Table 3. The explanation of the WSD procedure for multiple contaminants can be found in Mirre (2007) and Marques (2008).

Table 3. Results for all segments.

INDUSTRIAL SEGMENT	Condition studied	Contaminant	Initial water consumption (t/h)	Water consumption with WSD (t/h)	Water reduce (%)	Water reduce from literature (%)
Pulp and Paper	Maximum reuse	Cl^-	1360	142.1	89.5	-
	Regeneration with reuse			0	100.0	-
Citric Juice	Maximum reuse	COD[1]	240.3	181.3	24.5	21.6[4]
	Regeneration with reuse			164.9	31.4	30.0[4]
Textile	Maximum reuse	COD	43.6	35.8	17.9	17.9[5]
	Regeneration with reuse			21.4	50.8[2]	50.8[5]
Petrochemical	***Simple contaminant***					
	Maximum reuse	SS[3]	126.54	106.72	15.7	14[6]
	Regeneration with reuse		126.54	100.73	20.4	17.5[6]
	Multiple contaminants					
	Maximum reuse	SS	152.79	109.83	22.1	-

[1] Chemical Oxygen Demand; [2] Regeneration with reuse and recycle; [3] Suspended solid; [4] Thevendiraraj *et al.* (2003); [5] Ujang *et al.* (2002); [6] Mann e Liu (1999).

4. Conclusion

The Water Source Diagram procedure applied to four industrial different segments achieved satisfactory water reduces and much better than others procedures from literature. The case studies demonstrated that the WSD application can also be easily used in cases involving maximum reuse and regeneration with reuse through simple calculations.

Abstract

The Pulp and Paper industry has struggled to solve problems related to high water consumption. One alternative is to use tools like Process Integration (PI) which includes "Water Pinch", a graphical method, and mathematical programming, which can be used to optimize the water circuit. In a case study in Brazil these two techniques were applied. Data was collected in real time from an integrated thermo mechanical pulping and newsprint mill and then used to develop a simulation that served as the base case model. The analysis is based on residual water reuse in other parts of the process under constraints of concentration limits of dissolved solids and fine fibers. The concentration limits of contaminants were frequently exceeded as shown when recalculated by simulation. Therefore, the results had to be corrected before they became valid. So if the predicted value for reduction of fresh water consumption is 31%, in actual fact is only 23%, which is still a good result.
Keywords: Process Integration, Pinch, Mathematical Programming, Newsprint Mill

1. Introduction

The water circuit analysis by process integration, which can be developed through graphical methods or mathematical programming, is an approach that has its origin in the industrial chemical process. El-Halwagi; Manousiouthakis (1989) introduced the notion of "Mass Exchanger Network Synthesis" (MEN), which initiated a sequence of other publications related to the subject. Alva-Argaéz et al. (1998) used the concept of Process Integration and developed a super structured model, combining graphical methods and mathematical programming. Bagajewicz; Savelski (2001) researched water circuits where only one contaminant is present in the process. Their work showed the possibility of optimizing the water circuit using linear programming. In order to develop graphical methods, Dhole et al. (1996) devised the "composite curve" method where a graph is built using curves of the sources and the demands of water in a process. Other authors like Hallale (2002) have also presented graphical methods to minimize the fresh water consumption. In the pulp and paper sector, Jacob et al. (2002) analyzed, as part of their work, the water circuit using the Pinch method as applied to TMP and newsprint manufacture. In this case, the method was not able to reach multi-objectives targets and the use of mathematic programming was needed to overcome the obstacles. Others authors (Mariano et al. 2007; Jödicke et al 2001) mention that a model has to approach the actual process taking into account environmental and infrastructure aspects. Process simulation in the pulp and paper industry (Syberg; Wild; Simons, 1992) became a useful tool for studies that involve the minimization of water consumption. However, according to Jutila; Leiviska (1981), the problem with simulations of systems in the pulp and paper industry are related to calculation techniques in the model containing recycled streams and it has not yet been entirely solved. Dabros et al (2005) developed a

model after observing the operation of thermo mechanical pulping integrated with four newsprint machines. Simulation was used to analyze sheet breaks and develop alternatives to increase the paper machine runnability.

2. Mill Description

The mill operation consists of two TMP lines and one paper machine responsible for producing 185000 t/y of newsprint paper. The simulation was modeled in Cadsim software.

2.1. TMP production

Stored chips are transferred to the refining system, where they are mechanically processed to form pulp with a consistency of approximately 30-35%. The refining consists of two stages: primary refining, where the chips are refined, followed by secondary refining, where the processed chips from the primary stage are refined to produce the optimal fiber quality. When chips are defibered at high temperatures and high consistence, as occur in the refiner, the fibers are in a high energetic state called latency. The pulp is diluted with a high volume of water and after passing through the latency tank, the pulp is sent to the screens where impurities and residual fibers are removed. The rejects from both lines are diluted before going to a tank which feeds the rejects press. In this stage, the extracted water is reused in the process and the rejects are sent to the refiner located in the line 1. The accepts are sent to the filters, whose function is to concentrate the pulp to a consistency between 7 and 10%. The concentrated pulp is then stored and the residual water returns to the process.

2.2. Mass Preparation and Paper Production

The TMP is mixed with others components necessary to produce newsprint paper, i.e., recovered fiber, refined kraft pulp and paper reject. The mix tank receives the proper proportion of each component. The pulp is then diluted to about 1%, screened and centrifugally cleaned before going to the paper machine headbox.

The paper production starts at the headbox, which has a position of extreme importance in the process. It is responsible for the distribution of fibers in suspension in the forming section. After the headbox, the fiber suspension is dewatered on the forming wire utilizing foils and suction boxes. The next stage in the process is the press section, where the sheet dryness increases from 16-18% to 43%. The press section imparts important properties to the paper including the correct sheet density and is the most economical method of removing the water at this point of the process. After the press section the sheet is heated in the dryer section to increase the dryness to 90% which is its natural moisture level. The white water extracted in the forming section has considerable fiber content. Thus, the fiber recovery system is installed in order to separate two components: clear water for reuse and recovered fiber.

3. Saving Water through PI

Process Integration (PI) enables the development of efficient mass and energy systems for industries. It is based on applications of methods that facilitate the selection and modification of processes.

3.1. Water Pinch

The hypothesis for determining the “water pinch” is that water is used to absorb contaminants. This section presents the graphical method introduced by Dhole *et al* (1996) to deal with conditions where water flows are more important than contaminant load. According to Jacob *et al* (2002), this graphical tool has been applied with success

in the Pulp and Paper area. After defining the sources and demands in the water circuit, the composite curve can be constructed. The curve is used to find the desired consumption of freshwater and to analyze the potential of water reuse with fixed flows. The outflow of each operation that consumes water can be considered a *source* of water. Analogously, the inflows of each operation are the *demands* that have limits for contaminants concentration and can be supplied by a source. The sources and demands flows are indicated in the abscissa, while the respective purities are indicated in the ordinate in decreasing order.

Table 1: Data for source and demand curves

Description	**Order fiber/DS**	**fiber**	**SD**	**Flow**	**Description**	**Order fiber/DS**	**fiber limit**	**DS limit**	**Flow**

					Water for mixing pump	D14/D15	0,300	3000	43822,8
					Dilution of latency tanks	D15/D6 D16/D9	0,100	5000	8279,3
					Fresh water for TMP	D17/D17	0,018	2500	787,0
					Fresh water for Paper Machine	D18/D18	0,018	2500	3420,0

The advantage of Pinch method is that one source can be splitted into many streams to satisfy different demands, which affect the capital costs. For this reason, the results presented in this paper will focus on the application of this method, although linear programming has also been applied successfully.

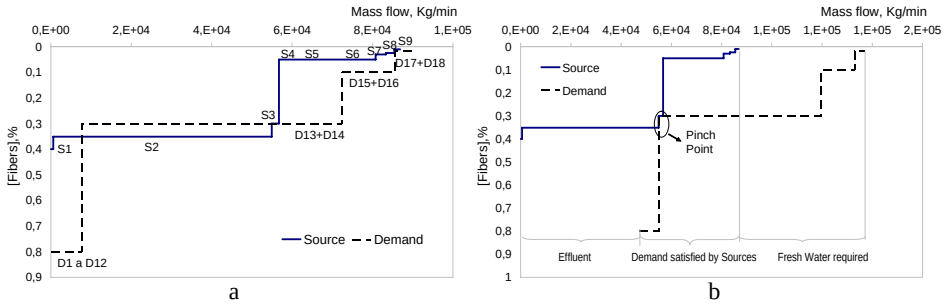

Figure 1 – Construction of sources and demands curves (a). Then the pinch point found after dislocation of demand curve (b).

Figure 1a shows the curves of sources and demands. The objective is to dislocate the demand line to the right and find the pinch point. Figure 1b divides the graphic into three ranges: a) The minimum effluent flow (low purity) is below the pinch point; b) The demands that can be satisfied by available sources; c) Fresh water is used above pinch point to satisfy the demands with high purity;
This system can be improved in order to reduce the consumption of fresh water and effluent flow if "water pinch" point is dislocated. It can be achieved if we increase the purity by mixing the sources. At figure 2a, source flows S2, S3 and part of S4 are mixed to create the stream (S2+S3+S4') to obtain the purity of D3+D14 and thus, dislocate the demands curve to the left in order to find a new pinch point.

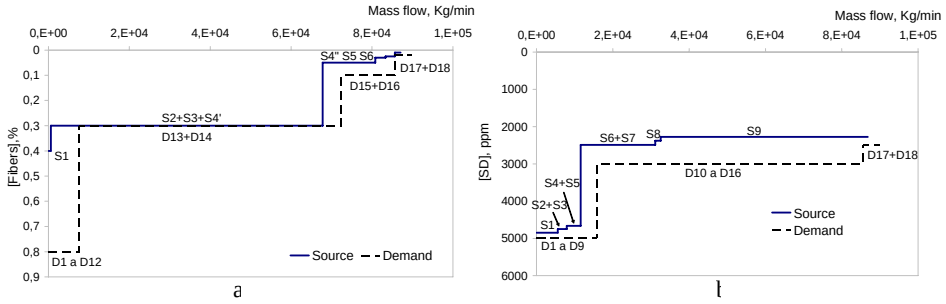

Figure 2 – Mixing of sources to satisfy the limits of demands (a). Mixing of sources to satisfy the limits of DS (b).

According to figure 2b, there is no need to manipulate the curves of water sources and water demands due to the level of dissolved solids. As observed by Jacob et al. (2002), pinch method can be partially automated but is applicable for only one contaminant. On the other hand, linear programming applied to this work for one contaminant added to a concentration of pulp fines, is totally automated and better suited for complex systems.

3.2. Linear Programming

This section explains the concept of mathematic programming, which is an effective method for the analysis, synthesis, and modification of industrial systems aiming for the reuse of water and the minimization of effluent. According to Jacob *et al.* (2002), linear programming is a powerful tool to analyze, simultaneously, the reduction of fresh water consumption and the reduction of and recoverable fibers going to effluent.
Linear programming is able to overcome the disadvantages of Pinch method when applied to this work. It can be used to optimize the water circuit through multi

component analysis, while on the other hand, the Pinch method is restricted to only one component. In order to formulate a case study, Jacob *et al.* (2002) stated that the following constraints have to be defined: (1) The total demand flows fed by a source i cannot be higher than the flow available of this source; (2) Each demand j must be totally satisfied; (3,4) The amount of contaminants provided to demand j cannot be higher than the maximum admissible value defined for this demand.

$$\sum_{j=1}^{n} p_{ij} \le F_i \quad (1) \qquad \sum_{i=0}^{m} p_{ij} = D_j \quad (2) \qquad \sum_{i=1}^{m} c_i p_{ij} \le D_j C_j \quad (3) \qquad \sum_{i=1}^{m} f_i p_{ij} \le D_j F_j \quad (4)$$

The objective function f(x) is the amount that must be minimized under constraints defined by linear equations. Since the objective of the analysis is to minimize fresh water consumption, the objective function is cited as follows:

$$f(x) = \sum_{j=1}^{n} p_{0j}$$

The intention of the method is to reduce the effluent flow and fresh water consumption using qualitative and quantitative constraints imposed by the model. Despite the possibility of analyzing the recovery of fibers in the circuit, this paper will focus on this area. The linear programming in the present work was developed in *MatLab*.

4. Results after Simulation

There is a disadvantage for both methods when the results are transferred to the simulation model. It happens because when original sources are manipulated to satisfy the desired demands, the optimized flows of sources are changed. Since new limits for contaminant concentrations are imposed by the user, the flows defined by the consistency control valve are affected. Besides that, the sources that originated from the filters have fixed consistencies in the model but actually vary with changes in the process. Table 4 shows some differences between the original and optimized values.

Table 4 – Original, simulated, and corrected data after applying Pinch method

	[DS] limit	[DS] Simul.	[DS] after correction	[fibers] limit	[fibers] Simul.	[fibers] after correction	Flow original	Flow Simul.	Flow after correction

Additional Water								**0**	**320,0**
Fresh Water								**4207,0**	**2886,1**

Streams have flows exceeding the concentration limits and therefore appropriate and feasible corrections should be done. Since the software allows the easy manipulation of objects and streams, some new configurations were tested. After testing, the results and their comparison are described also in table 4. The modification requires additional fresh water in some specific points of the process.

5. Conclusion

Both methods, pinch and linear programming, can be used to minimize fresh water consumption with regard to the constraints imposed by the critical contaminants. For the methods applied in the present work, it is very important to know how to define limit values for the concentration of contaminants. Unfortunately, these values are not easily discernable and must be carefully studied and analyzed. Imposing different limit values for the same study case, e.g., can generate significant impacts on the final result, independent of the optimization method utilized. With the integrated paper machine and TMP process, the reduction rate by Pinch and linear programming achieved in the vicinity of 31%. Unfortunately simulation studies demonstrated that many of the streams had unacceptable concentrations of fines and dissolved solids (see table 4). Therefore water usage was increased in the water circuit model in order to reduce the values to acceptable limits, which decreased water savings to 23%, still significant for the industrial unit modeled. The results also show that the application of the Pinch method on an industrial scale is more feasible for industries due to less capital investment.

Abstract

In this work we present a methodology aimed to use the data contained in R&D databases efficiently in order to assist the design of new products by providing models that relate formulations to properties, which are introduced into an optimization problem that represents the design problem together with constraints proposed in order to avoid inaccurate predictions. In this work the methodology is applied to obtain optimal formulations of brake fluids satisfying rigid technical norms and market specifications.
Mixture models are built with Principal Components Regression (PCR) and Partial Least Squares Regression (PLS) which are adequate for systems with incomplete or redundant information, because the informativity of the data with respect to the models is not guaranteed. The models are integrated in an optimization problem, in order to perform the design, which is solved by Mixed Integer Linear Programming (MILP) techniques. Equations that restrain the solution to a set where the information is more trustable are added to the problem. They avoid inaccurate extrapolations that could result in an excessive number of experiments to confirm predictions. The results obtained by this methodology presented good agreement with validation experiments.
The models and optimization tools generated in this work are currently being used at Oxiteno S.A. R&D laboratories and have led to a reduction of time and effort during the development of new formulations.

Keywords: brake fluid, formulations, modeling, optimization

1. Introduction

In this work we present a methodology aimed to use the data contained in R&D databases efficiently. R&D laboratories of chemical industries possess large databases that compile information on a large number of formulations, together with their final properties, of products that were studied once in time. This extremely rich information is in general not exploited as systematically as it could for further product design. In general, the information is in hands of specialists who are in charge of intuitively proposing and devising new formulations. The methodology presented here is aimed to assist the design of new products by providing models that relate formulations to properties, which are optimized with constraints, proposed in order to avoid inaccurate predictions. In this work the methodology is applied to obtain optimal formulations of brake fluids satisfying rigid technical norms and market specifications.

Models are built with adequate techniques for systems with incomplete or redundant information, such as Principal Components Regression (PCR) and Partial Least Square Regression (PLS).

2. Brake Fluids

Brake fluid is the lifeblood of any hydraulic brake system. It is what makes the system operate properly (Scharff, 1989). They are made of mixtures of liquid raw materials employed to transmit pressure within the brake system. In order to do that, brake fluids must perform a variety of functions and must comply with stringent requirements such as Equilibrium Boiling Point, kinematic Viscosity at -40ºC, Evaporation Loss, Wet Boiling Point, Elastomer Swelling, among others. These requirements are defined in various standards of similar content (SAE J1703 - Society of Automotive Engineers J1703, FMVSS 116 - Federal Motor Vehicle Safety Standards 116, ISO 4925 - International Organization for Standardization 4925 and ABNT NBR 9292 - Brazilian Association of Technical Norms). The performance data contained in FMVSS 116, mandatory in the U.S., also works as an international reference (Bosch, 2004). The U.S. Department of Transportation (DOT) has classified the brake fluids into different types such as DOT3, DOT4 and DOT 5.1.

The optimization of brake fluid formulations represents a great competitiveness potential in the automotive segment because it can lead to better quality products with a lower cost. In this work we present the optimization of DOT 3 formulations, used in Brazil mainly in the aftermarket. Besides of that, the raw materials involved in this kind of formulation (mainly glycols and glycol ethers) are available from Ethylene Oxide manufacturers, such as Oxiteno S.A..

The formulations of brake fluids presented here are mixtures of 6 to 8 raw materials chosen out of 18 basic compounds. Each one of the compounds confers different characteristics to the final formulation.

Models are used in order to develop mathematical representations of the design problem that are solved by Linear Programming (LP) techniques. Equations that limit extrapolation problems by restraining the solution to the set where the information is available can be added to the design problem. The problem solved here is similar to the one used in the optimization of formulations of heat stabilizers Poly Vinyl Chloride (Carrillo Le Roux and, da Cruz, , 2006), applied in this case to brake fluid formulations.

In order to validate the methodology, solutions obtained are compared to validation experiments.

3. Materials and methods

3.1. Materials

The development of new products proceeds through steps which target properties are firstly defined and many different “recipes” for obtaining the desired product are tested. The steps that compose the methodology presented here are based on the analysis of historical R&D database, employed in a systematic manner, in order to build models that correlate the final product properties with the compounds in formulations.

This subject is extensively discussed in a recent work (Gani, 2004) where is mentioned that much of the current work in product design is carried out through empirical trial and error approaches, involving time-consuming experiments. Gani (2004) emphasizes the importance to capture the knowledge gained from the past experiments and apply them in a systematic manner in order to reduce the efforts of future trials and, as a consequence, experimentation. According Gani (2004) the major effort is to understand

the molecular structure-property relationships, collect the experimental data, develop the mathematical models and apply the solution techniques.

3.2. Multivariate Calibration

The objective of multivariate calibration techniques is to represent an important quantity of information contained in data that describes a problem by a reduced set of variables, without losing of the relevant information (Carrillo Le Roux and da Cruz, 2006).

In this work, Principal Components Regression (PCR) and Partial Least Squares Regression (PLS) were used in order to build models for mixtures based on historical data and their performances were compared. They are useful to solve collinearity problems (Ferreira et al., 1999; Geladi; Kowalski, 1986; Martens; Naes, 1989).

PCR e PLS generally have similar performances (Beebe; Pell e Seasholtz, 1998; Wise et al., 2003; Rodriguez-Nogales, 2006). According to Esbensen (2006) in the case of modelling only one Y variable, PCR and PLS give similar results, although PLS normally reaches the goal with a less number of factors.

3.3. Optimization

Optimization problems generally can be formulated with mathematical models that involve continuous and/or discrete variables, selected to find equations and/or inequalities, while optimizing the objective function (Grossmann; Biegler, 1995). In the present work the problem was formulated as a Mixed Integer Linear Programming (MILP). Although the *X* variables used here are continuous, binary variables were included in the problem because of the limited availability and/or purity of the raw materials.

4. Application

4.1. Introduction

In this work we present the optimization of DOT 3 formulations, used in Brazil mainly in the aftermarket. Besides of that, the raw materials involved in this kind of formulation (mainly glycols and glycol ethers) are available from Ethylene Oxide manufacturers, such as Oxiteno S.A.. The higher end of the methyl glycol ethers production, such as triethylene glycol methyl ether, is used in hydraulic fluids.

The data set consists of formulations obtained during years of product development, in which 18 different compounds were mixed in different proportions. Formulations are mostly mixtures of 6 to 8 compounds. A more deep description of the formulations will not be presented here because of industrial proprietary reasons. They are grouped into 5 matrices *X* and 5 vectors *Y* that represent respectively the predictors variables (compositions of the formulations) and the chosen properties of DOT3 to be modeled (table 1).

Table 1 - Matrices and vectors dimensions

Variables	Properties of Brake Fluids Formulations				
	BP	VISC	EL	WBP	ESB120
X	170x18	181x18	91x18	63x18	51x18
Y	170x1	181x1	91x1	63x1	51x1

BP - equilibrium reflux boiling point at 760 mmHg (ºC); VISC - kinematic viscosity at -40ºC (cSt); EL - evaporation loss (%w); WBP - wet equilibrium reflux boiling point at 760 mmHg (ºC); ESB120 - effect on styrene butadiene rubber (SBR) at 120°C (mm).

The properties described in table 1 were obtained according to the ABNT NBR 9292 specifications.

4.2. Numerical Tools

Matlab version 6.5 (Mathworks Inc.) was chosen as the framework for the development of the PCR and PLS models, with the use of PLS Toolbox version 3.0 (Eigenvector Vector Inc.).

The problem of optimization was solved by using the Lingo 9.0 solver (Lindo Systems Inc.) that can perform mixed integer linear programming (MILP).

4.2.1. PCR and PLS Linear Mixture Models

In this work we will restrict the analysis to linear mixture models using the equation:

$$\hat{y} = \sum_{i=1}^{18} a_i x_i \qquad (1)$$

In order to transform the data into the most suitable form for the analysis, *X* and *Y* variables were preprocessed, as suggested in the literature (Esbensen, 2006; Ferreira et al., 1999; Geladi; Kowalski, 1986; Martens; Naes, 1989). *X* variables were normalized between -1 and +1 and *Y* variables were autoscaled.

The number of Principal Components (PCs) in the PCR or Latent Variables (LVs) in the PLS were chosen based on the the analysis of the Root-Mean-Square Error of Cross-Validation (RMSECV). This was done using the leave one out methodology, i.e. where each sample is left out of the model formulation and predicted once. In each case, the RMSECV and R^2 was estimated by:

$$RMSECV = \sqrt{\frac{\sum_{i=1}^{n} (\hat{y}_i - y_i)^2}{n}} \qquad (2)$$

$$R^2 = 1 - \frac{\sum_{i=1}^{n} (y_i - \hat{y}_i)^2}{\sum_{i=1}^{n} (y_i - \bar{y})^2} \qquad (3)$$

4.2.2. Optimization

The MILP model used in this work was formulated in order to minimize the relative cost of the brake fluid formulations and considering that the sum of mixtures compositions must be 100%.

$$min\ f(x) \quad subject\ to:\ h(x,y)=0 \qquad (4)$$

$$lb \leq g(x,y) \leq ub \qquad (5)$$

$x \in R,\ y=\{0,1\}$

where: $f(x)$ - objective function (relative cost of the brake fluid formulations); $h(x,y)=0$ - equations (PCR/PLS models, sum of mixtures compositions must be 100% or decisions variables); $lb \leq g(x) \leq ub$ - inequalities that represent the lower and upper boundaries values for x and y variables.

4.3. PCR and PLS Results

The RMSECV and R^2 statistics for PCR and PLS models are shown in the table 2.

Table 2 - RMSECV and R^2 for PCR e PLS models

Properties	PCs or LVs numbers		RMSECV		R^2	
	PCR	PLS	PCR	PLS	PCR	PLS
BP	16	7	0,282	0,292	0,934	0,930
VISC	18	11	0,259	0,276	0,943	0,938
EL	16	7	0,616	0,588	0,771	0,788
WBP	12	5	0,883	0,873	0,445	0,475
ESB120	13	5	0,597	0,605	0,818	0,810

4.4. Optimization Results

In order to validate the methodology it was used external validation by preparing 5 brake fluids formulations, whose properties were determined according to NBR 9292. They were compared to the previous solutions for the optimization problem. The results for PCR and PLS models are show in the tables 3 and 4 for 2 among the 5 formulations.

Table 3 - Results and relative experimental errors for PCR models

Properties	Formulation 1 - PCR			Formulation 2 - PCR		
	Model	Exp. Value	(% error)	Model	Exp. Value	(% error)
BP (ºC)	234,0	230,9	1,3	250,0	248,6	0,6
VISC (cSt)	1350,0	1366,7	-1,2	1200,0	1185,4	1,2
EL (w%p)	69,8	69,0	1,2	64,6	60,0	7,6
WBP (ºC)	150,2	148,2	1,3	151,3	154,6	-2,1
ESB120 (mm)	0,28	0,33	-15,2	0,29	0,23	26,1
Cost of the formulation	136,36			143,75		

Table 4 - Results and relative experimental errors for PLS models

Properties	Formulation 1 - PLS			Formulation 2 - PLS		
	Model	Exp. Value	(% error)	Model	Exp. Value	(% error)
BP (ºC)	234,0	230,7	1,4	250,0	246,7	1,3
VISC (cSt)	1350,0	1381,4	-2,3	1200,0	1213,2	-1,1
EL (w%p)	70,6	68,8	2,6	63,7	57,2	11,3
WBP (ºC)	149,8	150,2	-0,3	151,1	151,7	-0,4
ESB120 (mm)	0,25	0,20	25,0	0,28	0,37	-24,3
Cost of the formulation	136,23			143,40		

5. Conclusions

PCR and PLS showed no significant differences in their predictive abilities, although PLS required fewer latent variables than PCR. The results obtained by this methodology

presented good agreement with validation experiments. The models and optimization tools generated in this work are currently being used at Oxiteno S.A. R&D laboratories and have led to a reduction in time and effort during the development of new formulations.

Prediction of Efficiencies through Simultaneous Momentum, Mass and Energy Transfer Analyses in a Distillation Sieve Tray by CFD Techniques

Dirceu Noriler[a], Henry F. Meier[a], Antonio A. C. Barros[a], Maria Regina Wolf Macel[b]

[a]Regional University of Blumenau, Blumenau, Brasil; [b]State University of Campinas, Campinas, Brasil

Abstract

The main objective of this work is to apply a CFD model under Eulerian-Eulerian framework for gas-liquid flows, with capability to predict the momentum, mass and thermal phenomena of multiphase flows. A two-phase, three-dimensional and transient model with chemical species, energy and momentum conservation balances have been applied for predicting volume fractions, velocity, pressure, temperature and concentration fields, of two-phase flows on sieve distillation tray. The mathematical model was applied in the CFD commercial code for numerical studies, with the construction of a particular numerical grid and with proper sub-routines in FORTRAN language for the closure equations of the model. The results show the profiles as a function of the time and of the position in the distillation sieve tray. The model implemented in this work allows direct application to predict efficiencies in distillation plates, more specifically point, plate, component and global efficiencies.

Keywords: Distillation Sieve Tray, CFD, Efficiency, Mathematical Modeling.

1. Introduction

The equilibrium and nonequilibrium stage models are available to predict the behavior of distillation columns in the open literature [1]. However, they assume perfect mixture in the phases on the plates. However, it has been recognized that the flow pattern on a distillation tray present a large importance on the mass and energy transfer mechanisms. Recent advances and interest in the use of CFD techniques have allowed the study of fluid dynamic in processes and equipments [2]. Contributions have been made in modeling and simulation of gas-solid flow [2-3] and gas-liquid flows, as for example ozonation towers [4-11]. Bubble columns have been firstly considered for modeling bubbling flows [6]. Some works on gas-liquid flow on a distillation tray using CFD techniques can be mentioned [7-10]. The liquid phase flow patterns by solving the time-averaging equations of continuity of mass and momentum only for the liquid phase were studied and the modeling of two-phase flow considering the importance of liquid phase and the gas action with empirical equation were also evaluated [7]. van Baten and Krishna [8] suggested a three-dimensional and multiphase model to represent the hydrodynamics on a distillation sieve tray. The authors use the Eulerian-Eulerian framework and the Reynolds Averaged Navier-Stokes (RANS) equations for modeling turbulent gas-liquid flows assuming that momentum exchange considers only bubble-liquid interaction, i.e., the bubble-bubble interaction was not considered. The two-phase flow behavior considering that the drag force between phases is very high for

distillation cases implies that the gas and the liquid velocities are the same. van Baten and Krishna [8] showed a comparison between heterogeneous and homogeneous models for free surface flow and bubble columns. Gesit et al. [9] applied the heterogeneous model for commercial-scale sieve tray and compared the results with experimental data. Noriler [10] proposed to use the homogeneous model for predicting the hydrodynamic on a distillation sieve tray. Nevertheless, the energy and mass conservations are neglected in most of the works. The model is an improvement of the model proposed by Liu et al. [7] that considers the effects of the gas phase on the liquid phase by empirical equations. The energy equation was available in Noriler et al. [11] that use a two-phase model with empirical equations for momentum and energy inter-phase transfers. The momentum transfer was correlated using the equation proposed by Krishna et al. [8] and the energy inter-phase transfer using the Nusselt number for a sphere particle. The results showed that the temperature fields have an unsteady state behavior, as also occur with volume fraction and velocity fields. The authors demonstrated that the liquid temperature decreases from the inlet up to the weir and the gas temperature increases from the holes up to the top of the tray. In this work, a CFD model under Eulerian - Eulerian framework for gas-liquid flows was implemented, with capability to predict the main phenomenological aspects of multiphase flows. The two-phase, three-dimensional and transient model, with mass continuity, energy, momentum and chemical species conservations have been applied for predicting the volume fractions, velocity, pressure, temperature and composition fields of the two-phase flow on the distillation sieve trays. The model was implemented in the CFD commercial code that uses finite-volume method with variables located in a generalized co-ordinate system for typical operating conditions taken from the literature.

2. Mathematical Modeling

The model considers the flows of gas and liquid in an Eulerian-Eulerian framework, where each phase is treated as inter-penetrating continuum having separated transport equations. A two-phase, three-dimensional and transient model with chemical species, energy and momentum conservation balances have been applied for predicting volume fractions, velocity, pressure, temperature and concentration fields, of two-phase flows on sieve tray distillation. The closure equations for interphase momentum, energy and mass transfers were obtained from van Baten and Krishna [8] methods and the correlation for global coefficient mass transfer from Ranz-Marhan [11]. The turbulence was treated by k-ε standard model.

2.1. Boundary and Initial Conditions

Due to the elliptical characteristics of the partial differential equations of the model, boundary conditions of all frontiers of the physical domain are necessary: at the inlet, uniform profile of velocities and turbulent properties are imposed; no slip conditions on the wall for both phases; and pressure conditions in the outlet were also applied for the two phases.

3. Solution Methodology

Due to the model complexity in a 3-D space-time, it is necessary an efficient strategy to guarantee the stability of the numerical solution. Therefore, it was formulated a methodology to obtain the solution composed by four steps. The first step consists on to solve the model without the energy and chemical species equations. This solution was carried out up to 15 s of real time. Then, this result was used as initial condition to the

second step of the solution, where the energy equation together with the energy interphase transfer were incorporated to the model and the solution was carried out up to 35 s of real time. From this solution, started the next step, which considers the chemical species equations in the model, but without interphase chemical species transfer. In this step, the solution carried out up to 50 s of real time. In the last step, the interphase chemical species transfer was incorporated to the model and the solution was carried out until the system reached the quasi-steady state condition, i. e., about 80 s of real time for all cases analyzed in this work. Noriler [10] presents the solution analyses of the partial differential equations of the model. Based on this, it was applied the Finite Volume method on generalized coordinated and collocated grid to solve the model. A high-order interpolation scheme was used for hydrodynamic equations and upwind for turbulence equations. The pressure-velocity coupling was obtained using SIMPLEC algorithm. The improved RHIE-CHOW algorithm was used to calculate the velocity at the cell faces in order to avoid numerical problems like check-boarding and zigzag. The relaxation factors were not used.

4. Results and Discussions

Based on the physical domain, it was used a distillation sieve tray with 0.30 m diameter, D, and 0.180 m weir length, W. The column has a rectangular entrance for the liquid with 0.180 m x 0.015 m. The weir height, h_w, is 0.080 m, and the fractional holes area to bubbling area, A_h/A_b, is 0.0654. The length between the liquid inlet and the weir is 0.240m with 180 holes in the tray. Figure 1 shows the clear liquid height as a progress variable of the solution.

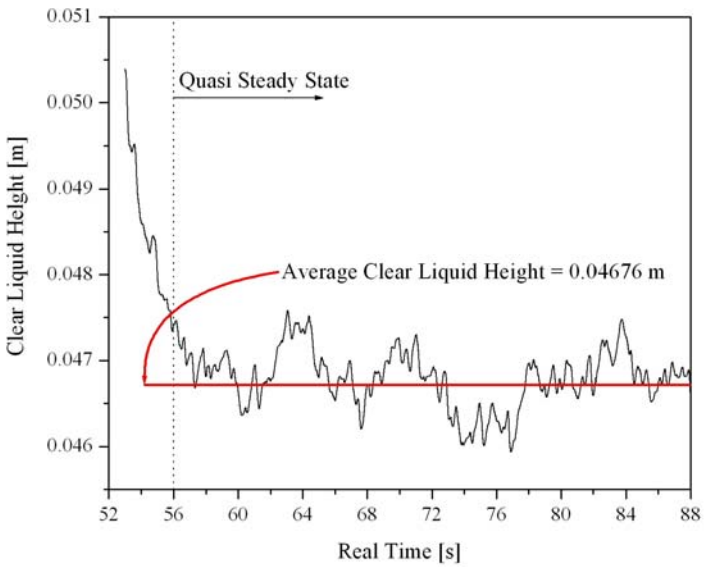

Figure 1: Clear liquid height as a function of real time.

It can be seen in Figure 1 that the flow does not present a steady state well defined, but indeed, present a chaotic regime, characteristic of the quasi steady state, as it was verified in previous works [8-11].

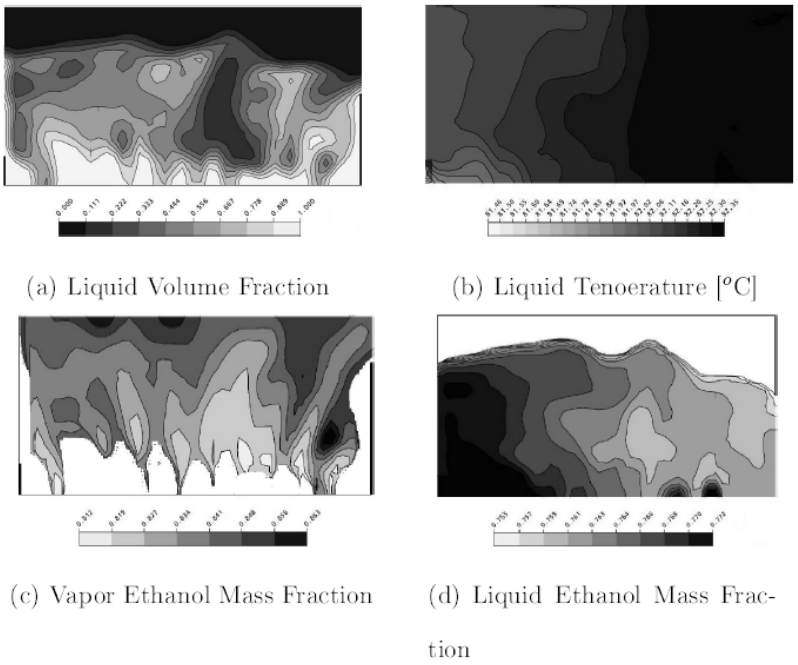

Figure 2: Snapshots of the central plane from the liquid inlet up to the weir of sieve

Figure 2 presents the snapshots of the central plane from the liquid inlet up to the weir of the sieve tray for the liquid volume fraction (Figure 2a), liquid temperature (Figure 2b), ethanol mass fraction in the vapor (Figure 2c), and ethanol mass fraction in the liquid (Figure 2d). It can be seen in Figure 2a, a high liquid volume fraction region near to the bottom, a froth region and a region of the continuous vapor. In this way, Figure 2b evidences that the liquid temperature field is not influenced by the volume fraction field, presenting higher temperature gradients in the liquid flow direction. This fact is due to the high global heat transfer coefficient that results in a high interphase energy transfer rate. In Figures 2c and 2d, it is observed the ethanol mass fraction in the vapor and in the liquid phases, respectively. The white regions in these figures represent absence of the phase. The vapor mass fraction of ethanol increases in the vapor flow direction, from the basis of the tray up to the top of the tray, while the liquid ethanol mass fraction decreases in the liquid flow direction, from inlet liquid up to the weir. These results can be used for developing equations of sieve distillation tray efficiencies based, for example, on the fundaments proposed by Murphree [13] and West [14]. From the results presented in Figure 2, it is possible to determine the global tray efficiency. For the operational and geometric conditions used in this case, the efficiency for this plate and system is 64.16 %. When it is applied the point efficiency concept suggested by West [14], where the tray is divided in regions and then is applied the Murphree [13] efficiency, it can be calculated the efficiency as a function of the position. This information can be used to understand the tray behavior and then to optimize it. The point efficiency is observed in Figure 3. It can be noted that the tray presents high efficiencies near to the inlet and near to the weir. This is due to the recirculation zones that appears together the inlet and weir. Near to the weir, the efficiency reaches the maximum value because the recirculation zones increases the liquid residence time and the ethanol in the vapor phase is the minimum. In the middle of the tray, the efficiency

has small value due to the fact that the liquid phase presents the preferential way in this region.

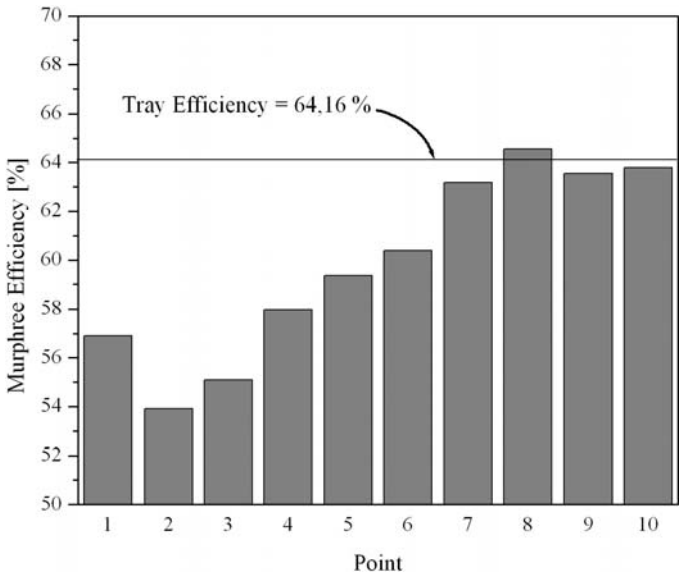

Figure 3: Point efficiency

5. Concluding Remarks

The methodology proposed in this work showed to be suitable, with capability to describe, from CFD techniques, the vapor-liquid flow on a sieve distillation tray. It was possible to calculate the tray efficiency based on models that consider spatial variation in all properties, besides pressure and velocity variations. This is important to design and to optimize distillation trays.

Abstract

In this paper, we overview and discuss the implementation of some topological approaches to modeling and analyzing industrial process data. The discussed methods are used in visualizing process measurements and extracting information by exploiting the metric structure of the observations. Emphasis is given to modeling with the Self-Organizing Map (SOM). The SOM is a standard method for dimensionality reduction and vector quantization equipped with many displays for visualization. Some of the possibilities of the SOM with process data are discussed by exploring measurements from a full-scale gas treatment plant where the goal is to identify important operational modes and sensitive process variables before developing an alternative control strategy.

Keywords: Process monitoring, Process supervision, the Self-Organizing Map.

1. Introduction

Modern process plants are motivated to maintaining and improving product quality and profit while satisfying more stringent environmental and safety constraints. For efficient operation, any decision-making action related to plant operation requires the knowledge of the actual state of the processes. The availability of easily accessible displays and intuitive knowledge of the states is invaluable with immediate implications for profitability, management planning, environmental responsibility and safety.

Due to the advances in measurement and information technology, process industry is also passing through the era of data explosion; historical data are available in abundance. The data derived approach to process monitoring and supervision seeks to construct a representation of a process from a set of easily accessible measurements that quantify its behavior, without explicitly assuming any *a priori* knowledge of the underlying phenomena. However, the task is daunting and remains a major concern. It is necessary the availability of effective methods that *i*) model the data to extract the structures existing in the measurements, *ii*) automatically identify and reconstruct the most relevant structures for the scope at hand, and *iii*) allow for easily interpretable displays where the states' information is presented to the plant operators. Intuitive knowledge of all visited states is invaluable for a safe plant operation and trustworthy methods are a necessary part in a modern supervision and control strategy.

---

[*] On leave, from the Department of Chemical Engineering, Louisiana State University, USA.

In this paper, we discuss a data derived approach to model, visualize and analyze the information encoded in industrial process data. The approach is based on a classical machine learning method, the Self-Organizing Map, SOM (Kohonen, 2001). The SOM combines many of the properties of other techniques and shares many commonalities with two standard methods for data projection (the Principal Components Analysis, PCA; Jolliffe, 2002) and clustering (the K-means; Hartigan and Wong, 1979). In addition, the SOM is also provided with a set of tools that allow for efficient data visualization in high-dimensional settings. Kaski (1997) and Vesanto (2002) discussed the use of the Self-Organizing Map in exploratory data analysis, and their methods are widely known in many fields, see Oja et al. (2003). The major contributions in using the SOM on process data were proposed by Alhoniemi (2002) and Laine (2003). The SOM is here used as a common framework to identify the process modes for a full-scale gas treatment plant and present the extracted information on intelligible displays.

2. Topological data analysis with the SOM

The Self-Organizing Map is an adaptive formulation of the quantization paradigm on a low dimensional space. Thus, the method singles out from other machine learning techniques because it performs both data clustering and projection. The main advantage of the SOM is in the visualization tools that allow for an intuitive data exploration.

The basic SOM consists of a low-dimensional regular array of K nodes where a prototype vector $\mathbf{m}_k \in \mathbf{R}^p$ is associated with every node k. Each prototype acts as an adaptive model for the observations $\mathbf{v}_i \in \mathbf{R}^p$. During the computation, the data are mapped onto the SOM array and the model vectors adapted according to the expression:

$$\mathbf{m}_k(t+1) = \mathbf{m}_k(t) + \alpha(t) h_{k,c(\mathbf{v}_i)}(\mathbf{v}_i(t) - \mathbf{m}_k(t)). \quad (1)$$

In the learning rule in Eq. 1, t denotes the discrete coordinate of the mapping steps and $\alpha(t) \in (0,1)$ is the decreasing learning rate. The map is computed recursively for each observation. The scalar multiplier $h_{k,c(\mathbf{v}i)}$ indicates the neighborhood kernel that, if chosen in its Gaussian form, as in Eq. 2, acts as a smoothing function

$$c(t) = \alpha(t) \exp\left(-\left\|\mathbf{r}_l - \mathbf{r}_c\right\|^2 / 2\sigma^2(t)\right), \quad (2)$$

centered at the Best Matching Unit, BMU (the model $\mathbf{m}_c(t)$ that best matches with the observation $\mathbf{v}_i$). The vectors $\mathbf{r}_l$ and $\mathbf{r}_c$ (both in $\mathbf{R}^2$, for the 2D map) represent the geometric location of the nodes on the array. Upon performing a parallel comparison algorithm, the subscript c (in Eq. 1 and 2) is assigned to the BMU. The competitive criterion for comparison is usually the Euclidean norm. During calibration, the model vectors learn a nonlinear manifold in the original space such that the relevant topological and metric properties of the observations are preserved on the low-dimensional map. Here, the structures are represented by geometric relationships.

In the case of a slightly modified algorithm with a fixed kernel function, the SOM can be also understood from the optimization of a cost function (Heskes, 1997). The cost closely relates to the objective of the K-means algorithm; the only difference being in the neighbourhood function. In that sense, the SOM operates as the conventional clustering method, if the width of the kernel is constantly set to zero. The SOM has also neat projection properties: the cost also closely resembles the objective optimized by Curvilinear Components Analysis, CCA (Demartines and Herault, 1997).

In the typical case of projections onto 2D arrays, the SOM offers excellent displays for data exploration. In that sense, the approach to topological data analysis with the SOM is mainly visual and intuitive. The visualization techniques used in the experiments are the common component planes and the U-matrix (Vesanto, 2002).

3. Application to an industrial deethanizer

To illustrate the potentialities of topological data analysis using the SOM, a set of measurements from a full-scale process was considered. The monitoring problem consists of modeling and analyzing the operational behavior of an industrial deethanizer, starting from a set of online process measurements. The motivation for choosing this unit is merely illustrative. The column offers a variety of behaviors that reflects the operational usage, hence an interesting groundwork for discussion.
The deethanizer, in Fig. 1, is operated to separate ethane from a feed (a light naphtha) while minimizing the ethane extracted from the bottom (an economical constraint for the subsequent unit in the plant). The operational constraint is in the maximum ethane loss from the bottom; at present, the operational threshold is set to be smaller than 2%.

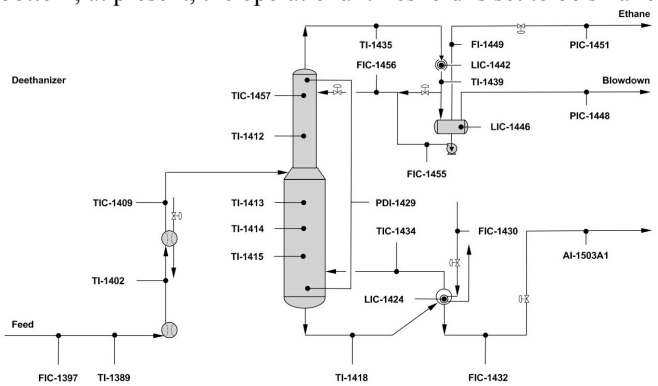

Figure 1. Deethanizer: Simplified flow-sheet.

In order to analyze the behavior of the unit, measurements from a set of process variables was collected from the plant's distributed control system (DCS). The data correspond to 3 weeks of continuous operation in winter asset and 3 weeks in summer asset and are available as 3-minute averages; overall, 27 variables are acquired, for a macroscopic characterization of the unit. In addition, there are several control loops in the process. The column temperature TIC-1457 and the vapour temperature TIC-1434 out of the reboiler is controlled by manipulating the reflux flow-rate FIC-1456 and the steam flow-rate FIC-1430 to the reboiler, respectively; both loops are cascaded to the corresponding flow-rates. The distillate pressure PIC-1451 is controlled by the distillate flow-rate FI-1449 and the reboiler's level LIC-1424 by the bottom flow-rate FIC-1432.
The operational objective of the column is to produce as much ethane as possible (minimizing the propane's concentration from the top of the column) while satisfying the constraint on the impurity from the bottom (ethane's concentration smaller than 2%). Based on the ethane loss from the bottom, three operational modes are identified:

- a *normal* status, corresponding to the operation of the column, where the concentration of ethane is within allowable bounds (in the 1.8% - 2.0% range),
- a *high* status, corresponding to the operation of the column, where the concentration of ethane is exceeding the allowable upper bound (>2%),
- a *low* status, corresponding to the operation of the column, where the concentration of ethane is below the allowable lower bound (<1.8%).

The two abnormal conditions have direct economic implications; when at *low* status, the process is delivering a product out of specifications whereas, when at *high* status the product is within the specifications, but an unnecessary operational cost is observed.

3.1. Exploration and analysis

To understand under which conditions such modes are experienced, the data were analyzed by exploring their clustering structure. Starting from a selection of relevant variables, we augmented this subset with an additional *dummy* indicator, specifically calculated to indicate the status. The new variable was defined so as to take values +1, -1 and 0, according to the operational status. Value 0 is assigned to the *normal* mode, whereas +1 and 1 correspond to *high* and *low* modes, respectively. Notice that the *dummy* variable requires online measurements for the ethane concentration; such a variable, (AI-1503A1), is available in the DCS from a continuous-flow chromatograph.

The set of variables, augmented by the *dummy* indicator, was used to learn a 2D SOM, from the winter observations only. The map consists of a hexagonal array of prototypes initialized in the space spanned by the eigenvectors corresponding to the two largest eigenvalues of the covariance matrix of the data. As usual, the ratio between the two largest eigenvalues was used to calculate the ratio between the two dimensions of the map. On the resulting map, the SOM's component planes and U-matrix were analyzed.

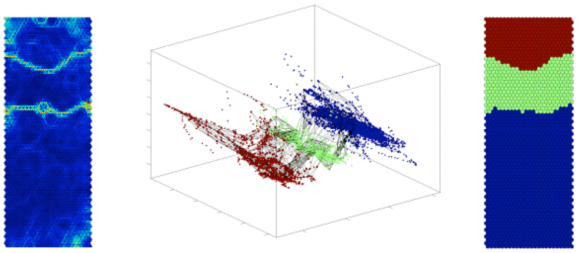

Figure 2. The U-Matrix with three clearly separated clusters in blue (left), the clustered SOM and the winter data after projection onto the principal components space (center) and the map dyed according to the cluster membership obtained from the K-means algorithm (right).

The U-matrix is the display used to visualize the distances between each prototype and its neighbors. The common way to present it consists of an initial projection of the distances onto a color axis and the subsequent display with dyed markers between each node. In the U-matrix, areas with homogeneous coloring (corresponding to small within-cluster distances) are recognized as clusters, whereas cluster borders are identified still as areas with homogeneous coloring but corresponding to large between-cluster distances. The U-matrix is shown in Fig. 2 (left), with a color-coding that assigns blue to close together prototypes (clusters) fading toward red as the distance increases (cluster separations). The visualization permits to recognize 3 distinct taxonomies, as well as several minor substructures. An analogous visualization of the prototypes' grouping is achieved by projecting the nodes onto a low-dimensional subspace, a 3D PCA space (in Fig. 2 (center)). Indeed, also this visualization illustrates the clustering. However, to obtain a quantitative characterization, the prototypes of the SOM can be regarded as a reduced data set and modeled separately with a specific clustering algorithm. We adopted the K-means coupled by the Davier-Bouldin index (as measure of cluster validity) to identify the optimal number K of taxonomies (Milligan and Cooper, 1995). As expected, optimality was found for $K=3$. The operational modes are located in the lower, middle and upper part of the map. The mode-cluster association is straightforward after dying the SOM's region in Fig. 2 (right) with different membership colors (blue, green and red) from the K-means according to a scheme that assigns them to the operational modes (+1, 0 and -1, respectively), and comparing it with the component planes of the *dummy* and ethane (Fig. 3 (left) and (center)).

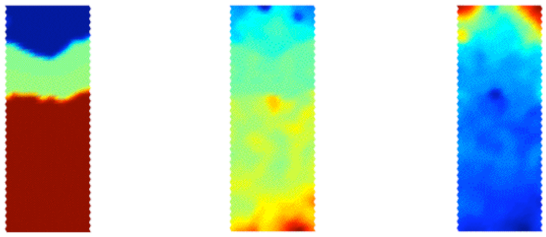

Figure 3. The component planes for the *dummy* variable (left), the ethane concentration (center) and the temperature TI-1414. The coloring ranges from blue (low values) to red (high values).

Fig. 3 also depicts the plane of the column temperature TI-1414 (right); looking for similar patterns in similar positions in the components planes shows a neat dependence between ethane concentrations and temperature measurements. Such pair of variables is characterized by near identical but reversed component planes, thus highlighting the presence of an inherent inverse correlation between the two variables.
To maintain the ethane concentration in normal conditions (within the 1.8-2.2% range, Fig. 4 (left)), the analysis suggests that such temperature should be controlled (within the 52-55°C range, Fig. 4 (center)). The information can be easily retrieved after dyeing the point measurements of the two variables with the corresponding mode membership. A possible variable to manipulate is the steam flow-rate FIC-1430, such a variable is, however, presently unused for control. During the winter period, an overall 85% of off-spec operation, was in fact observed, Fig. 4 (right). The summary is obtained by calculating the number of point measurements falling outside the normality conditions over the total number of observations, and it can be also visually recovered from the area distribution of the clusters in the SOM depicted in Fig 2 (right).

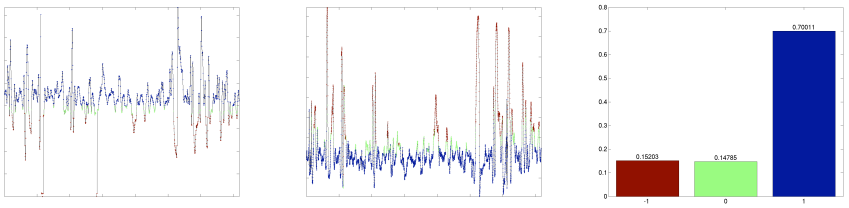

Figure 4. The colored time series for AI-1503A1 (left), TI-1414 (center) and the modes distribution during winter operation (right).

The winter map can also be used to visualize the behavior of the unit in extrapolation; for example, on the summer measurements. The analysis initially projects the new data onto the calibrated SOM, being the mapping based on a nearest neighbor criterion between the new observations and the prototypes. The winter map can be then enhanced by the inclusion of the summer point trajectories followed by the unit. The trajectory, which passes through all the BMUs of each new set of measurements, is shown as red line connecting the visited prototypes, marked as yellow dots. The trajectory makes it possible to indicate the current mode of the process and observe how it was reached.
In Fig. 5, the process trajectory is reported for a small time window corresponding to fifteen hours of continuous summer operation of the deethanizer. Following the temporal evolution, the diagrams show a process that is initially operated in *normal* condition, as for the ethane in the bottom and reference temperature. As the process moved further in time, new prototype vectors were visited and added to the trajectory

until the column leaves the normality region and crosses it towards the region of low ethane composition and starts oscillating. In a similar fashion, all the process variables changed coloring to match the visited modes. The abnormal situation was mainly due to an abrupt decrease in feed flow-rate and possibly composition. In turns, the variation triggered the action on steam to reboiler flow-rate FIC-1430, as well as the reflux to control the top temperature FIC-1436.

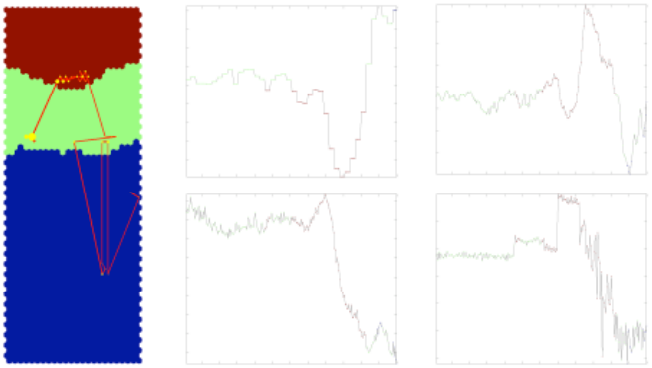

Figure 5. The trajectory and the colored time evolution for the ethane AI-1502A1, the temperature TI-1414, the steam to reboiler FIC-1430 and the reflux flow-rate FIC-1456, in clockwise order

4. Conclusions

In this work, we implemented and discussed a strategy to model, visualize and analyze the information encoded in industrial process data using the Self-Organizing-Map. In particular, the proposed strategy was applied to an industrial distillation column allowing us to illustrate on simple displays how the clustering structure of the measurements corresponds to the operational modes of the units and the possibility to define an alternative control strategy for maintaining it in the normal operating state.

Abstract

The Delaunay tessellation and topological regression is a local simplex method for multivariate calibration. The method, developed within computational geometry has potential for applications in analytical chemistry and process monitoring. This study investigates the applicability of the method for estimating the aromatic composition in Light Cycle Oil (LCO) by Near Infrared (NIR) spectroscopy.

Keywords: Process monitoring, multivariate calibration, Delaunay tessellation, nearest-neighbor regression.

1. Introduction

Real-time monitoring is an essential component in modern process industry for optimizing production toward high-quality products while reducing operating and off-specification costs. The tools of process analytical chemistry like Infrared (IR) and Near Infrared (NIR) spectroscopy fulfill the necessary requirements for real-time analysis of important properties for a broad variety of materials (Workman, 1999).

The principle underlying process monitoring from spectra is the existence of a relationship between the spectrum of a given product and the property of interest. The relationship is rarely known *a priori* but it can be reconstructed from data by calibrating multivariate models. Multivariate calibration methods are often divided into local and global approaches. The latter use all known (calibration) observations to learn the parameters of a single regression model. The former use only small subsets of the calibration data to build different calibration models located in the neighborhood of the observation whose properties have to be estimated. Classical parametric approaches like Principal Components Regression (PCR) and Partial Least Squares Regression (PLSR) are available in both local and global variants (Gemperline *et al*., 2006). Among local methods, non-parametric approaches as topological regression (Jin *et al*., 2003a and Jin *et al*., 2003b) have gained recent interest, mostly driven by industrial motivations; e.g., an inherent ability to handle nonlinearities and the possibility to minimizing models' maintenance tasks while retaining the prediction accuracy.

With the goal to investigate alternative calibration methods that reduce the maintenance costs associated to continuous recalibrations, this paper discusses the Delaunay

Tessellation and Topological Regression (DTR) method (Jin *et al*., 2003b) and its application to calibrating the aromatic composition in Light Cycle Oil (LCO) by NIR spectroscopy. The application is framed within the intense research activity that has characterized the recent trends in refining aimed at optimizing the use of low-value products. LCO is a low-value stream in the diesel boiling range produced in Fluid Catalytic Cracking (FCC) units. Due to its poor characteristics (i.e., high total aromatic content and a considerable percentage of compact structure poliaromatics, among others), LCO is usually not blended directly in the finished diesel fuel pool but it can be upgraded to the higher value diesel if processed in hydrotreatment units (where aromatic compounds are hydrogenated). Within this framework and in order to assure the required process and environmental standards of the hydrotreated products, rapid and cost effective (and possibly on-line) evaluation of the aromatic content is mandatory. Among the many chemometric methods available for such purposes, the DTR method has recently been proposed as an application of computational geometry. It singles out from standard approaches because of its potentiality to achieve accuracies comparable with PCR and PLSR while being much simpler to develop and maintain/upgrade (Jin *et al*., 2005 and Jin *et al*., 2006). In order to assess the potential of the method, a feasibility study with comparison to standard regression methods was performed.

2. Delaunay tessellation and regression

The Delaunay Tessellation and Topological Regression is a local multivariate calibration method developed from arguments in computational geometry. In its basic formulation, the DTR consists of three main steps: 1) a dimensionality reduction based on the known input observations (e.g., NIR spectra), 2) the generation (in the low-dimensional space) of an unstructured mesh by Delaunay tessellation and 3) a nearest-neighbor (or topological) regression for estimating the outputs (e.g., the aromatic content in hydrocarbon mixtures) for a set of unknown observations.

2.1. Dimensionality reduction

The dimensionality reduction step aims at projecting the input observations onto a system of lower coordinates in such a way that certain properties of the data points are preserved as faithfully as possible. The mapping can be either driven only by the input data points (as in PCR) or by both the input and output data points (as in PLSR).

In general, there is a wide range of other methods to performing dimensionality reduction (e.g., see Lee and Verleysen, 2007) that can be considered in this phase. This study is confined to a projection based only on input data, because this representation can be common to all the output properties; thus, minimizing problems and costs associated to the models' recalibration and maintenance. For the sake of simplicity, a PCA was used to characterize the experiments; in that sense, the local property of the data that is preserved is in the set of pair-wise distances between them (Jolliffe, 2002).

2.2. Delaunay tessellation

Once the input observations are projected onto a low dimensional system of coordinates (e.g., the principal components), the known part of this space is partitioned, by generating a mesh using all the available data points. The elements of the mesh are simplexes delimited by known observations (i.e., input data points with known values for the output properties, the calibration set). Within each simplex, the locality conditions are assumed because similar data should be mapped close to each other.

A well-known method for generating a mesh of simplexes is the Delaunay tessellation (Gudmundsson *et al*. 2002). For a given set of point observations in two dimensions, the Delaunay tessellation constructs a mesh of triangular simplexes (hence, the common

name Delaunay *triangularization*) by using all the input data points as vertices; one triangle is a valid simplex if and only if its circumcircle does not enclose any other point in the set (the empty circle condition). In 3 dimensions, the simplexes are tetrahedrons, and so on. Generally, the Delaunay tessellation of a point set exists and is unique.
Notice that the DTR method requires a mesh generation performed on as many dimensions as those obtained in the dimensionality reduction step. For a reduction to *s* dimensions, the elements of the tessellation are simplexes defined by *k=s+1* points.

2.3. Topological regression

Once the mesh is built, it is used for estimating the properties of new observations; that is, data points for which only the input values are known. Also the new observations must be projected onto the same low dimensional system obtained in the first step.
The standard case for estimation is when a new observation **x**(i) (in the *s*-dimensional projection space) happens to fall within the convex hull that contains the know data points. In such a situation, the new point also falls within one of the simplexes.
In two dimensions, the simplex is a triangle with vertexes **x**(1), **x**(2) and **x**(3) (three known observations, also in the *s*-dimensional space), and the position of the new observation with respect to its three neighboring points (the vertexes) is found as a weighted sum of their input coordinates subjected to the convexity constraints (i.e., the weights, $\boldsymbol{\alpha}$(i), are bounded to the unit interval and sum up to one). For each such new data point, only the enclosing triangular simplex fulfills the convexity constraints.
The following equations are used for calculating $\boldsymbol{\alpha}$(i) in two dimensions:

$$\alpha_1(i) = \frac{\big(x_2(i) - x_2(2)\big)\big(x_1(3) - x_1(2)\big) + \big(x_1(i) - x_1(2)\big)\big(x_2(2) - x_2(3)\big)}{\big(x_2(1) - x_2(2)\big)\big(x_1(3) - x_1(2)\big) + \big(x_1(1) - x_1(2)\big)\big(x_2(2) - x_2(3)\big)},$$

$$\alpha_2(i) = \frac{\big(x_2(i) - x_2(1)\big)\big(x_1(3) - x_1(1)\big) + \big(x_1(i) - x_1(1)\big)\big(x_2(1) - x_2(3)\big)}{\big(x_2(2) - x_2(1)\big)\big(x_1(3) - x_1(1)\big) + \big(x_1(2) - x_1(1)\big)\big(x_2(1) - x_2(3)\big)}, \quad (1)$$

$$\alpha_3(i) = \frac{\big(x_2(i) - x_2(2)\big)\big(x_1(1) - x_1(2)\big) + \big(x_1(i) - x_1(2)\big)\big(x_2(2) - x_2(1)\big)}{\big(x_2(3) - x_2(2)\big)\big(x_1(1) - x_1(2)\big) + \big(x_1(3) - x_1(2)\big)\big(x_2(2) - x_2(1)\big)}.$$

The weights α_1(i), α_2(i) and α_3(i), with $0 \le \alpha_1(i), \alpha_2(i), \alpha_3(i) \le 1$ and $\alpha_1(i)+\alpha_2(i)+\alpha_3(i)=1$, are the contributions of the known observations (i.e., the vertexes of the triangle**)** to the new data point **x**(i) and determine its position within the enclosing simplex. Any property *y*(i) of the new observation is estimated as a weighted sum of the properties of the known points:

$$\hat{y}(i) = \alpha_1(i)\, y(\mathbf{x}_1) + \alpha_2(i)\, y(\mathbf{x}_2) + \alpha_3(i)\, y(\mathbf{x}_3), \quad (2)$$

where $y(\mathbf{x}_1)$, $y(\mathbf{x}_2)$ and $y(\mathbf{x}_3)$ are the values of the property for the vertexes. Once the weights are calculated, the estimation of any property is immediate. It is also straightforward to generalize Equation 1 and 2 to more than two dimensions.
The special case is for the estimation of a new observation that does not fall inside the convex hull defined by the known data points; hence, not even in any of the constructed simplexes. In this situation Equation 1 does not hold as the convexity constraints cannot be satisfied. Some of these observations are outliers (in a strict sense) but can also be good data located in region of the input space that was unknown when the initial calibration set was defined. It is worthwhile noticing that, in this sense, the main

limitation of the DTR method is its near-absolute lack of extrapolation ability. However, this limitation is not as dramatic as it may appear, because of the simplicity to update both the projection and the tessellation to account for the *outlying* data points
For the estimation of the properties of such observations, several approaches are reported in the literature (Fernández Pierna *et al*, 2002, Fernández Pierna *et al*, 2003, Jin *et al*., 2003a and Jin *et al*., 2003b) and can be adopted. In this applicative study, an estimate for a new observation situated outside the mesh is obtained by projecting it onto the closest simplex, as identified by its centroidal point (i.e., an artificial observation with a set of identical positive weights that sum up to one). The property is then estimated as equal to what calculated for the centroid of such a simplex.

3. Estimation of aromatics in LCO

A total of 91 LCO and Hydrotreated LCO (HDT LCO) samples were acquired for the present study. The HDT LCO samples were obtained at Sartec S.p.A. in a bench-scale pilot unit (Vinci Technologies) operating at various temperatures and pressures, by processing from different LCO feeds provided by the Saras Refinery (Sarroch, Italy). The unit mimics the most typical industrial operations and ensures the range of variation in the total aromatic content and in the distribution of the mono-, di- and tri+ aromatic classes expected in the full-scale case. The NIR spectra of the samples were recorded using a Varian Cary 500 Scan double-beam spectrophotometer in the wavelength range 1600-800 nm (*1 nm* resolution). The aromatic content (*w%*), was determined with the HPLC method EN-12916 using a modular Agilent 1100 Series system with refraction index detection. For the development of the multivariate models, the observations were divided in a calibration and validation set (respectively, 58 and 33 data points) chosen in order to contain samples that provide examples of all products' qualities and spanning the entire range of variation in the concentrations of the aromatics.

3.1. Results and discussion

Based on the data points in the calibration set, a dimensionality reduction with the Principal Components Analysis was performed, as a first step. As discussed in Section 2, the technique of choice uses only the input observations (the NIR spectra, Fig. 1a). After mean centering the observations, PCA was performed and the calibration spectra projected, Fig. 1b. The number of retained principal components is two. The selection was performed by inspection of the eigenvalues of the covariance matrix of the data; the two retained directions account for over *90%* of the total variation in the input space.
Upon projecting the input observations in the calibration set onto the first two principal directions, a Delaunay tessellation was performed, Fig. 1c. Each element of the mesh is a triangular simplex; the set of simplexes is enclosed in a bi-dimensional convex hull.
Subsequently, also the testing observations were mean-centered and projected onto the principal components space (Fig. 1d) where topological regression is performed. Again, it is worthwhile noticing that being the DTR model the same (the weights are calculated only once, from Eq. 1) for all the properties to be estimated, only a single regression model (Eq. 2) is needed; thus, minimizing the calibration and maintenance tasks.
The regression model was found by resolving for the coordinates of the testing observations and, then, calculating the respective properties from the known measurements. As for the testing observations that do not fall inside the convex hull determined by the calibration points (only 5, and all rather close to the boundaries of the convex hull, Fig 1d), the centroids method was used. The estimation results for the independent set of testing observations are depicted in the Fig. 2 and reported in Table 1 for the mono-, di- and tri+ aromatic content. In addition, we are reporting also the

results obtained when estimating the density of the samples. Density (*g cm-3*) was measured according to analytical method ASTM-4052.

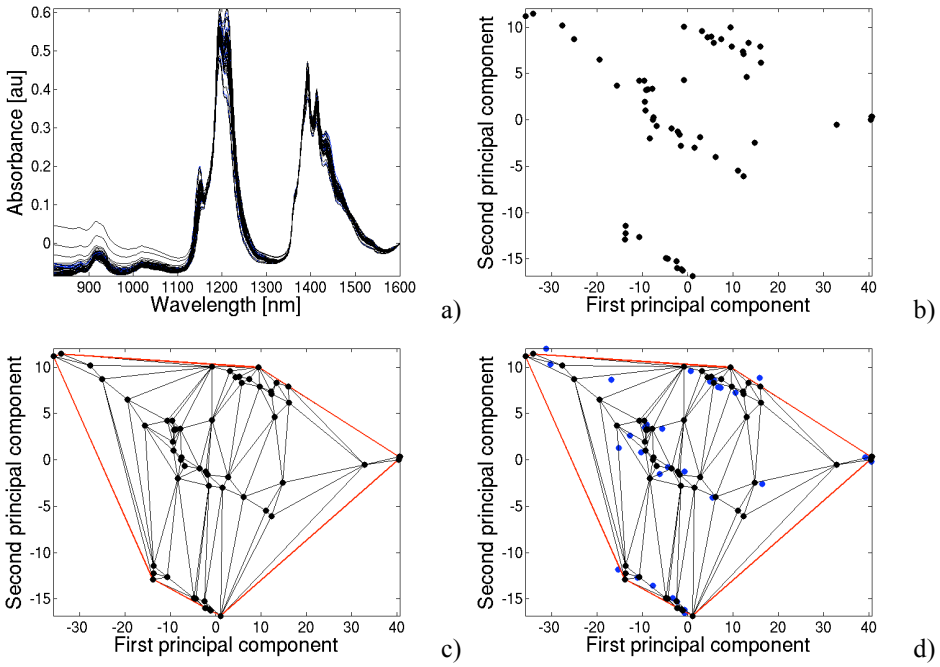

Figure 1. The spectral observations (calibration set in black and testing set in blue) in the original wavelength/absorbance space (a), projected in the principal components space (b), the mesh of simplexes generated by Delaunay triangulation (c) and, with the projected testing data points (d).

The accuracy of the estimates, expressed in terms of Root Mean Squared Error (RMSE) is within the repeatability range of the analytical measurements, and comparable with what obtained using a set of PLSR models independently cross-validated by Leave One Out (for the number of latent factors, 5). Table 1 also presents the results obtained with a set of PLSR models calibrated with 11 factors.

	Mono AH (*w%*)	**Di AH** (*w%*)	**Tri+ AH** (*w%*)	**Density** ($g\ cm^{-3}$)
DTR (2)	2.73	1.23	0.50	0.0021
PLSR (5)	2.06	0.98	0.80	0.0039
PLSR (11)	1.27	0.72	0.52	0.0021

Table 1. The estimation results (as RMSE) on the independent set of testing observations.

4. Concluding remarks

The results using the Delaunay Tessellation and Topological Regression presented here for the calibration of the aromatic content in Light Cycle Oils are at least comparable with the results of standard PLSR. The main advantages of the DTR method are in the simplicity of the calibration and ease to upgrade, but also the fewer components, thus leading to more robust and manageable models.

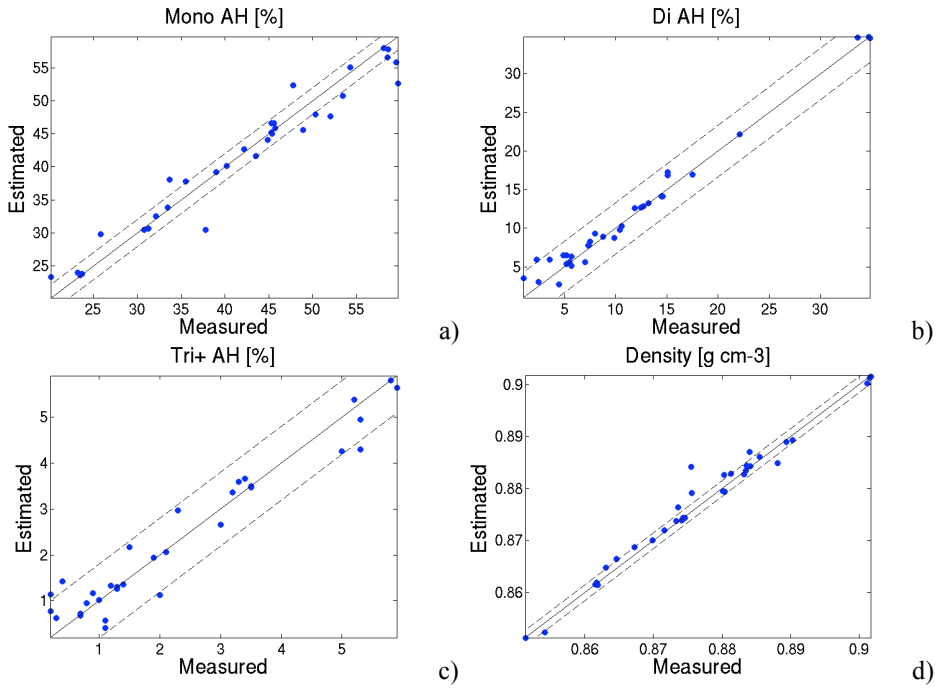

Figure 2. Estimation results (as scatter-plot) and the ASTM repeatability bands.

An Evolutionary Approach to Derive Adaptive Optimal Control Policy for Chemical Reaction Processes

Yoshiaki Shimizu

Department of Production Systems Engineering, Toyohashi University of Technology, 1-1 Hibarigaoka, tenpaku-cho,Toyohashi 441-8580, Japan

Abstract

To obtain a near optimal control policy for real world chemical processes, in this paper, we focused our attention on a new meta-heuristic method termed differential evolution (DE). Compared with conventional approaches characterized by variational logic as well as by the inconveniences of simultaneous optimization methods for differential-algebraic equation, we have shown DE's ability to derive a near optimal solution adaptive to various requirements in practice. Since the algorithm is straightforward and flexible to manage various conditions that other conventional approaches could not cope with effectively, we can cope with high dimensionality and outstanding non-linearity peculiar to chemical process in real world applications. In numerical experiments, we provided three popular reaction processes, applied the proposed method under various meaningful conditions, and validated its adaptability in comparison with other methods.
Keywords: Process system, Optimal control, Differential Evolution, Piece-wise constant, Chemical reaction process.

1. Introduction

By virtue of the advanced progress of meta-heuristic optimization method, we are now ready to derive a near optimal control policy for multi-dimensional and complex real world applications in chemical processes. With such understanding, in this paper, we focus our attention on a new meta-heuristic method termed differential evolution (DE). In comparison with the conventional variational approaches, it can derive a near optimal solution efficiently but very simply without any differential information and additional relations like adjoint equations in Maximum Principle (MP) of Pontryagin (1962). Since it is also free from the complicated usage in simultaneous optimization methods, we can cope with high dimensionality, discontinuity, and outstanding non-linearity peculiar to real world chemical reaction processes.
The aim of this paper is to facilitate a wide application of simulation-based optimization methods like DE for optimal control problems. Finally, its manifold effects are validated through numerical experiments.

2. Problem statements

Optimal control problems , which belong to a class of the off-line dynamic optimal control problem, has been solved traditionally by a certain variational method innovated by the MP. Since singular control and state inequality constraint problems often appear in practical operations of chemical processes, it is almost impossible to solve high dimensional problems for such cases.
Roughly speaking, numerical methods to cope with differential-algebraic equation (DAE) optimization problems are classified into sequential and simultaneous strategies

(Biegler, Cervantes and Wachter, 2002). The former is a control variable parameterization method while the latter uses the difference equation forms both of control variables and state variables. Therefore, the simultaneous approach needs to solve an extremely large-scale non-linear programming problem though it can handle the algebraic constraints by the same manner, i.e., difference equations.

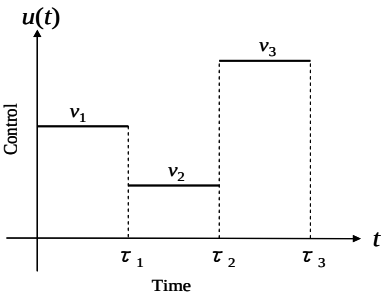

Fig.1 Piece-wise constant control

On the other hand, in the sequential or control variable parameterization approach, the search space is limited within a small region since the differential equations are not transformed into difference equations. However, it is not straightforward to handle the algebraic constraints.

Since, in many chemical processes, some controlling actions are operated discontinuously along time or space co-ordinate, this sequential approach should be highlighted by virtue of recent progress of optimization methods. Among them, piece-wise constant control (PWCC) (Fig.1) is one of the control classes that is easy to implement in reality. Hence, some meta-heuristic methods were successfully applied to obtain the optimal PWCC (Cruz et al., 2003; Kapadi & Gudi, 2004). However, these studies simply applied the methods to search only value of control variables and neglected an interval search and various practical conditions.

Since there has never existed any satisfactory answer to obtaining the optimal control from a practical point of view, it is essential to develop an approach realizing adaptive application to large-scale and complex systems in a flexible and straightforward manner.

2.1. Fixed-time Discrete Problem

Let us consider a system whose dynamics are described by

$$\dot{x} = f(x(t)), u(t), t), \quad x(t_0) = x_o \tag{1}$$

where $x(t)$ denotes an n-dimensional state vector, $u(t)$ an r-dimensional control vector, $f(\cdot)$ an n-dimensional vector function and t a time or time analog. Assuming a scalar control variable $u(t)$, for simplicity of description, the control policy of PWCC is prescribed by a set of pair (v_i, τ_i), where v_i is the value of $u(t)$ at i-th interval and τ_i is the i-th switching point. Then, the continuous problem can be transformed into the following $2N$-1 dimensional optimization problem where v and τ are the vector forms of the sequences of v_i (i=1,2,$\cdots$,N) and τ_i (i=1,2,$\cdots$,N-1), respectively.

$$\text{(p.1)} \ \underset{v,\tau}{Max} \quad J = K(x(\tau_N), \tau_N) \ \text{ subject to } \begin{cases} \dot{x} = f(x(t), v_i), (\tau_{i-1} \le t < \tau_i) \\ x(\tau_{i-1}^+) = x(\tau_{i-1}^-) \\ \underline{u}_i \le v_i \le \overline{u}_i \quad (i = 1, \ldots, N) \end{cases}$$

where $\underline{u}$ and $\overline{u}$ are lower and upper bound vectors of $u(t)$, and N denotes the number of division and controls the fineness of the control policy. In the case of equivalent interval, i.e., $\tau_j - \tau_{j-1} = \tau_{j+1} - \tau_j$, ($i$=1,2,$\cdots$,$N$-1), the dimension of search problem (v-mode search) reduces to just N, apparently. Moreover, it should be noted that $\tau_0 = t_0$ and $\tau_N = t_f$ are implied, and each τ_i ranges from 1 to N_T, satisfying the condition that $\tau_j > \tau_{j-1}, (j = 1, \ldots, N)$ where $N_T = (t_f - t_0)/H$ (H is an increment width of the numerical solution of the differential equation).

2.2. Free-time Discrete Problem

A typical example of the free-time problem is known as the time optimal control problem described in the following.

$$\text{(p.2) Min } J=t_f \text{ subject to } \begin{cases} Eq.(1) \text{ and } \underline{u} < u(t) \le \bar{u} \\ x(t_f) = x_f \end{cases}$$

Here let us note the additional boundary condition of the state variables at the final time. The present simulation-based approach is almost impossible to always satisfy this condition directly. To cope with this problem, we use the penalty function method by augmenting the boundary condition into the objective function as follows.

$$\text{(p.3)} \qquad t_f + P\left\|x(t_f) - x_f\right\| / \left\|x_f - x_0\right\|$$

where || || denote a certain norm of vector, and P a penalty coefficient whose value should be increased adaptively according to the following formula.

$$P := \begin{cases} P + \Delta p & \text{if} \quad G^k < G^{k-1} \qquad (\textit{coming up the target}) \\ P & \text{if} \quad G^k \geqq G^{k-1} \qquad (\textit{leaving the target}) \end{cases} \tag{2}$$

where G^k denotes the value of $\left\|x(t_f) - x_f\right\| / \left\|x_f - x_0\right\|$ at the k-th iteration, and Δp a certain incremental amount.

3. Evolutionary Optimization to Derive Adjustable Optimal Control

3.1. Application under various control policies

For solving (p.1) and (p.2), it is straightforward to apply DE in the following manner. The genetic code of DE is made of the sequence of $v_i \ \ (i = 1, \ldots, N)$ for the equal interval problem, and in addition to it, the set of the interval length, i.e., $z_i = (\tau_i - \tau_{i-1}) / H, \ \ (i = 1, \ldots, N)$ for the unequal interval problem. Once these values are prescribed, we can evaluate the objective function directly after solving the differential equations numerically. Then, we can utilize simply this value as the fitness of the DE. Since the interval length z_i should be integer, rounding-off is carried out to satisfy this condition. The initial population is generated randomly by scattering the value between the lower and upper bounds of the decision variables.

Generally speaking, when N is small, the control often changes rapidly between the consecutive sequences. Hence, it likely happens that actual control action cannot catch up such a large change instantly. When this is the case, it is possible to impose the following condition.

$$\left|v_{i+1} - v_i\right| / T_{setup} \le v_{speed}, \ (i = 1, \ldots, N-1) \tag{3}$$

where T_{setup} and v_{speed} denote a transient interval and an admissible switching speed of the control policy, respectively. Similarly, when the duration interval of each v_i is prescribed, we can design the strategy by imposing conditions such that $\tau_j - \tau_{j-1} \ge D$, ($i$=1,2,…,$N$) for the unequal interval case and $(t_f - t_0) / N \ge D$, for the equal interval case. Here D denotes the minimum duration interval.

On the other hand, when N becomes large, this often causes the chattering action within the bounded control region in numerical solution. To prevent such chattering, the condition $\left|v_{i+1} - v_i\right| \le \varepsilon, \ (i = 1, \ldots, N-1)$ is available to smooth the control policy, where ε is an appropriate small positive value.

3.2. State inequality constrained problem

Chemical processes are often controlled by manipulating flow rates and are restricted within a certain state space prescribed by temperature, pressure, and concentrations of chemical species, for examples. The latter condition requires us to augment the additional algebraic conditions like $g(x(t),u(t)) \leqq 0, \quad t_0 \leq t \leq t_f$ into the original model. Instead of the tedious procedures discussed previously (Takamatsu and Shimizu, 1978a), the present approach can manage this problem much more simply even for this DAE system. That is, it is enough to degrade the fitness value $Fit(v,\tau)$ of the DE according to the degree of violation of the state-inequality condition in the course of the transition as $Fit'(v,\tau) = Fit(v,\tau) + P \cdot \sum_{i=1}^{N} \delta_i(g)$, where P denotes the penalty coefficient and the psedo-heaviside function δ_i takes the value only when anyone of the state inequality constraints are violated at the *i*-th interval.

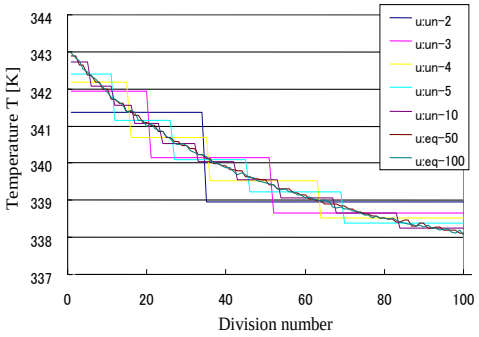

Fig.2 Control policies for various *N*
(Only *v*-mode search when *N*=50 and 100)

3.3. Insensitive control against parameter deviations

Describing explicitly a parameter vector *p* of the system model, let us note the existence of uncertainty in the model. Then we tried to obtain an insensitive control policy against the uncertain parameters. For this purpose, we derive the sensitivity equations with respect to *p*. Adjusting a certain norm of the sensitivity in an appropriate manner, e.g., $\|(\partial K/\partial x)(\partial x(t_f)/\partial p)\|$ for the objective function value, $\|(\partial x(t)/\partial p)\|$ for each state variable, and $\|(\partial g/\partial x)(\partial x(t)/\partial p)\|$ for the state-inequality constraints, for examples, we can give a suitable answer for the problem under consideration. Finally, this insensitivity goal is augmented to the original objective function J as $J' = wJ + (1-w)S$, where S represents the sensitivity term given by the appropriate norm exemplified in the above, and w is the weighting factor to adjust the trade-off between the two goals, i.e., J and S.

4. Numerical Experiments

In the following numerical experiments, DE/rand/1/bin (Storn & Price, 1997) is applied. After some preliminary numerical experiments, we set the tuning parameters as F=0.8, P_c=0.5, N_p=3(2N-1) for the unequal interval problem while 3N for the equal one and the sopping generation=$20N_p^2$, where F, P_c and N_p denote the scale factor, the cross-over rate and the population size, respectively. Under these conditions, we observed a good profile of convergence all in the following numerical experiments.

4.1. Temperature control of completely mixed batch reactor (A)

For the reaction scheme like $A \xrightarrow{k_1} B \xrightarrow{k_2} C$, the optimal temperature control problem that maximizes the production of the desired product *B* is well known and is formulated as follows.

$$\underset{T}{Max} \quad J = x_2(t_f) \quad subject\ to \begin{cases} dx_1/dt = -k_1 x_1, & x_1(0) = x_{10} \\ dx_2/dt = k_1 x_2 - k_2 x_2, & x_2(0) = x_{20} \end{cases}$$

where x_1 and x_2 are the concentrations of components *A* and *B*, respectively, t_f is the batch time, and k_1 and k_2 are the reaction rate constants of Arrhenius type.
As shown in Fig.2, the DE derived the solutions efficiently from N=2 up to the minimum grain interval problem, i.e., N=N_T=100. The only *v*-mode search has been done for N=50 and 100. When N=100, the result is almost equivalent to that of the variational method.

4.2. Catalyst blending problem (B)

The catalyst blending problem studied originally by Hofer (1976) is known to involve a singular control portion. With the prior knowledge that the optimal control is composed of three segment, i.e., upper bound, constant singular, and lower bound segments, a sensitivity method (Takamatsu and Y. Shimizu, 1978b) can derive the result very quickly by virtue of the differential information and small problem size. However, without such prior information, the DE outperformed this sensitivity method. Figure 3 depicts the results obtained by the proposed method. They are nearly identical to the profile of the sensitivity method when N=3 which is, in turn, almost same as the optimal control.

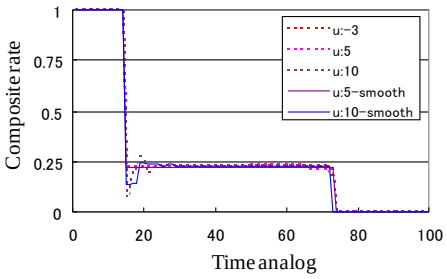

Fig.3 Result of control policy

4.3. The flow rate control under state inequality constraint (C)

4.3.1. Fixed-time Solution

For the first-order reversible exothermic chemical reaction (Siebenthal and Aris, 1964), let us suppose that the temperature in completely mixed batch reactor with cooling jacket must not exceed the upper limit $\overline{T}$. The optimal cooling control problem that will achieve the maximum production of *B* is described with dimensionless variables as follows (Takamatsu and Shimizu, 1978a).

$$Max \quad J = x_1(1) \qquad \text{subject to}$$

$$\begin{cases} \dot{x}_1 = p_1(1-x_1)\exp(p_2/x_2) - p_3 x_1 \exp(p_4/x_2), & x_1(0) = x_{10} \\ \dot{x}_2 = p_5[p_1(1-x_1)\exp(p_2/x_2) - p_3 x_1 \exp(p_4/x_2)] - p_6 u, & x_2(0) = x_{20} \\ \underline{u} \le u(\tau) \le \overline{u}, \quad x_2(\tau) \le \overline{x}_2 \quad (0 \le \tau \le 1) \end{cases}$$

where the kinetic rate constants are of the Arrhenius type. Due to the state-inequality constraint over the time horizon and the linearity of the control variable, this problem is known to be very difficult to solve.
Numerical results revealed that the good performance of the simplex method of Nelder and Mead is limited only to the small N, and the unequal interval search with moderate N (= 5) is enough to attain a satisfactory performance level (the gap to the optimal value is less than 0.3%). The chattering becomes heavily for N greater than 50 to imitate the optimal trajectory.

4.3.2. Insensitive control against parameter deviations

It is likely that the fouling degrades the performance of the cooling jacket, and the reactor temperature may exceed the limit. To prevent such defect a priori, an insensitive control policy against the parameter deviations (fouling) is more desirable to keep the safety or the long life of the reactor. To realize this aspect, the sensitivity

equations with respect to p_6 are derived. The present strategy for the insensitive control is to take an action when the state trajectory approaches the limit beyond a certain threshold value Δx_2 (= $0.01\overline{T}/T_0$). That is, $\|(\partial g/\partial x)(\partial x(t)/\partial p)\|$ in section 3.3 is defined as $\left\{\int_{t_2}^{t_1}(\partial x_2(t)/\partial p_6)^2\,dt\right\}^{1/2}$ where t_1 and t_2 prescribe the beginning and the ending points of the interval featuring the situation, $\bar{x}_2 - x_2(t) \le \Delta x_2$. By considering the insensitivity, the state trajectory tends to keep inside of the upper limit of temperature as illustrated Fig.4. Accordingly, the violation does not occur even with the 20% parameter variation (p_6' = 0.8 p_6). Moreover, it only causes a small degradation of the system performance both at the nominal (ordinary=0.9153 vs. insensitive=0.9143) and at the deviated (0.9074 (infeasible) vs. 0.9065).

4.3.3. Free Time Solution

The objective function of this problem will be changed as $Min \quad \tau_n \quad (\tau_n \le \tau_N$=100). Additionally, we need to add the terminal condition like $x(\tau_n) = x_f$. For three problems with different terminal conditions shown in Table 1, the proposed approach solved all cases within the square root error 0.0001 of the terminal condition. Figure 5 depicts the control policy for Run 1 when *N*=10.

Table 1 Numerical results for free time problem

Run	x_f	τ_n [-]
1	(0.88, 0.92)	63
2	(0.9, 0.9)	83
3	(0.9, 0.95)	86

(*N*=10; unequal interval policy)

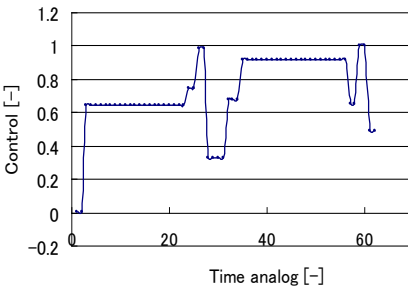

Fig.5 Profile of control for Run 1

5. Conclusion

To derive the optimize control policy for multi-dimensional and complex systems aimed at real world applications, we focus our attention on a new meta-heuristic method termed DE. Compared with the conventional approaches, we have shown DE's ability to derive optimal PWCC efficiently under various conditions popular in real world applications. In comparison with other methods through various numerical experiments, we have confirmed the great promise of DE as a practical solution method for optimal control problems.

A Novel Technique to Estimate Valve Stiction Based on Pattern Recognition

"Marcelo Farenzena, Jorge O. Trierweiler"

"Department of Chemical Engineering, Federal University of Rio Grande do Sul," Porto Alegre, RS, 90040-040, Brazil

Abstract

This work proposes a novel method to estimate valve stiction parameters that requires only normal operating data (process variable (PV) and controller output (OP)). The technique is based on pattern recognition, where a neural network, called Stiction Inference Model (SIM), predicts the stiction parameters. Thus, the quantification is very fast and robust, what allows the application in the industrial scenario, where a large number of loops should be analyzed. The SIM is described, as well as the procedure to its construction: the dataset construction, the variable selection, and the network training. The SIM obtained has a compact size (10 neurons) and a good performance for both parameters (R^2=0.99). The proposed method was applied in a set of valves, providing reliable results.

Keywords: Process control; Process monitoring; Valve stiction; Hysteresis.

1. Introduction

The diagnostics of the "valve health" is important to eliminate plant oscillations, allowing the process to achieve a more profitable operating point. The villain in chemical plants is high static friction (or stiction). Reports show that 20-30% of all control loops have bad performance because of stiction (Bialkowski, 1993). That is why preventive maintenance is essential to avoid off-spec products and waste of energy or raw materials. This scenario demands an automatic technique to detect and quantify valve.

In the last ten years, many works and methods have been proposed to diagnose and solve this valve disorder. A first group of works aimed at diagnosing stiction automatically, using only process variable (PV) and controller output (OP) (He et al., 2007; Horch, 1999; Rossi and Scali, 2005; Singhal and Salsbury, 2005; Yamashita, 2006). Some works have proposed specific stiction models for diaphragm type valves. A good survey about stiction models was recently written by Garcia (2008).

Furthermore, some authors have proposed to compute stiction parameters in real time. Choudhury et al. (2006) proposed two methods to quantify stiction parameters, based on ellipse fitting and *c-clustering*, using a one parameter empirical model. Subsequently, some authors have proposed to quantify stiction parameters using a more reliable model, with two parameters. Choudhury *et al.* (2008) have proposed a method based on optimization and grid search. Jelali (2008) has introduced one methodology to compute both stiction parameters, based on least-squares and global search algorithms. This method is computationally expensive what restrict its on-line application.

The main contribution of this work is to overcome this limitation, proposing a method to compute the two stiction parameters, where the stiction parameters are estimated with a very fast computational time. The technique is based on pattern recognition, where a neural network, called Stiction Inference Model (SIM), predicts the stiction parameters.

Thus, the quantification is very fast and robust. Moreover, the method needs only normal operating data, i.e. based on process variable (PV) and controller output (OP) patterns. No information about the valve stem is necessary. Based on these premises, the method can be applied industrially, where a large number of valves is analyzed. The procedure to build the SIM has used the stepwise regression to select the input variables and a neural network to capture the desired behavior input-output The SIM accuracy is slightly poorer – with less than 30% relative error when compared to the least-squares and global search algorithm. However, our objective is to propose a fast algorithm to allow its large-scale application.
The paper is segmented as follows: in section 2 the stiction phenomenon is defined and modeled. In the next section, Stiction Inference Model (SIM) is defined, as well as the procedure to build it. Next, in the section 4, the SIM is applied in a set of case studies. The paper ends with the concluding remarks.

2. Stiction: definition and model

The phenomenon of stiction can be summarized as follows (Ruel, 2000): "*Stiction is the resistance to the start of motion, usually measured as the difference between the driving values required to overcome static friction upscale and down scale. The word stiction is a combination of the words stick and friction, created to emphasize the difference between static and dynamic friction. Stiction exists when the static (starting) friction exceeds the dynamic (moving) friction inside the valve. Stiction describes the valve's stem (or shaft) sticking when small changes are attempted. Friction of a moving object is less than when it is stationary. Stiction can keep the stem from moving for small control input changes, and then the stem moves when there is enough force to free it. The result of stiction is that the force required to get the stem to move is more than is required to go to the desired stem position. In presence of stiction, the movement is jumpy.*"

2.1. Stiction model

A sticky valve has in the phase plot (Valve output (MV) versus Controller output (OP)), shown in Fig. 1, four components: deadband (*DB*), stickband (*SB*), slip jump (*J*) and moving phase (*MP*). The method assumes that the process and controller have linear behavior, while the sticky valve inserts in the loop nonlinear behavior.
When the valve changes the direction (A), the valve becomes sticky. The controller should overcome the deadband (AB) plus stickband (BC), and then the valve jumps to a new position (D). Next, the valve starts moving, until its direction changes again or the valve comes to rest, between D and E.
The stiction model consists of these two parameters: S, called staticband, (deadband+stickband) and J (slipJump). The deadband and stickband represent the behavior of the valve when it is not moving, although the input of the valve keeps changing. The magnitude of staticband and slipjump is essential to determine the limit cycle amplitude and frequency.

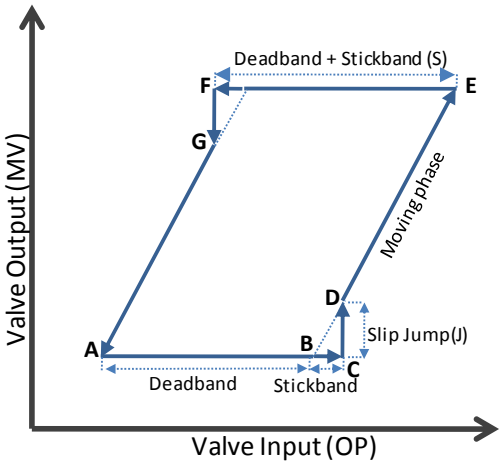

Fig. 1. Relation between controller output (OP) and valve position (MV) for a sticky valve.

The stiction model used in this work is proposed by Kano (2004), which is an extension of Choudhury's method, where stiction is modeled using two parameters. Their main advantage is that it can deal with both stochastic and deterministic signals.

2.2. Stiction evaluation

In the literature, two methods are available to compute the stiction parameters, using a two parameter model. The method proposed by Jelali (2008), a two step procedure is introduced. In the first step the stiction parameters are quantified using pattern search methods or genetic algorithms (GA). Following, the low-order linear plant model is identified, using a least-squares estimator. A second work of Choudhury *et al.* (2008) proposes a method based on a grid search. Initially, a grid using several different values of *J* and *S* is built and then based on the process output, the plant model is identified. Based on the mean square error (MSE) between predicted process output and actual output in each grid point, the stiction parameters are estimated.

3. Stiction Inferential Model (SIM)

The Stiction Inference Model (SIM), proposed in this work, can be defined as an inference model to evaluate the Staticband (*S)* and the SlipJump (*J*), whose inputs are parameters obtained only from normal operating data.

The procedure to construct SIM is analogous to the procedure to build a softsensor using neural networks. The steps are following listed and they will be explained in the next sections.

1. Dataset design: select plant models, disturbances, controller performance, and stiction parameters;
2. Generate the dataset and compute candidate inputs and outputs parameters;
3. Divide the dataset into test and training datasets;
4. Select the input variables for each stiction parameter;
5. Train the neural networks using, with variable number of neurons in the hidden layer;
6. Evaluate network performance for both datasets;

Each step will be described in details in the following subsections.

3.1. Dataset design

The dataset was designed based on a SISO loop, whose scheme is shown in Fig. 2.

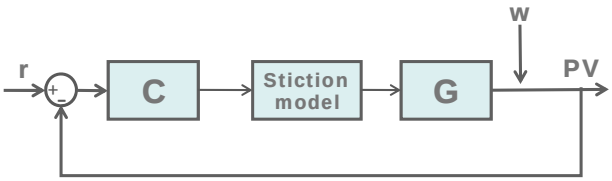

Fig. 2: SISO loop scheme

Where *C* is the PI controller, *G* is the first order plus time delay plant. The input *w* is white noise and *r* is the reference. In this work, we propose only a stiction inference model for first order plus time delay models. However it could be extended to higher order models or integrators. Tab 1 shows the variable parameters to generate the dataset and the interval for each parameter.

Tab. 1: Variable parameters used in the SIM data generation

Param.	Description	Interval
$\mathbf{K_p}$	Controller gain	[0.1: 0.2: 1.1, 2: 1: 5]
$\boldsymbol{\tau_I}$	Controller integral constant	[0.3τ: 0.3τ: 3τ]
$\boldsymbol{\tau}$	Process time constant	[5: 5: 20, 30: 10: 100]
S	Static band	[0.5: 0.5: 5]
J	Slip Jump	[0.5: 0.5: 5]
$\boldsymbol{\sigma^2(w)}$	White noise variance	[100 10 1]

The number of different scenarios in the dataset is 360,000. Subsequently, the complete dataset was randomly divided in two datasets - training dataset = 80% of the points and test dataset = 20% of the points

3.2. Input variables

The candidate variables to build the inference model and the procedure to select the best subset of them to describe the stiction are subsequently listed:

1. Δ_{PV}: Difference between the maximum and minimum value in PV;
2. Δ_{OP}: Difference between the maximum and minimum value in OP;
3. Ratio between Δ_{PV} and Δ_{OP}.
4. E_W: integral of square error of difference between PV and the best wave-shape curve interpolation (PV_W) (see (Rossi and Scali, 2005));
5. E_T: integral of square error of difference between PV and the best triangular curve interpolation (PV_T);
6. ZC: Number of zero-crossings in the zero-mean data;
7. ZC_{ACV}: Number of zero-crossings in the autocovariance function (Thornhill et al., 2003).

The variables were selected using stepwise regression (Rawlings, 1988). The inputs selected to estimate *J* are the same as the inputs to predict *S:*

- Δ_{PV}
- Ratio between Δ_{PV} and Δ_{OP}
- ZC_{ACV}

3.3. Neural-network training

To interpolate the training dataset, we use a feedforward backpropagation neural network (Haykin, 1999), from Matlab 5.3 (R11, Neural Network toolbox ver. 3.0.1). In the hidden layer, hyperbolic tangent sigmoid neurons were used, while in the output layer, linear neurons are used. In the training step, the layer performance is measured using mean square error. The training function used was Levenberg-Marquardt backpropagation (*trainlm*) and the learning function was Gradient descent with momentum weight and bias (*learngdm*).

We try networks with different number of neurons in the hidden layer to select the one that better predict the stiction parameters, with the minimum number of neurons. Initially, the SIM for Staticband (S) was designed. Tab. 2 shows the networks performance, with different number of neurons, for the training and test datasets.

Tab. 2: networks performance – output variable: Staticband (S)

Neurons	R^2 Training dataset	R^2 Test dataset
5	0.99	0.99
10	0.99	0.99
20	0.99	0.99
50	0.99	0.99

Based on Tab. 2, the best net configuration has 5 neurons in the hidden layer. Subsequently, the model for Slipjump (*J*) was designed. Tab. 3 shows the networks performance, with different number of neurons, for the training and test datasets.

Tab. 3: networks performance – output variable: Slipjump (J)

Neurons	R^2 Training dataset	R^2 Test dataset
5	0.97	0.97
10	0.98	0.98
20	0.98	0.98
50	0.98	0.98

Again, the best configuration, according to Tab 3, has 10 neurons in the hidden layer.

The final SIM structure for both parameters is:

- Neural network model with 2 layers;
- 1st layer (hidden): 10 hyperbolic tangent sigmoid neurons;
- 2nd layer (external): 1 linear neuron.

4. Case studies

This section illustrates the SIM application using simulation datasets. The comparison between the predicted and real values for stiction parameters will be made for a set of 6 valves, which are not used to train or test the SIM neural networks. Tab. 4 shows the results for original *J* and *S*, and its predicted values (J_P and S_P) by the SIM.

Tab. 4 clear shows the good performance of SIM, where the relative error for all controllers was lower than 30%. Using a Pentium D, 1 GB ram, the computation time for all cases was lower than 1 second. Using the same computer, to predict valve

stiction to 100,000 valves took 1 second, what allows the real-time and large-scale application of the proposed methodology.

Tab. 4: SIM prediction for 6 different sticky valves

Cont.	S	S_p	J	J_p
Cont1	10	13	9	9,9
Cont2	20	23	12	11
Cont3	20	20	15	15
Cont4	20	27	40	39
Cont5	30	33	30	30
Cont6	40	37	60	53

5. Conclusions

In this work, a novel algorithm to evaluate valve stiction, called Stiction Inference Model (SIM), has been proposed. It allows the computation of both stiction parameters (staticband *S* and slipjump *J*) using only routine operating data. The SIM is based on neural networks. Comparing the proposed method with to the least-squares and global search algorithm, the SIM accuracy is slightly poorer. However, its large-scale application is viable, because of its computational time.

Two-layer planning and scheduling of batch production processes under uncertainty

Martin Hüfner, Thomas Tometzki, Sebastian Engell

Process Dynamics and Operations Group, Department of Biochemical and Chemical Engineering, TU Dortmund, 44221 Dortmund, Germany

Abstract

This paper proposes a new combined algorithm to solve planning and scheduling problems of batch production processes under uncertainty. For the planning problem under uncertainty, a two-stage stochastic integer program is formulated and solved by a stage-decomposition algorithm. To evaluate the feasibility of a production plan, a priced timed automata model is set up for the scheduling problem of the next planning period and solved using reachability analysis. If the targets from the planning layer cannot be met, a penalty term is returned to the planning layer which is used to re-evaluate the candidate production plans. The two-layer concept is applied to a multi-product batch plant demonstrator.

Keywords: evolutionary algorithms, MILP, timed automata, multi-product batch plants

1. Introduction

For the economic operation of multi-product batch plants, high-quality *production plans* that reflect the uncertainties in market and technical parameters as well as feasible or optimal or at least feasible *operation schedules* are needed. *Production planning* is understood as the decision *which* products have to be produced in the planning periods with the limited set of plant equipment. *Scheduling* concerns the decisions *how* the scarce resources are allocated to the operations over time to produce the planned products in order to meet the targets. The combination of long-term production planning and of scheduling ensures the meeting of the economic objectives and timely completion of the tasks associated with the production plans. On the other hand, it is not necessary to determine precise schedules over long horizons because the uncertainties render such schedules obsolete after short periods of time.

The decision structure in production planning with uncertainties is reflected well by a mixed-integer recourse model with a finite number of scenarios in the form of a *two-stage stochastic integer program* (2-SIP) [1]. The recourse property reflects the ability to compensate the effects of a set of *here-and-now* (first-stage) decisions which have to be made under uncertainty by a second set of *recourse* (second-stage) decisions which can be made after the uncertainty has realized. This type of models is particularly appropriate for moving horizon production planning where the movement of the horizon is accompanied by the realization of uncertainties and their compensation.

In [2], a similar temporal decomposition approach to the coupled production planning and scheduling problem is applied, where first the time period and the products that are considered in short-term scheduling are determined, and then the scheduling problem is solved for the immediate future. In [3], a simultaneous solution of production planning and scheduling problem is addressed through a hierarchical framework. The planning problem aggregates orders in the planning period and considers uncer-

tainty utilizing multi-stage stochastic programming. Using a moving horizon strategy, the production targets for the current stage are provided to the scheduling layer, which is solved using a continuous-time MILP formulation.

Optimal scheduling of multi-product batch plants (resource allocation, sequencing and timing) has been in the focus of research for many years now. A promising new approach to scheduling problems is to model them by *timed automata* (TA) and to perform optimization by *reachability analysis* [4, 5]. Modeling is completely graphical and the problem can be represented in a modular and transparent fashion with independent small models for recipes, resources, etc. that are connected by synchronization labels and shared variables and can be composed automatically.

2. Two-layer algorithm for production planning and scheduling

In this contribution, the coupled problem of production planning and plant scheduling is solved by a two-layer algorithm, where the planning (upper-layer) problem under uncertainty is represented as a *two-stage stochastic integer program* (2-SIP) and the scheduling (lower layer) problem is solved using a *timed automata* (TA) approach. The algorithm for the upper layer problem (see Section 4) interacts with the algorithm for the lower layer problem (see Section 5) in a feedback loop.

The upper layer algorithm iteratively generates a set of production plans. After every iteration, the upper layer passes the first stage solution with the best objective value to the lower layer. The lower layer algorithm computes an optimal or at least a feasible schedule for the first-stage periods and returns a penalty value to the upper layer if the due dates are not met. The penalty value is added to the planning objective value of the passed solution. Thus another production plan from the set may have a better objective. Then the scheduling is repeated for the new best solution and the resulting penalty is passed to the upper layer. The procedure iterates until the best solution from the set has been found.

3. Multi-product batch plant case study

In order to illustrate the approach, a small demonstrator batch plant [6] is considered (see Fig. 1). The end-products blue (**B)** and green (**G)** are produced from three raw materials, yellow (**Y)**, red (**R)** and white (**W)**. Two batches of materials **Y** and **W** react to produce one batch of product **B**, similarly two batches of **R** and **W** react to produce one batch of product **G**. The plant consists of 3 stages. The first stage consists of three buffer tanks which are used to store the raw materials **Y, R** and **W**. The second stage consists of three reactors that perform the reaction process to produce the end-products. Each reactor can be filled from each raw material buffer tank in the first stage; and it is possible to produce either product **B** or product **G** in each reactor. After processing the materials, a reactor contains one batch of product. The third stage consists of two buffer tanks which are used to store the end-products **B** and **G** exclusively. Once started operations must be finished without any interruption (non-preemptive scheduling). The production of one batch of a recipe (**B** or **G)** consists of 6 operations and involves timing

Fig. 1: Demonstrator batch plant

constraints between individual operations. After the materials are processed by the reactors, the end-products must be drained into the buffer tanks in the third stage immediately, imposing a zero-wait constraint between the operations.

The planning problem is based on a simplified discrete time multi-period model which represents capacity constraints and material balances. The buffer tanks in the first stage contain at most two batches of the raw materials. Each of the buffer tanks has a maximum capacity to store three batches of the respective products. Raw materials can be stored temporarily in a depot. The planning problem is subject to uncertainties in the product demands, revenues, production costs, and possible breakdowns of the reactors. The planning decisions which have to be made are the optimal choices of the purchases of raw materials and the batch numbers of products. The profit that has to be maximized is calculated from sales revenues, production costs, storage costs, and penalties for lateness. The scheduling problem is based on a continuous-time formulation containing all important plant characteristics such as non-intermediate storage policies, exclusive assignment of resources to tasks, intermediate release dates for the raw materials and intermediate due dates for the end-products. The purchased raw materials are released at time points which correspond to the beginning of the discrete periods. For each batch of a product a due date at the end of a period has to be met. The objective of the scheduling problem is to schedule the production orders with no delay.

4. Upper layer algorithm: Stage decomposition based hybrid approach

4.1. Two-stage mixed-integer program

The production planning problem under uncertainty is modeled as a 2-SIP. The uncertainty in the planning problem has Ω=32 realizations that are modeled by a discrete set of scenarios ω = 1,…, Ω. In a 2-SIP, the decisions are divided into the first-stage decisions **x** which have to be taken before the uncertainty is disclosed and second-stage decisions $\mathbf{y}_\omega$, which have to be taken after the uncertainty is realized.

$$\min_{\mathbf{x},\mathbf{y}_1,\ldots,\mathbf{y}_\Omega} \mathbf{c}^T\mathbf{x} + \sum_{\omega=1}^{\Omega} \pi_\omega \mathbf{q}_\omega^T \mathbf{y}_\omega \tag{1}$$

$$\text{s.t.} \quad \mathbf{A}\mathbf{x} \le \mathbf{b} \tag{2}$$

$$\mathbf{W}_\omega \mathbf{y}_\omega \le \mathbf{h}_\omega - \mathbf{T}_\omega \mathbf{x} \tag{3}$$

$$\mathbf{x} \in \mathrm{X},\ \mathbf{y}_\omega \in \mathrm{Y},\ \forall \omega = 1,\ldots,\Omega.$$

The objective of the problem (1) consists of the first-stage costs and the expected value of the second stage costs. The costs are calculated as linear functions of the first-stage variables **x** and the second-stage variables $\mathbf{y}_\omega$ with vectors of cost parameters **c** and $\mathbf{q}_\omega$. The two-stage model consists of inequality constraints on the first-stage decisions (2) and on the first- and second-stage decisions (3). The finite sets X and Y may contain integrality requirements.

4.2. Stage decomposition approach

The main idea of stage decomposition [7] is to remove the ties between the second-stage scenario subproblems by fixing the first-stage decisions **x**. The scenario subproblems are of significantly smaller size than the full two-stage problem. The master problem is a function of the vector of first-stage variables **x** only:

$$\min_{\mathbf{x}} f(\mathbf{x}) = \mathbf{c}^T\mathbf{x} + \sum_{\omega=1}^{\Omega} \pi_\omega Q_\omega(\mathbf{x}) \qquad \text{s.t.} \qquad \mathbf{A}\mathbf{x} \le \mathbf{b}, \mathbf{x} \in \mathrm{X} \tag{4}$$

The evaluation of the second-stage value function $Q_\omega(\mathbf{x})$ for a given $\mathbf{x}$ requires the solution of Ω independent MILP subproblems over the second-stage variables y_ω:

$$Q_\omega(\mathbf{x}) = \min_{\mathbf{y}_\omega} \mathbf{q}_\omega^T \mathbf{y}_\omega \quad \text{s.t.} \quad \mathbf{W}_\omega \mathbf{y}_\omega \le \mathbf{h}_\omega - \mathbf{T}_\omega \mathbf{x}, \mathbf{y}_\omega \in Y, \forall \omega = 1, \ldots, \Omega. \tag{5}$$

The constraints of the master problem (2) are scenario independent, while the parameters of the second-stage constraints in (3) may vary from scenario to scenario. The vector of the first-stage variables $\mathbf{x}$ appears as a vector of fixed parameters in the constraints of the second-stage scenario problems. The main algorithmic idea is to address the master problem given by (4) by an *evolutionary algorithm*. To evaluate f(**x**), the Ω subproblems given by (5) are solved independently by a *MILP solver*.

4.3. Evolutionary Algorithm

The master problem (4) is tackled by an adapted (integer) *(μ ,κ, λ)-evolutionary algorithm*. Each individual $\mathbf{x} = (x_1, \ldots, x_n)$ of the population represents the choice of the numbers of batches of raw materials and batches of products for all first-stage periods. A population of μ individuals is initialized randomly within the bounds of the box-constrained first-stage feasible decision space $\mathbf{x}^{min} \le \mathbf{x} \le \mathbf{x}^{max}$. The fitness values of the initial population are calculated by the objective function f(**x**) of the master problem.

After the evaluation of the initial population, λ offspring individuals are generated by λ-fold application of the discrete recombination operator. The recombination chooses two individuals out of the μ parents with equal probability. Each x_i of the offspring is the corresponding value from the first or from the second parent with equal probability. After the recombination, the mutation operator mutates the λ offspring in two steps:

In the first step, the object parameters for the amounts of products are mutated. The reason for this is that the amount of products cannot exceed the amount of available raw materials. Each object parameter for the amount of a product x_i is perturbed independently from the others by a random number drawn from a normal distribution with an expected value of zero and a variance of one. This choice leads to an expected perturbation of 1 for each object parameter. For integer parameters, the random number is rounded to the nearest integer value. To maintain the bounds for the number of products, the search space is transformed into a periodic space, such that $x_i^{max} + 1 = x_i^{min}$.

In the second step, based on the amounts of products, the amounts of raw materials are generated. The minimum amount of raw materials which is needed to produce the desired amount of products is calculated for each period. Additional raw materials are added using the absolute value of random numbers from a discretized normal distribution. Beginning with the last period of the first-stage, the raw materials are shifted to earlier periods with low probability. In order to maintain feasible production plans, the amount of raw materials can only be shifted to earlier periods. All raw materials which are not needed can be stored.

The λ offspring candidate solutions are evaluated by the objective function f(**x**) of the master problem. The best solution **x*** is passed to the *lower layer scheduling algorithm* (see Section 5). The lower layer algorithm computes an optimal schedule for the immediate future (first-stage periods) and returns the penalty value $0 < p(\mathbf{x}^*) < p_{max}$ if the due dates are not met or a large penalty value $p(\mathbf{x}^*) = p_{max}$ if no feasible schedule exists. The penalty value p(**x***) is added to the fitness value f(**x***). By adding the penalty to the objective value f(**x***): = f(**x***) + p(**x***), the fitness based order of the individuals in the current population may change. Then the new best solution is passed to the scheduling algorithm and a new optimal schedule is generated and the penalty costs are calculated. The procedure iterates until the first solution in the sorted population no longer changes.

In the selection for population replacement, a truncation selection chooses the μ best ($1 \leq \mu \leq \lambda$) individuals out of the union of μ parents and λ offspring which do not exceed the maximum age of κ for the next iteration. The age of an individual is increased by one after each generation. After the new population is created, a new iteration loop starts if the termination criterion is not fulfilled.

5. Lower layer algorithm: Timed automata based approach

5.1. Background of timed automata

The underlying scheduling problem is solved using a priced timed automata approach. Timed automata (TA) are *finite state automata* extended by the notion of *clocks* to model discrete event systems with timed behaviour. An extension of TA with the notion of costs is known as priced TA. A priced TA is a timed automata equipped with an additional function which assigns costs for staying in locations and costs for transitions. The resources, jobs and timing constraints are modelled as sets of priced TA. For the problem considered in the case study, release dates and due dates for the production orders exist. The release date for a production order is modelled by the guards on the transition that represents starting of the first operation. The due date for each production order is modelled by a separate TA (due date automaton) and synchronized with the respective job automaton. The delay cost for the production order which miss the due date are computed using the clock in the due date automaton. A detailed explanation of the approach to model release dates and due dates using TA can be found in [8].

5.2. Cost-optimal reachability analysis

Once the individual automata have been created, the *composed priced TA* is realized by the tool. The composed priced TA is automatically created by synchronizing the transition labels in the sets of the individual priced TA. TAOpt performs a symbolic reachability analysis to explore the solution space and to derive production schedules with minimal cost. The reachability tree is created from the composed automaton. It consists of nodes and transitions; a node represents a combination of a state and clock valuations of all clocks including the global clock. A cost-optimal reachability analysis is performed starting from the initial location where no jobs are started and trying to find a path to the target location where all jobs are finished within the defined due date. A depth first search algorithm is used to explore the reachability graph. The search space reduction techniques weak non-laziness, sleep-set method and passed list inclusions were employed to prune parts of the reachability tree (for detailed explanations see [5]). The objective is to minimize the sum of the delay costs. A penalty of $p(\mathbf{x}) = 0$ is passed to the *upper layer planning algorithm* (see Section 4) if all due dates are satisfied or costs $0 < p(\mathbf{x}) < p_{max}$ which are identical to the cost of delays in the objective function on the planning layer.

6. Experimental Results

The proposed two-layer approach was tested for the case study. The decisions in periods 1 to 3 are considered as first-stage decisions, those in periods 4 to 6 as second-stage decisions. The uncertainties are represented by 4 realizations of the product demands, 2 realizations of the revenues, 2 realizations of the production costs, and 2 realizations of possible breakdowns of the reactors. The realizations (B, G) of the product demands for the end-products B and G are shown in the Table below. Overall the second-stage uncertainty is represented by 32 scenarios of equal probabilities. The upper layer hybrid algorithm was implemented in MATLAB 7.3. The MILP scenario problems were for-

Realization	1	2	3	4
Period 1	(3,2)	(3,2)	(3,2)	(3,2)
Period 2	(1,3)	(1,3)	(1,3)	(1,3)
Period 3	(4,2)	(4,2)	(4,2)	(4,2)
Period 4	(2,3)	(3,3)	(3,3)	(4,1)
Period 5	(3,2)	(2,2)	(4,3)	(2,3)
Period 6	(2,3)	(1,1)	(4,4)	(1,2)

mulated using GAMS 22.5 and solved by CPLEX 10.2. In total, the scenario subproblems consist of 8065 equations, 1249 continuous variables, and 4352 integer variables. TAOpt is employed for the optimization of the TA models in the lower layer. The global TA model is composed out of 69 TA models. It consists of 200 locations, 203 transitions, and 70 clocks. It was observed that TAOpt finds the first feasible solution after 3,000 explored nodes in most instances. TAOpt was stopped either after 20,000 nodes are explored or after a schedule with no tardiness is found. 10 runs were performed on a dual Xeon machine with 3 GHz speed. A population size of $\mu = 10$, an offspring/parents-ratio of $\lambda/\mu = 7$, and $\kappa = \infty$ were chosen. The progress plot in Fig. 2 shows the evolution of the objective function $f(\mathbf{x})$. The different lines represent the 10%-, 50%-, and 90%-quantiles. The proposed algorithm generates feasible solutions after 6 minutes. The quality of the objective is improved considerably in short time, thereafter convergence slows down. In the best run, the algorithm finds the optimum solution (determined by complete enumeration of the first-stage decisions in 36 hours) in 48 minutes which has an objective function value of -21.9775. The algorithm needs about 3 sec for the evaluation of one individual without scheduling. The computation of a schedule takes up to 3.5 sec.

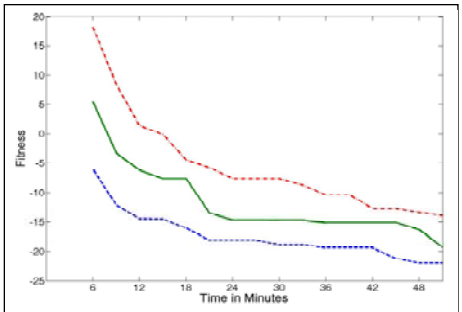

Fig. 2: Evolution of the two-layer algorithm

7. Conclusions

This work presents a successful application of a stage decomposition based hybrid algorithm for production planning and of the timed automata based approach for schedule generation to solve the coupled problem of production planning under uncertainty and scheduling. Ongoing work concerns the improvement of the interplay between planning and scheduling and the application to larger examples.

On line monitoring and diagnosis of the operation of a hybrid CSTR by using PCA models

Luis G. Bergh and David Gómez

Chemical Engineering Department, Santa Maria University, Valparaiso, Chile

Abstract

Testing strategies for process monitoring, diagnosis and control is expensive, and usually requires either complex pilot plant facilities or to deal with the hard constraints posed by experimentation in real plants. The experience developing hybrid systems, combining pilot plants and models is presented. A model is used to simulate the reaction, given measured and virtual variables. Feed temperature and flow rate and reactor temperature are measured on line, while feed component concentrations are given as a stochastic disturbance. The temperature in the reactor can be controlled by regulating the cold water flow rate in the coil.

The potential of developing this class of hybrid systems is illustrated by the use of principal component analysis (PCA) methodology to build a model from experimental data. Hotelling T^2 and Q residual tests were running on line every time a steady state is reached. Both tests are used to identify the main causes of two kinds of problems: when the process target (product concentration) is not met and when a measuring device failed. Examples of these applications are discussed.

Keywords*: reactor, control, modelling, monitoring, diagnosis*

1. Introduction

In the last decade a number of techniques have been proposed to improve the benefits of chemical process operations. Some of them are: process modelling, data reconciliation, soft sensors and pattern recognition, process monitoring, fault detection and isolation, control loop monitoring, control algorithms and supervisory control. What is common to most of these areas is that the theoretical advantages of novel methods have to be confronted and tested in real plants. Simulation of the application of novel methods by using a plant model has some advantages. Once a model of a plant is available, the new methodology can be tested under a number of different conditions, at low cost. However, some disadvantages of this approach are how the model used represents the real nature of the process, the error in measurements and the disturbances coming into the plant. Most of the time, the simulations are conducted under some idealties, neglecting those aspects, and thus increasing the uncertainty and reducing the validity of results. Comparisons of different methods made on such bases may become useless, and cannot replace experimentation in the real world.

On the other hand, experimentation carry on real plants poses its own difficulties. For example, the scale factor forces that changes on some variables must be inside a narrow band, to avoid risky operating conditions or high loses in products. Some disturbances cannot always be managed, interrupting and degrading the experiments, leading to

confusing results. In summary, it is more difficult and costly to conduct a designed experience, which collected data can be properly analysed to make right decisions.

Pilot plants can reproduce most of the advantages of experimenting in a real plant, but at a small scale that relaxes some of those constraints, at the same time that provides the chance to a wide experimentation. However, expensive chemicals, large storing facilities, waste treatment units and expensive on stream analysers remain as drawbacks.

2. A different approach

Some processes can be analyzed separating the phenomena in different levels. A first level is the process hydrodynamics, heat and mass balances. A second level is the chemical change by reaction. Sometimes changes in solute concentration may also change transport properties, and the artificial decoupling will not be effective. When process hydrodynamics are not significant influenced by changes in solute concentration, then the experimentation approach on pilot plants can be simplified in two senses: Experimentally each fluid may be substituted by low cost water in a liquid phase reaction, and the solute concentration will not actually change, but an estimation can be obtained from detailed models relating measured operating conditions, such as flow rates, temperatures, pressures, levels, and concentrations.

Therefore, if a model is available, and the pilot plant is operated by using these low cost fluids, a hybrid system is developed. The real plant behaviour is simplified but the main hydrodynamics characteristics are still well represented. The variables representing the target of the process are predicted by using the model, under a wide operating region. Now, distributed control of local objectives can be administrated by supervisory control strategies based on estimation of the crucial variables. Also process monitoring, diagnosis and fault detection, isolation and remediation studies can be developed under low cost and reasonable approximation to the behaviour of a real process.

Models of different kinds can be built and solved on-line (Bergh, 2007). Here, a steady state model is used to generate the data to build a PCA model, and then this model is used to test on-line the operation of the reactor.

3. Pilot CSTR unit

A P&ID of the pilot SCTR is shown in Figure 1. Both, feed and cooling water are measured and controlled by variable speed peristaltic pumps. The electric power supplied is under control, and it is used to simulate the heat of reaction. Inlet and outlet temperatures are measured. Virtual measurement of reactant A is generated in the computer, while the outlet concentration is calculated from the model by using the measured operating variables.

A first order kinetics exothermic and irreversible reaction is considered. The input variables measured are: feed flow rate (F) and temperature (Ti), cooling water flow rate (Fw) and temperature (Twi). The output variables measured are reactor temperature (T), cooling water temperature (Two) and ambient temperature (Ta). Given an input concentration (Cao) the output concentration (Ca) is calculated from:

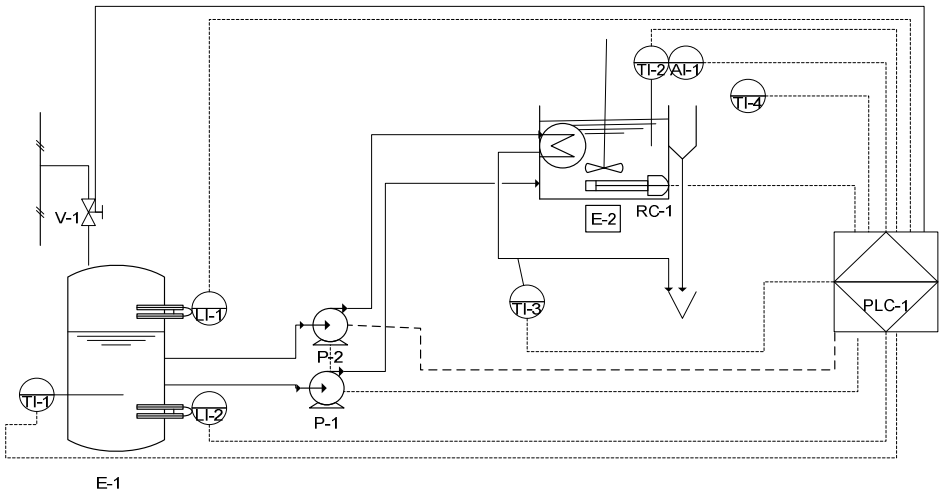

Figure 1. P&ID of pilot CSTR.

$$Ca = \frac{Cao}{(1+k\tau)} \tag{1}$$

with $k = k_0 e^{-\frac{E}{RT}}$ (2)

and $\tau = \frac{V}{F}$ (3)

The heat of reaction is calculated from: $Q = Ca \cdot k(-\Delta H)_r \cdot V$ (4)

The reactor temperature is measured at each sampling time (every 10 s), and k, Ca and Q are recalculated by using the model. The new value of heat of reaction is implemented by the electrical heater RC-1. Convergence is obtained after three or four iterations (less than one minute) and then the reactor reaches a steady state, where all material and heat balances are met. Similar iteration will occur if any of the input variable changes. This hybrid system will provide complete operating data that will be strictly valid only at steady state. In the transient period between steady states the estimation of reactor concentration will not be equal to the real one, but close enough to show smoothly the tendency. More details can be found in Gomez (2008).

4. PCA models

The key feature of PCA method is their ability to mathematically project high dimensional process and quality data into smaller dimensional, summary data sets via the development of linear models. The practical value of PCA modeling method is that this technique allows for the systematic examination and interpretation of the model outputs. Examination of the model outputs can provide insight into the operation of an industrial process during monitoring and quality assurance activities. With PCA, the systematic interpretation of dominant patterns in the data and the isolation of the most important contributors to these patterns are possible. This allows the classification of

data relationships according to normal and abnormal operation. Some of these numerous advantages of PCA method has over traditional monitoring and prediction technologies are: provision for data dimension reduction and robustness to highly correlated, noise and missing data (Kourti and MacGregor, 1995).

The concept of a latent variable model is that the true dimension of a process is not defined by the number of measured variables, but by the underlying phenomena that drive the process. The latent variables themselves are modeled as mathematical combinations of the measured variables and describe directions of variation in the original data. A latent variable model can contain many fewer dimensions than the original data, it can provide a useful simplification of large data sets, and it can allow better interpretation of the measured data during analysis (MacGregor *et al*., 2007).

5. PCA model building

Nine variables were considered, seven were measured on-line, the initial concentration was given as a date and the output concentration was calculated using heat and mass balances and kinetic model. The data were collected for different feed flow rates and feed concentration. An example of a set of data collected every 5 seconds is shown in Figure 2. When all the variables have reached a steady state, this point is a candidate to form the data matrix, after filtering. A normal operation is defined when a conversion over 95 % is reached in the reactor. More than 200 steady states were collected and filtered. This data was processed using PLS_Toolbox from Eigenvalue Research.

A PCA model was built. A model with 4 latent variables was found to explain at least 95 % of the variance in the centered and scaled pretreated data. The T^2 Hotelling, at 95 % confidence interval (using the F distribution), was 10.99 and the residuals Q limit (following Jackson, 2003), at 95 % confidence interval, was 0.29. These statistics will be used to test when the reactor operation reached an abnormal situation, and which variables are contributing the most. Two kinds of problems were studied. First, when the conversion in under 95% and when a gross error in the measurement of one operating variable occurred.

When the reactor operated with a feed flow rate of 13 mL/s, a cooling water flow rate of 20 mL/s, and a initial concentration of 1.0 mol/L, the temperature was 32.5 °C and the heat of reation was 1420 W. The conversion was 93.7% and the Q test was satisfied while the T2 Hotelling test was failed. The contribution of each variable to the failure is shown in Figure 3. The output concentration was low mainly due to a combination of high feed flow rate and high cooling water flow rate (low k and τ).

If the feed flow rate measurement is deviated by a fractional error, then the T^2 test is satisfied and the Q test is failed for errors less than -0.2 and great than 0.4, as can be observed from Figure 4. Similarly, if the input concentration measurement is deviated by a fractional error, then the T^2 test is satisfied and the Q test is failed for errors greater than 0.2.

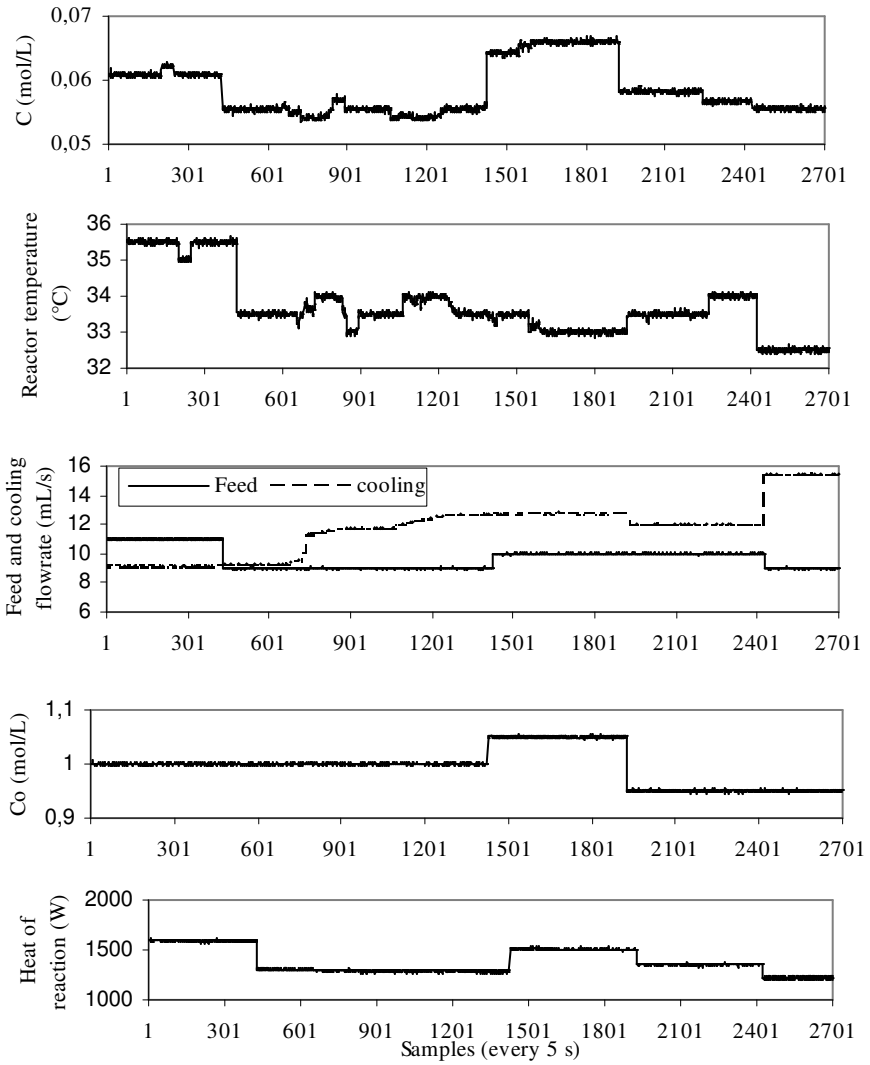

Figure 2. Operating data collected from pilot CSTR.

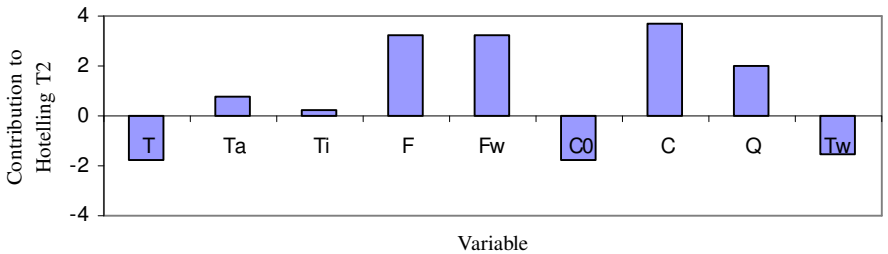

Figure 3. Contribution of variables to Hotelling's T^2.

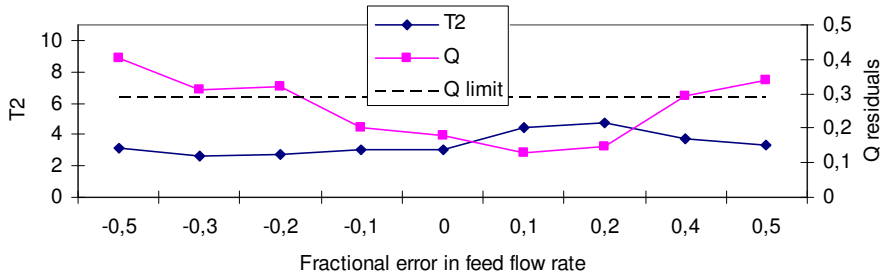

Figure 4. Sensitivity to detect fractional error in feed flow rate.

5. Conclusions

A heated and cooled tank has been operated combined with a phenomenological model to predict on-line the output concentrations of a CSTR reactor. This configuration permited to operate the reactor in a wide range, at low cost, and to test novel methodologies to detect, isolate and remediate operating and measurement failures.

The application of multivariate statistical methods, and particularly PCA, is a powerful tool to build linear models containing the essencial of the process phenomena with the minimum number of latent variables. The application of PCA models to monitoring a pilot CSTR has been demonstrated. These PCA models can be effectively used as part of a supervisory control strategy, specially when control decisions are infrequently made.

Abstract

Paper formation (the level of homogeneity in the distribution of fibers on the surface of paper) is a key quality parameter for paper products, being currently monitored off-line, at low sampling rates relatively to the high production speeds achieved with modern paper machines. In this paper, we address the problem of conducting such monitoring activity on-line, in situ, using wavelet texture analysis (WTA) on raw images acquired with a especially design sensor. Our analysis shows that either a reduced set of features derived from WTA (suggested by an ANOVA analysis), or a low dimensional sub-space (with two dimensions, obtained using PCA or PLS-DA), enable an adequate separation of the several paper formation quality grades, meaning that we can indeed follow, on-line, the quality status of paper formation. Furthermore, we will also show how statistical process control (SPC) can be properly conducted using WTA features, in a simple and robust way.

Keywords: Multivariate Image Analysis, Wavelet Texture Analysis, Paper Formation, Multivariate Statistical Process Control, Principal Components Analysis.

1. Introduction

Paper formation (the level of homogeneity in the distribution of fibres on the surface of paper) is a key quality parameter for paper products, as it impacts not only the aesthetic evaluation and visual perception of quality by the end users, but also affects other relevant properties such as the average strength of paper (a sheet with poor formation is weaker than a comparable sheet with a better formation), the quality of printing operations (which is inferior for papers with poor formation) and, furthermore, leads to process problems, such as, for instance, the increase of coating consumption, as paper formation gets worse. For these reasons, paper formation constitutes a matter of great concern to paper producers, being therefore routinely measured in the quality control laboratories in modern paper production facilities, either through visual inspection and comparison with a series of standards representing different quality levels of formation or, more frequently, with resource to instrumentation that scan the paper sheet, measuring the variation of light transmission through it. This monitoring activity occurs only a few times per day, according to the routine testing plans established in each paper mill. For instance, a possible routine may consist on taken a sample for each paper reel produced, which is then sent to the control laboratory, where, after some time, the measurements are performed and results introduced in the product quality information system. This whole process introduces a very significant delay in the supervision and

control tasks, given the high production rates achieved by modern paper machines, where paper is being currently produced at linear speeds that can be over 100Km/h. Therefore, we can easily conclude that such off-line process monitoring has strong limitations, being rather ineffective in promptly detecting problems in paper formation and leading to significant losses in quality when process upsets do arise. In this context, we address in this paper the development of technology for performing paper formation monitoring, on-line and in situ, using a state-of-the-arte texture analysis methodology: Wavelet Texture Analysis (WTA). WTA enables the extraction of informative image features regarding phenomena contained in the textures (Bharati *et al.*, 2004), which are computed from the 2D wavelet transform coefficients of raw images. Wavelet analysis has been already applied to the analysis of paper formation, but only the wavelet details coefficients for the second decomposition level were used (Bouydain *et al.*, 1999), something that, according to our results, may seriously hinder the discrimination ability that can be achieved among different level of quality in paper formation.
This article is organized as follows. In the next section we briefly describe the technology underlying the image acquisition system and address the main methodological steps of our analysis approach. Then, we present some results obtained, regarding both the discrimination ability that can be achieved using WTA features, and address how can they be used for conducting statistical process control (SPC) in a proper way. Finally, we briefly conclude with a summary of the main results achieved.

2. Materials and Methods

2.1. Image acquisition sensor

The image acquisition sensor is a critical element for the on-line monitoring and analysis of paper formation. Its function is to capture good quality images in the harsh environmental conditions prevailing in the forming section of the paper machine, which is essentially steamy and wet, with drops erratically flying everywhere around the camera. The technological solution developed for the formation sensor, consists of a digital camera within a housing that is able to rotate at high speed, in order to prevent dirt accumulation on the housing surface. Such design protects the camera from the environmental conditions, ensuring that the sensor will function properly with little maintenance. The camera used was a Jai A10 CL, with a Navitar DO-2595 lens. The strobe light consists of a led array emitting red light (CCS LDL-TP).

2.2. Methods

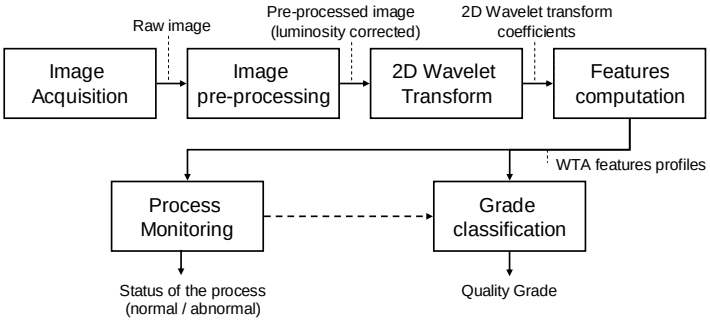

Figure 1. Scheme of the WTA methodology for monitoring and classification of paper formation.

The basic methodological steps considered in our analysis are as follows (Figure 1). Images are first acquired (i) and corrected for non-uniform illumination effects (ii), even

though this is not a critical step in the analysis, as our procedure is rather robust to this kind of problems (i.e., from our experience, final results do not change much upon removing such pre-processing task from the analysis). Then, we (iii) computed the 2D wavelet transform for each raw image (Mallat, 1999), which essentially consists of transforming a matrix of numbers (pixel intensities, as we are analyzing single-channel or grey-level images) into another, with the same size (same overall number of wavelet coefficients), containing blocks of coefficients regarding details for different scales (from the finest to the coarsest scale, which is known as the decomposition depth, J_{dec}) and along three different directions (horizontal, vertical and diagonal). In our case, the decomposition depth considered was $J_{dec} = 5$, and therefore each image will give rise to 16 blocks of data or sub-matrices ($=J_{dec}$x3+1; the "1" stands for the block of final approximation coefficients, containing the lowest resolution version of the image, after removing all the details corresponding to the finer scales). The next stage in WTA is (iv) to summarize the information contained in the wavelet coefficients in each of these blocks into a single number, from which a vector of WTA features will result. From the several possibilities available (energy, entropy, averaged l_1-norm, standard deviation) we used the standard deviation (the wavelet transform of uncorrelated homogeneous white noise is also white noise with the same standard deviation; therefore by using the standard deviation to summarize the information in each block, we are tactilely using a stochastic uncorrelated frame of reference against which we compare the texture in the images). As the end of this fourth stage, we have compressed the original analysis space composed by 512x512 pixels or intensity numbers, to just 16 numbers that are expected to contain the essential information necessary to discriminate different formation patterns. Finally, the extracted WTA features can be used for (v) classifying the acquired image by proposing a quality grade and/or for conducting statistical process control of this property. The first activity (classification) requires the development of a suitable classifier, which usually involves a feature selection/compression stage and a subsequent classification stage (Pal and Mitra, 2004). For the first task we have considered here variable selection (using ANOVA) as a feature selection methodology and partial least squares for discriminant analysis (PLS-DA), as well principal components analysis (PCA), for features compression. As to the second task (process monitoring), we applied multivariate statistical process control (MSPC) based on PCA, in order to deal with the high collinearity present in the WTA features (Jackson and Mudholkar, 1979; Kresta *et al.*, 1991).

3. Results

A set of 24 images, representing different paper formation patterns, was collected for analysis. These raw images were classified, by visual inspection, into three quality levels regarding paper formation: 1-"good", 2-"poor", 3-"bad" (Figure 2). For two images were given special annotations: a dubious sample was assigned the class label "1,5", and an outlier, possibly resulting from an image acquisition problem, was labeled with score "9". Fallowing the sequence of steps represented in Figure 1, these images were pre-processed for non-uniform illumination correction and transformed to 2D wavelet coefficients. Finally, the wavelet feature profiles were computed, containing 16 features for each image, based on which the subsequent analysis was performed. This analysis had two main components: assessing the discrimination ability of wavelet features to discern among different formation quality grades (classification) and to study how statistical process control could be conducted based on such features (monitoring).

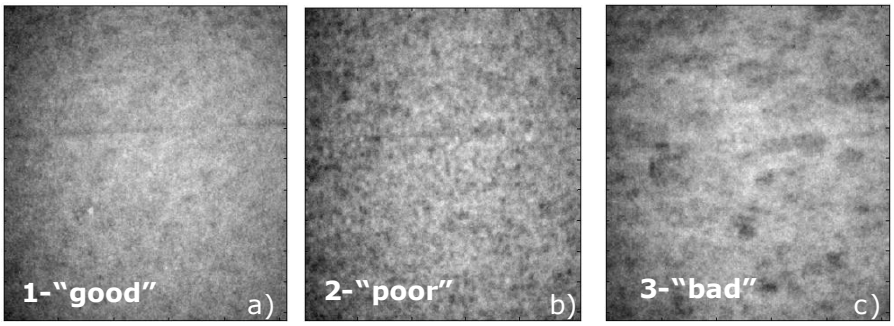

Figure 2. Images representative of the three main quality grades of paper formation.

3.1. Classification of paper formation

Even though the compression magnitude of the entire image information to 16 features is indeed quite large, such features are still highly redundant. For instance, the first principal component (PC) in a PCA analysis over these 16 features, represents 97.96% of the overall data variability. However, in order to achieve a proper discrimination, a minimum of two PC must be retained (we get to this number by computing the error rate estimated by "leave-one-out" cross-validation using an increasing number of retained PC, and applying the simple linear classifier to perform the classification task, from which we verified that, after retaining the second PC, the error rate dropped from ~ 23% to 0%). Figure 3 illustrates the separation ability obtained from different compression strategies (to reduce the number of features from 16 to 2), followed by the estimation of a linear classifier in the resulting reduced map (as the separation is so good, there is no need to use more complex classifiers): PCA, PLS-DA (Barker and Rayens, 2003) and variable selection (using ANOVA to select those features that most descriminate the various formation quality levels), followed by Fisher Discriminant Analysis (FDA), as this method alone is not appropriate to handle situations were the classifying features are heavily correlated, due to matrix inversion problems, as happens in this case. As we can verify, all methods successfully discriminate among the three levels of quality present in the sample images, meaning that WTA does provide an adequate basis for analyzing paper formation.

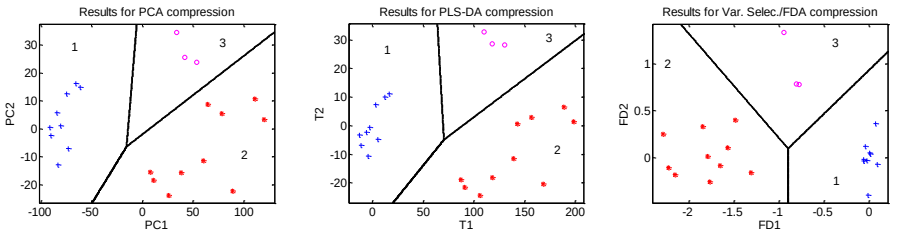

Figure 3. Results for the classification of samples after compressing the number of WTA features from 16 to 2: a) using PCA; b) using PLS-DA; c) using variable selection (based on ANOVA), where 3 variables were selected, and FDA.

3.2. Monitoring paper formation

In order to use the WTA feature profiles for monitoring purposes, a suitable statistical process control scheme was adopted, with well established results and adequate for

addressing the highly correlated nature of the data matrix of wavelet features: multivariate statistical process monitoring (MSPC) based on PCA (PCA-MSPC) (Jackson, 1959; Kresta *et al.*, 1991). This methodology consists of modelling systems operation under normal conditions using a PCA model, in order to capture the normal correlation structure and variability relative to the so called "common" causes. For each (new) multivariate observation (x_i), two statistics are computed, one relative to the (Mahalanobis) distance from its projection onto the PCA subspace to the centroid of the normal operation conditions (NOC) cluster, also in the PCA subspace, usually referred as T_i^2, and another relative to the (squared) Euclidean distance to such a subspace, Q_i.

In order to assess the application of this approach to the on-line monitoring of paper formation, a sub-set of four images from class 1-"good" were selected, representing normal operation conditions (NOC; images 1, 2, 7 and 13), from which the method parameters, including the statistical control limits, were estimated. All the remaining images, with representatives from all grades of quality, were used for testing the monitoring procedure. Figure 4 depicts the projection of all samples into the PCA subspace estimated from the wavelet features for the four reference images, where it is clear that all reference and testing samples from normal operation conditions fall inside the NOC region (95% control ellipse, also computed only using the reference set), whereas abnormal samples are also correctly signalled as such, falling outside the NOC ellipse.

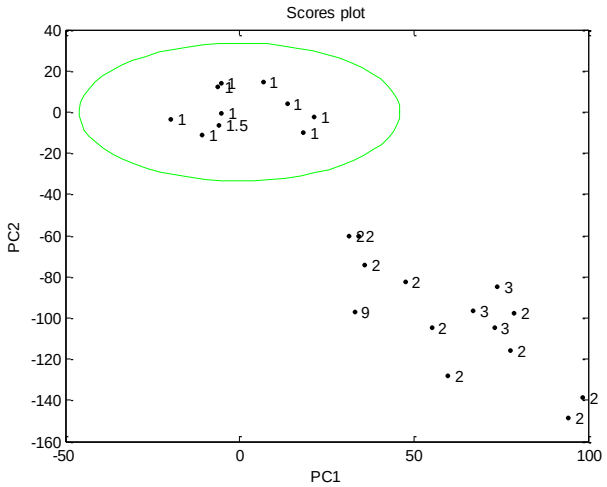

Figure 4. Projection of all samples (train and test) on the PCA subspace estimated from the four training images of quality grade 1-"good", taken as representative of NOC, with the associated 95% NOC control ellipse. All abnormal samples in the test set (class 2 or 3) fall outside the control ellipse.

From Figure 4, it is possible to see that the dubious sample labelled "1.5" also falls inside the NOC region, which is not unexpected given its similarity to other images from this class. However, an analysis of the method statistics (T^2 and Q) clarify its status and rather abnormal texture (see plot for Q), indicating that it is indeed an abnormal image (Figure 5; note the logarithmic scale used in the YY' axis, given the large magnitude difference between the statistics values for the normal and abnormal situations).

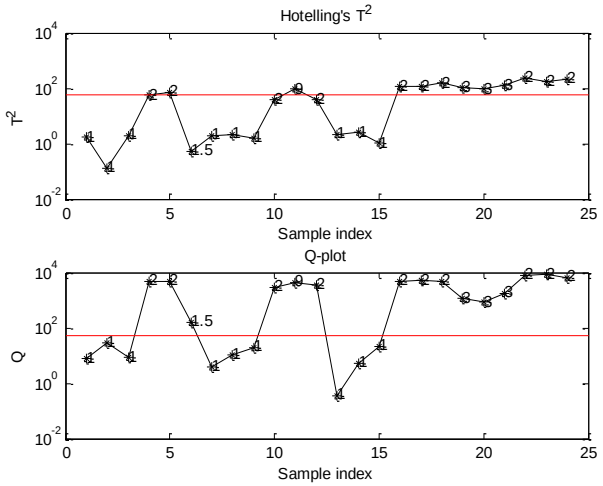

Figure 5. Control charts for the T^2 and Q statistics, regarding the implementation of PCA-MSPC over all images (train and test). Using the combination of the two statistics, all samples are correctly classified as normal or abnormal. (Note the logarithmic scale used in the plots).

4. Conclusions

In this article, we have presented an approach for classifying the quality grade of paper formation based on the WTA features profiles computed from images taken on-line from a pilot scale paper machine. Furthermore, their application to process monitoring was also addressed. Our analysis showed that the classification task is successfully conducted in a reduced dimensional space (2 dimensions), using either a reduced set of features (suggested by an ANOVA analysis), or a low dimensional sub-space (obtained through PCA or PLS-DA). Regarding the monitoring task, it was also possible to verify that statistical process control (SPC) can be properly conducted using WTA, in a simple and robust way. Therefore, we can conclude from the results presented, that it is possible to simultaneous monitor and assess formation quality, on-line and in-situ, using WTA-analysis of images acquired with the special designed sensor developed.

Numerical Pitfalls by State Covariance Computation

Nina P. G. Salau,[a] Jorge O. Trierweiler,[a] Argimiro R. Secchi,[b]

Abstract

With the error past information, conveyed by state covariance matrix, a state estimator can predict the state vector one step ahead, thus providing system operators with more information to make control decisions such as security assessment and other related functions. A well-computed state covariance matrix avoids error propagation due to numerical pitfalls and, thereby, is crucial for a successful state estimator design. In this paper we investigate the numerical robustness of four EKF formulations and derive some results giving insights into their numerical performance. As benchmark case study, we have chosen a batch chemical reactor with reversible reactions whose system model and measurement are such that multiple states satisfy the equilibrium condition. Finally, we have shown that CEKF is the best alternative to EKF for such case study.

Keywords: nonlinear state estimation, state covariance, multiple solutions.

1. Introduction

It is well known that a suitable design of state estimators requires a representative model for capturing the plant behavior and knowledge about the noise statistics, which are generally not known in practical applications (Vallapil & Georgakis, 2000). In practical applications, however, some pitfalls such as numerical round-off, plant-model mismatch and state unobservability deserve also special attention because they can lead to divergence problems (Brown & Hwang, 1996). Any state covariance matrix equation is composed by states and measurements linear models and noise covariance statistics and, hence, all of the mentioned pitfalls may increase the error propagation conveyed by this matrix. In the literature, several modified implementations of the EKF are presented in an effort to avoid numerical pitfalls (Simon, 2006). The basic difference between these formulations is concerned with the state covariance matrix computation. In this work we investigate the numerical robustness of four EKF formulations applied to a system tending to an equilibrium condition. Firstly, we outline a condition that leads to a classical EKF formulation to converge to physically unrealizable state and demonstrate the potentiality of two other EKF formulations to handle with this numerical pitfall. Next, we demonstrate that the constrained extended Kalman filter (CEKF) is the best alternative to EKF for such system due to the possibility of incorporating constraints into an optimization problem preventing, hence, the estimator from converging to physically unrealizable states.

3. Formulation and Solution of the Estimation Problem

Consider the following nonlinear dynamic system to be used in the state estimators of this work:

$$\dot{x} = f\left(x,u,t\right) + \omega\left(t\right) \tag{1}$$

$$x_k = f_{k-1}\left(x_{k-1}, u_{k-1}, t_k\right) + \omega_{k-1} \tag{2}$$

$$y_k = h_k\left(x_k, t_k\right) + \nu_k \tag{3}$$

where u denotes the deterministic inputs, x denotes the states, and y denotes the measurements. The process-noise vector ω (ω_k) and the measurement-noise vector v_k are assumed to be white Gaussian random processes with zero mean and covariance Q (Q_k) and R_k, respectively.

1.1. Unconstrained EKF formulations

We have selected three different unconstrained EKF formulations to be compared in our work: a classical EKF formulation known as discrete EKF (DEKF), the EKF with continuous Riccati equation (EKF-CRE) and the reduced-rank extended Kalman filter (RREKF). The basic difference of these formulations is related to state covariance matrix computation, as given in Table 1.

Table 1. Three unconstrained formulations of EKF

Filter	State Covariance Matrix		
DEKF	Transition	$P_{k\|k-1} = F_{k-1}P_{k-1\|k-1}F_{k-1}^T + Q_{k-1}$	(4)
	Update	$P_{k\|k} = \left[I_n - K_k H_k\right]P_{k\|k-1}$	(5)
EKF-CRE	Transition & Update	$P_{k\|k} = P_{k-1\|k-1} + \int_{k-1}^{k}\begin{bmatrix} F(\tau)P(\tau) + P(\tau)F(\tau)^T + Q(\tau) \\ -P(\tau)H(\tau)^T R(\tau)^{-1} H(\tau)P(\tau)\end{bmatrix} d\tau$	(6)
RREKF	Transition	$P_{k\|k-1} = F_{k-1}P_{k-1\|k-1}F_{k-1}^T + Q_{k-1}$	(7)
		$P_{q,k\|k-1}^{rr} = \sum_{i=1}^{q}\lambda_{P,i}\upsilon_{P,i}\upsilon_{P,i}^T$	(8)
	Update	$P_{k\|k} = \left[I_n - K_k H_k\right]P_{k\|k-1}$	(9)

1.2. Moving Horizon Estimator

MHE is described by the following optimization problem (Muske & Rawlings, 1994; Rao & Rawlings, 2003).

$$\min_{\substack{\omega_{k-N-1\|k},\cdots,\omega_{k-1\|k} \\ \nu_{k-N\|k},\cdots,\nu_{k\|k}}} \Psi_k^N = \begin{bmatrix} \hat{\omega}_{k-N-1\|k}^T \left(P_{k-N-1\|k-1}\right)^{-1} \hat{\omega}_{k-N-1\|k} \\ + \sum_{j=k-N}^{k-1} \hat{\omega}_{j\|k}^T \left(Q_{k-1}\right)^{-1} \hat{\omega}_{j\|k} + \sum_{j=k-N}^{k} \hat{\nu}_{j\|k}^T \left(R_k\right)^{-1} \hat{\nu}_{j\|k} \end{bmatrix} \tag{10}$$

The state covariance matrix is computed by the Riccati discrete equation (Rao & Rawlings, 2003).

1.3. Constrained EKF

CEKF follows from MHE for a zero-length horizon (N=0). If the measurement equation is linear, the resulting problem is a quadratic program which can be solved with small computational effort (Gesthuisen et al., 2001). CEKF is similar to EKF because also takes into account a zero-length horizon in the updating stage.

2. Example of Numerical Pitfalls by State Covariance Computation

2.1. Case Study

As benchmark case study, we have chosen a batch reactor process, as introduced by Haseltine & Rawlings (2005). All reactions are reversible and follow the ideal gas law:

$$\begin{aligned} A &\underset{k_2}{\overset{k_1}{\rightleftharpoons}} B + C \\ 2B &\underset{k_4}{\overset{k_3}{\rightleftharpoons}} C \end{aligned} \tag{11}$$

Multiple states satisfy the equilibrium condition for a given measurement, which in this case is the system pressure at the equilibrium, evaluated by the following equation:

$$y = p = \left(c_A + c_B + c_C\right) RT \tag{12}$$

Table 2 presents the possible theoretical solutions, without measurement or state noise, at the equilibrium pressure given by the initial state: $c_0 = \begin{bmatrix} 0.5 & 0.05 & 0 \end{bmatrix}$. Note that only the solution EQ1 has physically realizable states (nonnegative concentrations).

Table 2. Equilibrium points

Component	EQ1	EQ2	EQ3
c_A	0.0122	-0.0267	-1967.4
c_B	0.1826	-0.2372	-9.9454
c_C	0.6669	1.1257	1978.2

The state estimation parameters and the poor initial guess $\bar{x}_0$ used for this example were obtained from Haseltine & Rawlings (2005):

$$\Delta t = t_k - t_{k-1} = 0.25\ min \tag{13}$$

$$P_0 = diag\left(0.5^2 \quad 0.5^2 \quad 0.5^2\right) \tag{14}$$

$$Q = diag\left(0.001^2 \quad 0.001^2 \quad 0.001^2\right) \tag{15}$$

$$R = 0.25^2 \tag{16}$$

$$\bar{x}_0 = \begin{bmatrix} 0 & 0 & 4 \end{bmatrix} \tag{17}$$

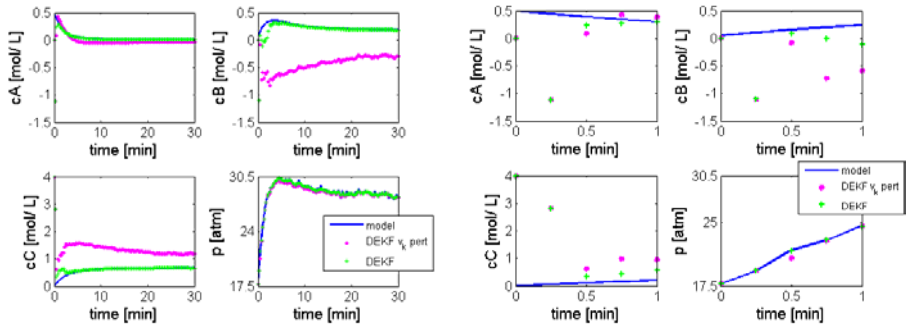
According to the authors, EKF fails in this example because the system model and measurement are such that multiple states satisfy the equilibrium condition and is given a poor initial guess of the state for the estimator. Nonetheless, we cannot assert that EKF fails because two equilibrium points (EQ1 and EQ2 in Table 2) are possible due to the poor and incoherent initial state and its respective state covariance initial guess used in this example. Further, the theory of EKF formulations assumes system observability, i.e., the state dynamic system is uniquely determinable from its inputs and outputs, given a model for the dynamic system. Since at least two states exist that realize the same equilibrium pressure, the batch reactor system is considered unobservable according to the nonlinear observabilty. Because this system satisfies the observability rank condition (linear observability), it is also considered locally weakly observable (Hermann and Krener, 1977). As the nonlinear observability assumption is violated, it is not surprising that the theory of EKF formulations may not work for this example. Details on observability definition can be found in Sontag (1998).

2.2. Results and Analyses

2.2.1. Measurement Noise Perturbation

Firstly, uniform and normally distributed random measurement noises were simulated. Either solution EQ1 or solution EQ2 is obtained in accordance with the set of random measurement noise employed into DEKF. Thus, we have chosen a set of random measurement noise which leads DEKF to converge to the solution EQ1 and added a noise measurement perturbation in order to lead it to converge to solution EQ2. As it

can be seen in Fig. 1, a noise measurement perturbation of 0.754 *atm* at t = 0.5 *min* changes the estimated states trajectory from solution EQ1 to solution EQ2.



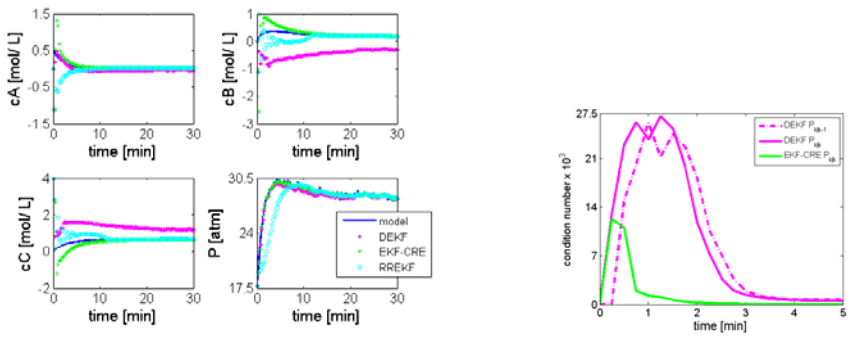
(a) (b)

Fig. 1. Comparison between the performances of DEKF with and without a noise measurement perturbation of 0.754 *atm* at t=0.5 *min*: (a) until final batch time and (b) until t=1 min.

We have also experienced that other numerical pitfalls can lead DEKF to converge to solution EQ2, such as low-precision arithmetic, gradient (linear model) calculation by finite differences, poor guess of P_0 and incorrect values of tuning parameters Q and R.

2.2.2. Comparison between Unconstrained EKF formulations

To prevent the state estimator from converging to EQ2, two other unconstrained EKF formulations were applied to this example. In spite of a measurement noise perturbation, RREKF and EKF-CRE have converged to solution EQ1, as shown in Fig. 2(a).



(a) (b)

Fig. 2. Comparison between (a) DEKF, EKF-CRE and RREKF performances; (b) the condition number of DEKF and EKF-CRE state covariance matrices.

RREKF disregards non-dominant eigenvectors which implies zero variance in the respective directions and no effect of measurement updates. For this example, the non-dominant eigenvector is orthogonal to the tangent of solution EQ1 (the scalar product approaches zero). RREKF converges to EQ1 because it applies no correction in the non-dominant eigenvector direction.

EKF-CRE is not subjected to errors due to model discretization and the term $PH^T R^{-1} HP$ inserts nonlinearity into the respective state covariance matrix. Besides, the state covariance matrix computed by EKF-CRE in a single stage (Eq. 6) presents a smaller condition number, i.e., it is less sensitive to perturbations than the states

covariance matrices computed by DEKF (Eqs. 4 and 5), as shown in Fig. 2(b). The mentioned advantages of EKF-CRE over DEKF justify the convergence of this formulation to EQ1, even with a measurement noise perturbation.
Although EKF-CRE and RREKF have prevented from physically unrealizable states at the final batch time, physically unrealizable states (negative concentrations) were unavoidable during the batch. This fact is justified by the poor state and respective state covariance initial guesses.

2.2.3. Comparison between clipped DEKF and CEKF

To prevent physically unrealizable states, we have constrained DEKF with an ad hoc clipping strategy in which negative update values of the state are set to zero (i.e., if $\hat{x}_{k|k} < 0$, set $\hat{x}_{k|k} = 0$). The comparison between clipped DEKF and CEKF performances are shown in Fig. 3(a). Before eventually converging to the actual states, the pressure filtered by the clipped DEKF is quite larger than the measured one. Due to a lower initial guess of the state covariance matrix, $P_0 = diag\left(0.022^2 \quad 0.022^2 \quad 0.022^2\right)$, the clipped DEKF in our work has presented a better performance in comparison to performance of the clipped DEKF in Haseltine & Rawlings (2005). In their paper, the clipped DEKF drives the predicted pressure 3 orders of magnitude larger than the measured pressure before eventually converging to the actual states at a longer time scale (1 order larger than the converge time obtained in our work). A clipped DEKF, however, disregards the assumption that v_k is a Gaussian random noise and does not let the Kalman gain to distribute properly the measurement residual throughout the estimated state and, thereby, corrects them. On the other side, CEKF swiftly converges to the actual states and minimizes ω_k and v_k in a least square sense, incorporating constraints into an optimization problem, which prevents from bad noises distribution. Fig. 3(b) illustrates the distribution of v_k for the clipped DEKF and the CEKF.

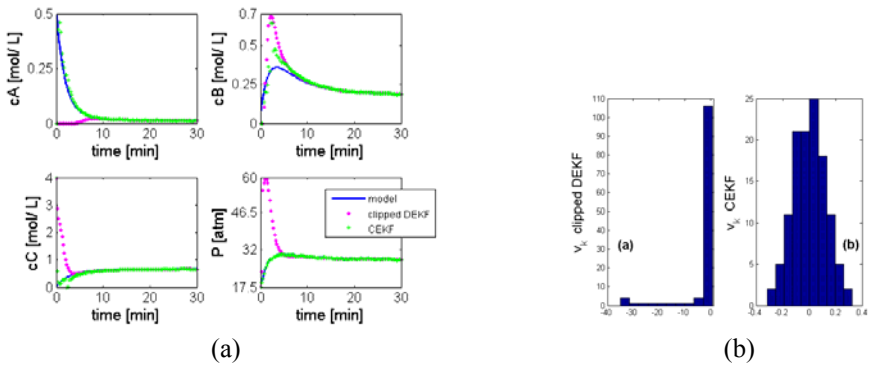


Fig. 3. Comparison between (a) clipped DEKF and CEKF performances and (b) the distribution of v_k for clipped DEKF (non-Gaussian) and CEKF (Gaussian).

Finally, we have compared the performances between CEKF and MHE (N=2). The high computational effort of MHE (2 orders larger) is not justified for this process as the improvement of estimation results is marginal, as shown in Fig. 4.
Due to the small computational effort of CEKF, possibility of incorporating constraints into an optimization problem, and the comparable estimation results to MHE, this approach seems to be the best choice for our case study.

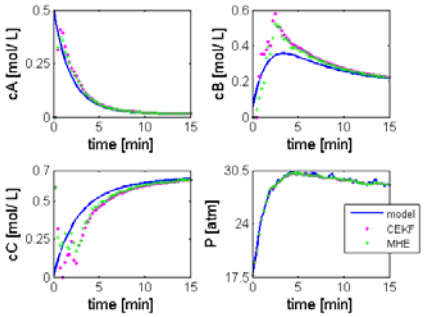

Fig.4. Comparison between CEKF and MHE (N=2) performances.

3. Conclusions

This paper outlines the numerical robustness of four EKF formulations for a chemical engineering example whose system model and measurement are such that multiple states satisfy the equilibrium condition. With a measurement noise perturbation, we outline a condition that has led a classical EKF formulation (DEKF) to converge to physically unrealizable state. According to our results, EKF-CRE and RREKF are more numerically robust in computing the state covariance than the DEKF. As both formulations have avoided an increase in error propagation due to a measurement noise perturbation, they were able to converge to the desired final state solution. Thus, a suited choice of the EKF formulation based on the state covariance equation is essential to prevent from physically unrealizable states. However, due to the poor initial states and its respective state covariance initial guess for the batch reactor, EKF-CRE and RREKF have not prevented from physically unrealizable states during the batch. Hence, CEKF can be seen as the best alternative to systems with such behavior due to the possibility of incorporating constraints into an optimization problem to prevent from physically unrealizable states. Besides, it is simpler, computationally less demanding than the MHE, and has comparable performance.

IPL2&3 Performance Improvement Method for Process Safety Using the Event Correlation Analysis

Junya Nishiguchi, Tsutomu Takai

Yamatake Corporation, 1-12-2, Kawana, Fujisawa-shi, Kanagawa, Japan

Abstract

Alarm management efforts have recently intensified in the world, and there are many tools based on a guideline EEMUA191 to evaluate alarm system performance. However, the improvement and rationalization of alarm systems have not made satisfactory progress, because these tools usually just provide with alarm system performance metrics but not useful information to improve and rationalize alarm systems. In this paper, a novel method for performance improvement of IPL2&3 including alarm system using the event correlation analysis was proposed.

Keywords: EEMUA, IPL, alarm management, event correlation, clustering

1. Introduction

Safe operation is the top priority for process plants. As a concept of safe design to provide protection from hazardous incidents, Independent Protection Layers (IPLs) which consist of eight layers as shown in Table 1 has been extensively applied to the various plants (AIChE/CCPS 1993). The second layer (IPL2) and third layer (IPL3) are related to alarm system. The primary purpose of IPL2 is the supervision of the plant under the normal operation with Basic Process Control System. When the process variables deviate from the set points, the system activates alarms and requires the corrective actions of the operator. On the other hand, IPL3 represents the critical alarms and corresponding operator interventions. Failure in the functions of IPL2&3 is resulting to production loss. Therefore, it is important that IPL2&3 should be able to function effectively from both safety and production standpoint.

Table 1. Independent Protection Layers for Process Safety

Layers	Definitions	Functions	
IPL8	Community Emergency Response	Minimize damage from an incident	
IPL7	Plant Emergency Response		
IPL6	Physical Protection (Dikes)		
IPL5	Physical Protection (Relief Devices)		
IPL4	Automatic Action SIS or ESD		
IPL3	Critical Alarms, Operator Supervision, and Manual Intervention	Ensure safe and productive operations	Prevent an incident from happening
IPL2	Basic Controls, Process Alarms, and Operator Supervision		
IPL1	Process Design		

For rationalization of alarm system, EEMUA191 (EEMUA 1999) is widely accepted as a de facto standard guideline. In EEMUA191, alarm system is defined as *a very important way of automatically monitoring the plant condition and attracting the attention of the process plant operator to significant change that require assessment or*

action. It specifies several performance metrics that can be used to assess the alarm system performance:

- *Operator questionnaires*
- *Alarm usefulness surveys*
- *Assessment of number of alarms in a system*
- *Measurement of average alarm rate*
- *Measurement of number of alarms following a major plant upset*
- *Measurement of operator response time*
- *Measurement of number of standing alarms*
- *Analysis of the priority distribution of alarms configured and occurring*
- *Correlation techniques*

Unfortunately the effective correlation techniques from the standpoint of rationalizing IPL2&3 had not been defined well. Analyzing correlation between the alarms and operator actions in a process upset is expected to estimate the propagation path, source origin, and nuisance alarms, which can be useful information to improve the alarm system and understand the IPL2&3 performance properly.

2. New Method for IPL2&3 Performance Improvement

2.1. Concept

As referred to in EEMUA191, every alarm should be defined uniquely to notify a specific upset situation, and every operator action should be defined to solve the corresponding alarm. Once a certain upset causes alarms in the plant with the poor IPL2&3, it will propagate via the process fluid and consequently leads to the alarm flood; meanwhile, alarms without the corrective actions will increase operators' workload as nuisance alarms. Therefore, in order to rationalize IPL2&3 performance, every alarm and operator action should be properly related each other.

As a conventional method for fault propagation analysis, Signed Directed Graphs (Shiozaki et al. 1989) has been actively researched. However, it is difficult for this method to put into practical use because it requires much effort to adjust process model whenever the process devices are replaced. Also, to our knowledge there has not been any systematic method for rationalizing operator actions.

The concept of our method is to provide a fast, easy, and effective way to improve IPL2&3 performance. The relationship and occurrence order between events, which contain alarm and operator action events, are extracted from event log data with Event Correlation Analysis (Nishiguchi et al. 2005). In this method, the event pairs with constant occurrence time lags are considered to be similar events, since the time lags depend on the time delay of the process dynamics and human reaction time. From the similarity and the occurrence time lag calculated by the Event Correlation Analysis, we can estimate the group with the consequential events as well as their occurrence order. Our method enables us to extract the relationships between process variables change and operators' behavior only with accumulated log data. The solutions to improvement for the IPL2&3 design and management are found rapidly and easily. The examples of extracted relationships and corresponding solutions are as follows.

I. Consequential Alarms

When the several alarms are strongly related, these alarms are likely to be consequential alarms, which can be reduced by alarm filtering techniques.

II. Complex Operator Actions

When the several operator actions are strongly related, the operator actions are likely to be complex sequential operations, which can be reduced by automating operations.

III. Redundant Alarms

When there is a high frequent alarm without the related operator actions, it may be redundant alarm, which can be reduced by changing set point or replacing into message.

IV. Causes of upset

When constant occurrence order of alarms and operator actions is found, the first occurrence event is likely to be the source of plant upset.

2.2. Event Correlation Analysis

Event Correlation Analysis quantifies the relationship and occurrence order between alarms and operator actions. Although correlation coefficient is usually used to measure the relationship between two continuous values, it is well known fact that the coefficient cannot be applied for event data (Li 1990), such as alarms and operator actions log data. In this method, similarities between all event pairs are calculated from the log data with probability distribution of correlation regarding independent event pairs (Figure 2).

The alarms and operator actions log data obtained from Distributed Control System (DCS) contains occurrence time and event kind. The log data is converted into event time series $s_i(t)$ defined as binary series for each event i, which is 1 if the event occurs within the time window Δt and 0 if does not.

$$s_i(t) = \begin{cases} 1, & \text{if some points in } (n\Delta t, (n+1)\Delta t] \\ 0, & \text{otherwise} \end{cases} \quad (1)$$

where Δt is window size, and n is time unit.

The cross correlation function (2) between event i and j indicates the occurrence counts that event j follows event i in the time range of ($m\Delta t$, (m+1)Δt].

$$c_{ij}(m) = \begin{cases} \sum_{n=1}^{T/\Delta t - m} s_i(n) s_j(n+m) & m \geq 0, \ -K \leq m \leq K \\ c_{ji}(-m) & m < 0 \end{cases} \quad (2)$$

where T is observation time, and K is maximum lags of time unit.

From (2) maximum correlation value c^*_{ij} and time lag at maximum correlation m^*_{ij} are defined as follows.

$$c^*_{ij} = \max c_{ij}(m), \ m^*_{ij} = \arg\max_m c_{ij}(m) \quad (3)$$

As a result, the similarity between two events R_{ij} is defined with the probability that the correlation between two independent events is lower than c^*_{ij} within time lag K.

$$R_{ij} = P\left(c_{ij}(m) < c^*_{ij} \mid -K \leq m \leq K\right) \cong \left\{ \sum_{l=0}^{c^*_{ij}-1} \frac{\nu^l e^{-\nu}}{l!} \right\}^{2K+1} \quad (4)$$

where ν is the expected value of Poisson distribution regarding the occurrence of independent events, which is approximated by the average co-occurrence number between independent two events as shown in equation (5).

$$\nu = \frac{T}{\Delta t} \cdot p_i \cdot p_j \cong \frac{\Delta t}{T} \sum_{n=0}^{T/\Delta t} s_i(n) \cdot \sum_{n=0}^{T/\Delta t} s_j(n) \quad (5)$$

In other word, this method conducts the statistical test of hypothesis that two events i and j are generated independently. The actual maximum correlation c^*_{ij} is compared

with the distribution of correlation value between independent two events. The similarity R_{ij} is defined with the value, which is subtracted the reject rate from one.

By applying some clustering algorithm (e.g. hierarchical clustering) with the similarities of every event pair, the event groups with similar events will be extracted automatically. In addition, the occurrence order of each event pair is estimated with the time lag m^*_{ij}, which represents the most probable time delay.

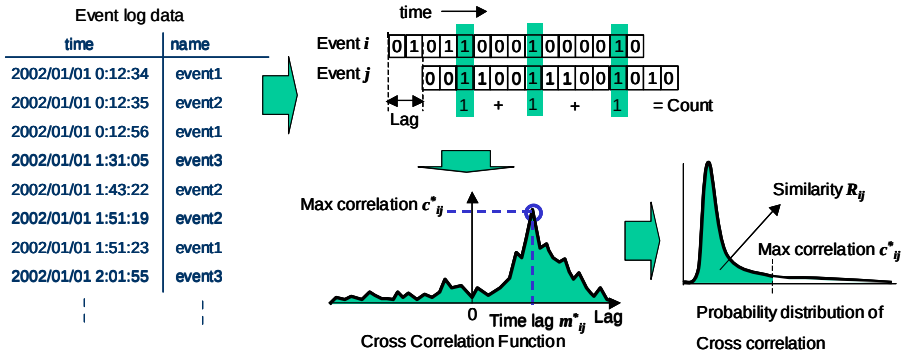

Figure 2. Event Correlation Analysis

2.3. Numerical Experiment

We evaluated the Event Correlation Analysis with synthetic data consists with six event type generated with the following rules for 30 days in one-second units.

- Event 1 and 4 are generated by Poisson distribution with mean of 0.0001 and 0.0004, respectively.
- Event 2 and 3 are generated from event 1, added with noise of Poisson distribution with mean of 0.000005 and removed with the probability 50%. In addition, occurrence time of each event is shifted with Normal distribution $N(600,100)$ and $N(1800,100)$, respectively.
- Event 5 and 6 are generated from event 2, added with noise of Poisson distribution with mean of 0.0002 and removed with the probability 50%. In addition, occurrence time of each event is shifted with Normal distribution $N(600,100)$ and $N(1800,100)$, respectively.

Table 3. Results for the synthetic data

Order i –> j	Similarity c^*_{ij}	Delay m^*_{ij}	Order i –> j	Similarity c^*_{ij}	Delay m^*_{ij}
1 –> 2	0.99	600	4 –> 5	0.98	600
1 –> 3	0.98	1800	4 –> 6	0.97	1900
2 –> 3	0.96	1200	5 –> 6	0.95	1100

Table 3 shows the similarity and delay time of the related event pairs with higher similarity than 0.9. From the table, we can see the proposed method properly extracted the related event pairs and their occurrence time lags even though the data contained noise.

3. Validation with Actual Plant Data

3.1. Target Plant

The proposed method was applied for actual chemical plant data for validation. The target plant has the typical multiple-stage gas purification unit. According to the event log data obtained from this unit, a total of 1,267 types of alarms and operator actions occurred a total of 56,350 times over a period of two months.

3.2. Results

The event log data was analyzed with Alarm Analyst R20, the software product that implements the Event Correlation Analysis. The software generated the groups with the consequential events for a few seconds. From the discussions with the plant engineers and operators, we were able to plan the solutions for IPL2&3 performance improvement regarding the top 35 groups accounted for 60% of occurrences within only six hours. We will next give some examples of the results, which show actual process property and operators' behavior correctly.

I. Consequential alarms

The five events listed in Figure 4 were occurred synchronously and the total count was 702. From the result of the Event Correlation Analysis, we found Alarm 1, 2, 3 and 4 followed after Operation 1 at around midnight everyday. From the interview with the operators, when they switched the blower to the manual operation, Alarm 4 notified them of pipe blowing. As a result, the air and steam flow rate became unstable and consequently Alarm 1, 2 and 3 occurred. Since these alarms did not have corresponding operator actions in this situation, it was decided that Alarm 1, 2 and 3 were inactive with alarm filtering technique during manual pipe blowing procedures. In addition, Alarm 4, which gave only guidance to the operators, was changed to a message.

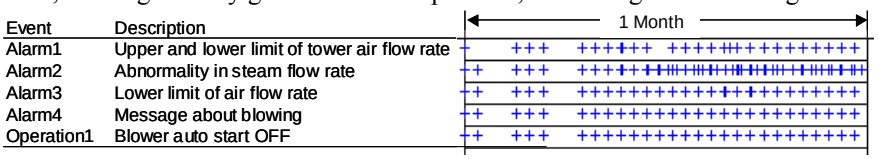

Figure 4. Example of consequential alarms

II. Complex operator actions

The five events listed in Figure 5 were also occurred synchronously and the total count was 495. From the result of the Event Correlation Analysis, we found Operation 2, 3 and Alarm 6 occurred simultaneously at around 4:00am, and Operation 2, 4 and Alarm 5 occurred simultaneously at around 4:00pm. The investigation of the daily report found that these events are related to the pipe flushing. In the system A, operators firstly invalidated alarms with Operation 2, followed by flushing procedure with Operation 3 and the notify of pipe flushing with Alarm 6. Likewise, in the system B, operators firstly invalidated alarms with Operation 2, followed by flushing procedure with Operation 4 and the notify of pipe flushing with Alarm 5. In general, operators should not intervene with such regular procedures. Therefore, Operation 2, 3 and 4 were automated with the timer, and Alarm 5 and 6 were changed to message.

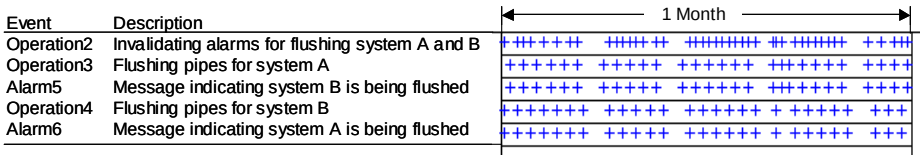

Figure 5. Example of complex operator actions

III. Redundant alarms

Alarm 7 is a flow rate alarm with lower limit type and occurred 657 times. According to the result of the Event Correlation Analysis, there were not any alarms or operator actions related to Alarm 7. Thus, this alarm is considered to occur independently with other alarms and operator actions. In fact, the operators told they usually did not take any actions in response to this alarm, but waited until it returned to stable by itself. We removed the alarms like this alarm that did not function as alarm, because they could deteriorate the sensitivity of the operators to alarms.

IV. Cause of upset

Figure 6 shows the example of the cause of plant upset. As shown in Figure 6, these six events occurred at the devices located near each other. From the event log data, Operation 5 was a manipulated variable change action, Operation 6 was an upper threshold change action, and Alarms 8, 9, 10 and 11 were all upper limit alarms. The occurrence order estimation found that Alarm 8 occurred first and Operation 6 occurred last. According to these results, it must be a problem with the pipes near the heat exchanger subjected to cooling with seawater. In fact, a field investigation revealed that the pipe easily became clogged, resulting in poor seawater cooling. Therefore, it was decided that this pipe should be cleaned regularly to solve this problem.

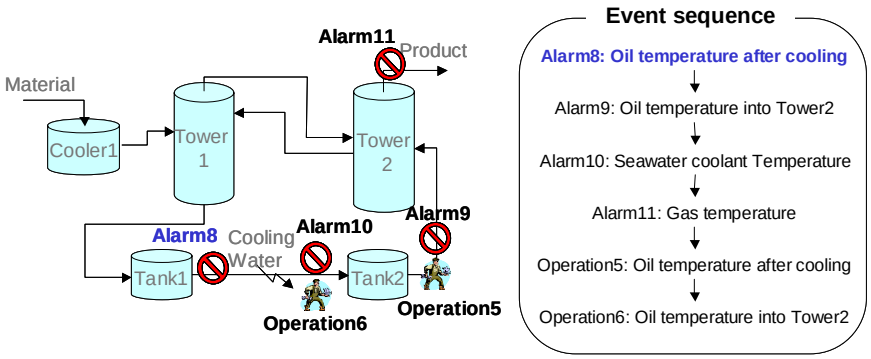

Figure 6. Example of cause of upset

4. Conclusion

In this paper, a new method for IPL2&3 performance improvement using Event Correlation Analysis was proposed. The validation result with the actual plant data shows our method is considered to improve process safety as well as productivity rapidly, easily, and effectively. In addition, since this method extracts the operators' behavior from the log data, it leads to standardization of operator actions.

Collaborative Multi - Agent based Process Monitoring System for Offshore Oil and Gas Production

Sathish S Natarajan, Kaushik Ghosh, Rajagopalan Srinivasan*

Department of Chemical and Biomolecular Engg, National University of Singapore
10 Kent Ridge Crescent, Singapore, 119260.

Abstract

Offshore oil and gas production platforms are uniquely hazardous in that operating personnel have to work in a perilous environment surrounded by extremely flammable hydrocarbons. A failure in an equipment could quickly propagate to others resulting in leaks, fires and explosions, causing loss of life, capital invested and production downtime. A method for preventing such accidents is to deploy intelligent monitoring tools which continuously supervise the process and the health of equipments to provide context–specific decision support to operators during safety-critical situations. A dynamic model of an offshore oil and gas production platform was developed using gPROMS and data to reflect operating conditions under normal, fault conditions and maintenance activities were simulated. These data are used to train three monitoring algorithms based on multivariate statistics (Principal Component Analysis), two of which are specialized in monitoring certain sections of the platform. These multivariate monitoring algorithms are considered as individual agents and the results produced by each are then integrated using a multi-agent collaborative framework. A consolidator agent, which uses voting based, Bayesian probability and Dempster Shafer fusion strategies for conflict resolution and decision fusion is developed. The ability of this agent based monitoring scheme to detect and diagnose faults in a more precise manner than any single FDI agent in offshore oil and gas production platforms is demonstrated.

Keywords: offshore production, process monitoring, agent based.

1. Introduction

Offshore Oil and Gas production has accounted for most of the increase in worldwide production of hydrocarbons over the last few decades. Given that most of the significant hydrocarbon discoveries in recent times have happened offshore, it is expected that the contribution of offshore production to our overall energy mix would only increase further. Hence it is imperative that these offshore production platforms are operated in a safe and efficient manner.

Operations personnel in offshore platforms face many unique challenges: The workforce lives and works in a restricted location for significant periods of time without a break. The environment is characterized by confined space, constant noise and activity while the production process has the potential for the rapid escalation of hydrocarbon related incidents. This inherently hazardous nature combined with the extremely harsh

*Corresponding Author
Ph: +65 65168041, Email: chergs@nus.edu.sg

and stressful environment is the prime reason for the unusually large number of accidents. A study by the UK Health and Safety Executive shows that process related failures account for nearly 80% of the risk to offshore personnel. Currently, onboard operating personnel are expected to detect failures as and when they occur and take corrective action to prevent them from escalating into severe accidents. However given the cognitive limitations of operators working in a remote facility some failures are not detected.

A method for preventing accidents on offshore platforms is to deploy intelligent monitoring tools which continuously supervise the process and the health of the equipments to provide context – specific decision support to operators during safety critical situations. Historically, the offshore processing industry has sought to improve its safety performance using the proactive strategy in which the basic process design is made inherently safe and robust. The main shortcoming of this strategy is that even if all the hazards have been identified, it may not be economically or technically feasible to eliminate them. The reactive strategy seeks to overcome this through improved process control using advanced process monitoring and supervision. There is plenty of literature on process monitoring, fault detection and identification (Venkatasubramaniam et al, 2003) for petrochemical industries but these monolithic monitoring strategies are not suited for the offshore production process due to the lack of large scale computational facilities on board. Hence, a remote agent based distributed monitoring scheme would be more suited. Also, due to the complexity involved a single FDI agent would not be capable of handling all the fault scenarios. A method in which the results of several FDI agents, each specialized in monitoring certain sections of the overall process, are meaningfully fused by a consolidator agent, is proposed.

Since relevant process data for offshore platforms is not readily available in literature a dynamic model in gPROMS is developed, as detailed in Section 2. Process faults common in offshore production platforms (Khan et al, 2002) is introduced into this model. The operations data collected from this model was used to train three different multi-variate statistical models, each specialized in identifying a fault in a particular section of the platform, as discussed in Section 3. The results from these individual methods are then combined using different fusion strategies.

2. Dynamic Model of Offshore Natural Gas Production

The first step towards achieving a representative dynamic model is always a good steady state simulation. Hence a steady state model of a typical natural gas production platform was developed in Hysys. The steady state operations data from the Hysys model served as the initial conditions to the dynamic model in gPROMS. Three flow lines involving the usual combination of safety, master, wing and choke valves were modeled. The flow lines were combined into a production header and a separator header. As shown in Figure 1, a test separator is included which is brought online occasionally when a stream has to be analyzed. An important maintenance activity in the operation of these platforms is the pig-launching operation, during which the platforms are required to be shut down; hence shutdown and startup procedures were incorporated. Other maintenance activities include corrosion inhibitor and kinetic hydrate inhibitor injection. Apart from capturing the dynamics during these normal operations, three fault cases were simulated as indicated in Figure 1.

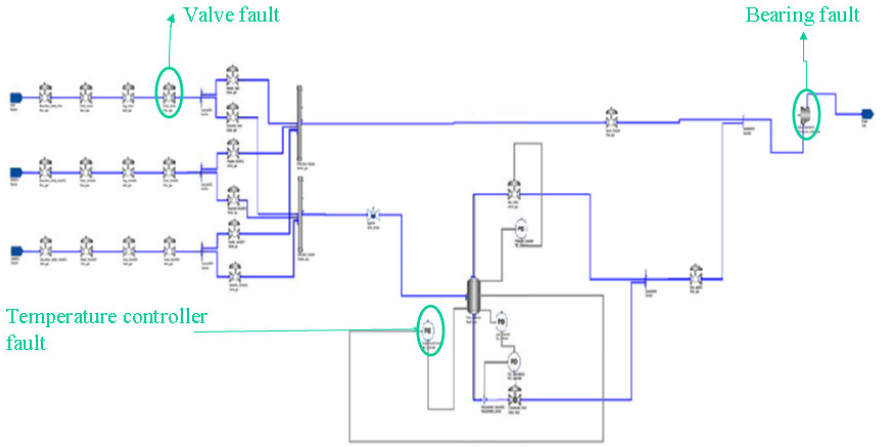

Figure 1. Process Flowsheet of Offshore Natural Gas Production from industrial case study

(1) A valve leak fault in a flow line in which the flow through the line was reduced from its normal range by 10% as a step change.
(2) Test separator temperature controller fault in which during the operation of the separator the heat input was reduced resulting in a temperature drop by 2%.
(3) A bearing fault on a compressor in which the eccentric vibrations and currents were simulated. This fault was not simulated as a complete failure of the bearing, but as an incipient fault like a dent in the raceways producing eccentricities.

Figure 2 shows the simulated data for these three faults along with their corresponding expected normal behavior.

3. Multivariate statistical models for monitoring

Three different models were developed as individual agents. The three agents were a process monitoring agent, which monitors the overall process, a specialized separator monitoring agent and a specialized compressor monitoring agent. The first two were based on principal component analysis (Jackson, 1991) while the third is based on spectral principal component analysis.

3.1. Process Monitoring Agent

The normal operating data from 34 variables measured at various points in the process were used to train a PCA model. The data from the three fault conditions were then projected onto this PCA model. The valve leak fault is detected and diagnosed with a delay of 14 samples. The temperature controller fault is detected with a delay of 4 samples and diagnosed after 16 samples. This process monitoring agent does not detect the bearing fault on the compressor.

3.2. Separator Monitoring Agent

Of the 34 variables measured, 5 were chosen around the separator. A separate PCA model is developed using normal data for these 5 variables and the fault data projected onto this. Being specially suited to detect abnormalities around the separator this agent detects and diagnoses the temperature controller fault with a delay of only 4 samples and is unable to detect the bearing fault around the compressor.

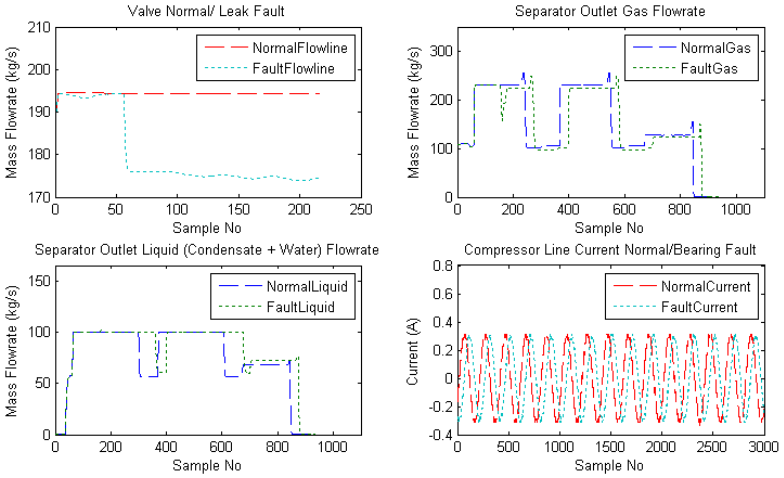

Figure 2. Simulated data for normal operating condition as well as Valve Leak Fault, Separator Temperature Controller Fault and Compressor Bearing Fault

3.3. Compressor Monitoring Agent

The eccentricities produced by the bearing fault are oscillatory in nature. Hence a Spectral PCA method is used for monitoring the compressor. The novel feature of spectral PCA is that the rows of the data matrix *X*, are the single sided power spectra P(*f*) of the signals over a range of frequencies (Thornhill et al, 2002). The data matrix *X* is then decomposed in the usual PCA procedure and the T^2 and Q statistic measured. 5 variables were chosen around the compressor including the simulated vibration and current signals. This agent is capable of detecting and diagnosing the bearing fault alone after 11 samples.

4. Collaborative Multi-agent based fusion

As is evident from Table 1, no single FDI method is capable of detecting all the faults. Instead of developing a suitable monolithic method, the results from these individual methods could be meaningfully combined using a consolidator agent to produce good results. This consolidator agent utilizes voting, Bayesian, or Dempster Shafer fusion strategies. Using such methods, the strengths of the individuals agents are accrued while their drawbacks are overcome resulting in improved performance.

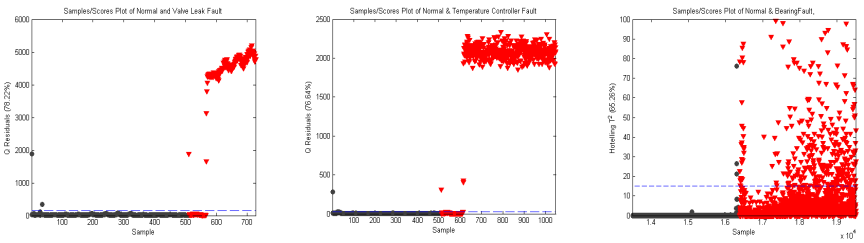

Figure 3. Sample/Score plot of Normal vs. Valve Leak Fault, Separator Temperature Controller Fault and Compressor Bearing Fault

Table 1. Performance of the individual agents, F1 - Valve Leak Fault, F2 - Separator Temperature Controller Fault, F3 – Compressor Bearing Fault

Fault	Process Monitoring PCA		Separator Monitoring PCA		Compressor Monitoring Spectral PCA	
	Detection Delay (x30s)	Diagnosis Delay (x30s)	Detection Delay (x30s)	Diagnosis Delay (x30s)	Detection Delay (x30s)	Diagnosis Delay (x30s)
F1	14	14	22	-	-	-
F2	4	16	4	4	-	-
F3	-	-	-	-	11	11
Average Delay	9	15	13	4	11	11
Recognition rate (%)	62.23		50.39		47.42	

Voting based fusion is the simplest and most commonly used decision fusion strategy. The class assigned to each sample by an FDI agent is considered as a vote for that class. The class with the maximum number of votes is the combined prediction. The major drawback of this method is that all agents are treated equally although in practice some agents outperform others and should hence be given more weightage.

Both Bayesian and Dempster-Shafer strategies utilize the prior performance of an agent for combination. The prior performance of a FDI agent is recorded in the form of a confusion matrix in which the rows are the actual classes while the columns are the assigned classes. For each FDI method, P(Ci/Cj) is the probability of assigning a sample to class Ci given class Cj. For k FDI methods, Bayesian Belief Value for class Ci is calculated as

$$Bel(C_i) = \frac{\prod_k (P_k(C_i / C_j))}{\sum_i \prod_k (P_k(C_i / C_j))}$$

The class with maximum Bayesian belief value, *Bel(Ci),* is the assigned class upon combination using Bayesian fusion strategy.

Table 2. Performance of different fusion strategies, F1 – Valve Leak Fault, F2 – Separator Temperature Controller Fault, F3 – Compressor Bearing Fault

Fault	Voting Based Fusion		Bayesian Probability based Fusion		Dempster Shafer based fusion	
	Detection Delay (x30s)	Diagnosis Delay (x30s)	Detection Delay (x30s)	Diagnosis Delay (x30s)	Detection Delay (x30s)	Diagnosis Delay (x30s)
F1	22	-	14	14	14	22
F2	4	16	4	4	4	4
F3	-	-	11	11	11	11
Average Delay	13	16	9.67	9.67	9.67	12.33
Recognition rate (%)	49.53		97.85		97.17	

The Dempster-Shafer (D-S) method is popular in uncertainty reasoning which is used to combine separate pieces of evidence by assigning a belief value. The difference between Bayesian and D-S is the fact that the Bayesian method precisely assigns a probability value to each class, whereas D-S method assigns a BPA (Basic Probability Assignment) value to the union of all possible classes. The combined BPA values are obtained by using D-S combination rule.

$$Com\_BPA(C_i) = \frac{\sum_{A \cap B = C_i} BPA_I(A)\, BPA_{II}(B)}{1 - \sum_{A \cap B = \phi} BPA_I(A)\, BPA_{II}(B)}$$

Where Ci is the subset formed by the intersection of A and B and ϕ is null or empty set. The subset with highest combined BPA value is the resulting class upon combination.

The individual agents have recognition rates, which is defined as the percentage of sample correctly classified in the range of 47-62% shown in Table 1. Upon combination using Bayesian and Dempster Shafer based fusion strategies the recognition rates are improved to around 97% shown in Table 2. Voting based scheme does not perform as well as it requires at least 2 of the agents to concur for collaboration. We are able to achieve complete fault coverage and also improvement in fault detection and diagnosis time by using Bayesian and Dempster Shafer combination strategies.

5. Conclusion

An intelligent collaborative agent based monitoring system was proposed in this paper. Using data simulated from a dynamic gPROMS model three monitoring agents were developed, two of which were specialized. The results from these individual agents were then combined using different strategies. Upon combination we achieve significant (from about 60% to 97%) improvement in fault recognition rates and reduction in fault detection and diagnosis time. Thus, we have demonstrated that by using fusion we are able to combine the advantages of the individual methods while their respective shortcomings are overcome resulting in improved monitoring performance for offshore oil and gas production. Our future work would be to develop a remote agent based monitoring strategy, building upon these results for the offshore oil and gas industry, the first step of which would be the development of an ontological framework for efficient agent interaction.

Abstract

Advances in numerical algorithms have rendered the application of advanced process control schemes feasible for complex chemical processes that are described by high-order first-principles models. Applying real-time iteration schemes reduces the CPU requirement such that rigorous models can be applied that enable a precise forecast of the system behaviour. In this paper, a moving horizon state and parameter estimation scheme for chromatographic simulated moving bed SMB processes is presented. The simultaneous state and parameter estimation is based on a high-order nonlinear SMB model which incorporates rigorous models of the chromatographic columns and the discrete shifting of the inlet and outlet ports. The estimation is performed using sparse measurement information: the concentrations of the components are only measured at the two outlet ports (which are periodically switched) and at one fixed location between two columns. The goal is to reconstruct the full state of the system, i.e. the concentration profiles along all columns, and to identify model parameters reliably. The state estimation scheme assumes a deterministic model within the prediction horizon, state noise is only present in the state and in the parameters prior to and at the beginning of the horizon. The scheme can be applied online. The advantage of this estimation scheme is that it is applicable to all process scenarios encountered during the real operation of an SMB plant, e.g. start up, transition periods, varying flows and switching times, since no model simplification nor a state reduction scheme are applied. Numerical simulations (start up of the SMP process) of a validated model for a separation problem with nonlinear isotherms of the Langmuir type demonstrate the efficiency of the algorithm.

1. Introduction

The Simulated Moving Bed (SMB) process is an efficient chromatographic separation technology that is increasingly applied in the food, fine chemicals, and pharmaceutical industries. A SMB process is realized by connecting several chromatographic columns in a closed loop as illustrated by Fig. 1. Since SMB processes and its variants are characterized by mixed discrete and continuous dynamics, spatially distributed state vari-

ables with steep slopes, and slow and strongly nonlinear responses of the concentrations profiles to changes of the operating parameters, they are difficult to control. In the literature, relatively few contributions that deal with state estimation of SMB processes can be found. The published work is either based upon simplifications or deals with the engineering of tailored estimation schemes. Recently, a rigorous moving horizon estimation approach for SMB processes was proposed in [2]. In this formulation of the MHE, a deterministic behaviour of the process on the estimation horizon and Gaussian independent identically distributed measurement noise are assumed. The initial state at the beginning of the horizon and its covariance are computed by an Extended Kalman Filter (EKF). The state noise covariance and the initial error covariance of this EKF are the only tuning parameters of this scheme. A fast online solution of the underlying constrained least-squares optimization problem is obtained by using the direct multiple shooting method [3]. A full rigorous model is applied and therefore no assumption that the plant is close to the periodic steady state is needed. Along with the states, key adsorption parameters are estimated online. Simulations demonstrate that the states and critical model parameters can be reconstructed successfully. The computation times are such that the estimator can be applied online. Since a rigorous full scale SMB model is used, the MHE approach of [2] can also handle transition periods. In this contribution, the moving horizon state and parameter estimation scheme is applied to reconstruct the state variables in the start-up phase.

2. The Simulated Moving Bed Process

Chromatographic separation is based on the different adsorption affinities of the molecules in the liquid to an adsorbent which is packed in a chromatographic solid bed. A counter-current movement between the liquid and the adsorbent is implemented by switching the ports in the direction of the liquid flow periodically, illustrated by Fig. 1.

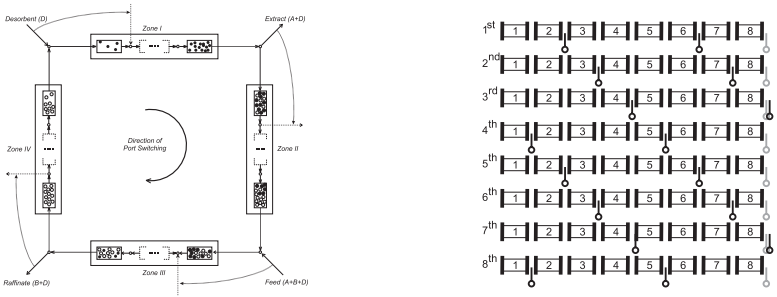

Fig. 1: Principle of the Simulated Moving Bed process (left) and positions of the extract, raffinate, and recycle port measurements over a cycle of operation (right)

In this paper, the counter-current flow of the solid and the liquid phases is modeled as it is achieved in the real plant by periodically switching the inlet and outlet ports in the direction of the liquid flow after period m with period length τ has passed. The state variables thus represent the concentrations in the physical columns and do not exhibit jumps. Only the input flow rates and the inflow concentrations change discontinuously. The dynamic simulation of the SMB process is achieved by integrating the differential equation over period m

$$\dot{x} = f(x, Q_m, p) \quad t \in [(m-1)\tau, \tau]; \qquad x(t_0) = x_{m,0} \tag{1}$$

followed by the switching of the flows $Q_{m,j}$:

$$Q_{m+1,j} = M_Q Q_{m,j} \qquad j = De, Ex, Fe, Ra, \mathrm{Re} \tag{2}$$

with differential states x and parameters p. The vector $Q_{m,j}$ defines the inlet/outlet flow of port j (desorbent, extract, feed, raffinate) and the recycle stream at period m. The respective component of $Q_{m,j}$ represents the flow of the respective port j to the respective column. M_Q is a permutation matrix that shifts the flow ports after period m has passed. The recycle flow that defines the total flow rate in the zone in front of the desorbent port is also switched in the same manner. All zone flow rates result from the port flows and the recycle flow. For this paper, three positions where the concentrations of the two substances of the mixture are measured are assumed. The measurements are positioned behind the extract port, behind the raffinate port, and behind one column in the process where physically the closing of the loop is realized. The extract and raffinate concentration measurements move together with the ports while the third measurement remains at its physical location throughout. Fig. 1 illustrates the measurement positions over a full cycle of operation that is defined by the time that passes until the ports are back at the starting positions after having moved around the closed loop of columns. The positions of the inlet and outlet ports are then repeated periodically. From mass balances of the components around the inlet and the outlet ports, the internal flow rates and the inlet concentrations can be calculated according to:

$$\begin{aligned}
&\textit{Desorbent node}: && Q_{IV} + Q_{De} = Q_I;\; c_{i,IV}^{out} Q_{IV} = c_{i,I}^{in} Q_I \qquad i = A,B \\
&\textit{Extract node}: && Q_I - Q_{Ex} = Q_{II} \\
&\textit{Feed node}: && Q_{II} + Q_{Fe} = Q_{III};\; c_{i,II}^{out} Q_{II} + c_{i,Fe} Q_{Fe} = c_{i,III}^{in} Q_{III} \qquad i = A,B \\
&\textit{Raffinate node}: && Q_{Ra} + Q_{IV} = Q_{III}
\end{aligned} \tag{3}$$

where $Q_{I\text{-}IV}$ are the flow rates in the corresponding zones, Q_{De}, Q_{Ex}, Q_{Fe}, and Q_{Ra} denote the external flow rates and $c_{i,in}$ and $c_{i,out}$ denote the concentrations of the component i in the streams leaving and entering the respective zone. The column distribution over the four separation zones considered here is 2/2/2/2, i.e. each zone consists of two columns. The chromatographic columns are modelled by the General Rate Model where it is assumed that there are no radial gradients in the column and that the particles of the solid phase are uniform, spherical, porous (with constant particle porosity ε_p), and that the mass transfer between the particle and the surrounding layer of the bulk is in a local equilibrium. The concentration of component i is denoted by c_i in the liquid phase and by q_i in the solid phase. D_{ax} is the axial dispersion coefficient, u the interstitial velocity, ε_P the void fraction of the bulk phase, $k_{l,I}$ the film mass transfer resistance, and D_p the diffusion coefficient within the particle pores. The concentration within the pores is denoted by $c_{p,i}$. The following partial differential equations of a column can be derived from a mass balance around an infinitely small cross section area of the column with a constant radial distribution of the interstitial velocity u and the concentration c_i.

$$\frac{(1-\varepsilon_b)3k_{l,i}}{\varepsilon_b}(c_{b,i} - c_{b,i|r=R_p}) = D_{ax}\frac{\partial^2 c_{b,i}}{\partial^2 z} - u\frac{\partial c_{b,i}}{\partial z};\quad (1-\varepsilon_p)\frac{\partial q_i}{\partial t} + \varepsilon_p \frac{\partial c_{p,i}}{\partial t} = \left[\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2 \frac{\partial c_{p,i}}{\partial r}\right)\right], \tag{4}$$

with appropriate initial and boundary conditions. It is assumed that the concentration q_i is in thermodynamic equilibrium with the liquid concentrations in the particle and their relationship can be described by an adsorption isotherm. In the application considered here, the adsorption isotherm is of extended Langmuir type

$$q_i = H_i^1 c_{p,i} + \frac{H_i^2 c_{p,i}}{1+\sum_k k_k c_{p,k}}, \quad i = A,B, \tag{5}$$

with H_i^j and k_i as isotherm constants.

The resulting system of coupled differential equations can be efficiently solved by the numerical approach proposed in [4] where a Galerkin finite element discretization of the bulk phase is combined with an orthogonal collocation of the solid phase. As a result,

the initial values, boundary values, and partial differential equations (PDE) are transformed into a set of initial values and a system of ordinary differential equations (ODE) $\dot{x} = f(x,u,p)$ of order 352 (for n_{fe}=5, n_c=1, number of components n_{sp}=2, and number of columns n_{col}=8) where the flows Q are summarized in the input vector u. The system output is defined as $y=h(x,u,p)$.

3. Moving Horizon Estimation in SMB Processes

For the simultaneous estimation of the states and the parameters of SMB processes, we employ the Moving Horizon Estimation scheme introduced by Diehl, Schlöder, and Bock [2], which is modified in order to handle the shift of the inputs and of the measurements of the SMB process. The Moving Horizon Estimator estimates the states and the parameters based on the past measurements at specific time points that are located in the horizon $T_N=t_K-t_L$. t_K represents the current time and t_L is the time at the beginning of the horizon. A least-squares minimization is performed that minimizes the deviations of the real measurements η_k from the simulated measurements $h(x;t_k,u,p)$ at times t_k. The optimization problem of the MHE results as:

$$\min_{x(t_L),p} \left\{ \left\| \begin{matrix} x(t_L)-\bar{x}_L \\ p-\bar{p}_L \end{matrix} \right\|^2_{P_L^{-\frac{1}{2}}} + \sum_{k=L}^{K} \left\| \eta_k - h(x(t_k),u(t_k),p) \right\|^2_{V_k^{-\frac{1}{2}}} \right\} \quad \begin{matrix} s.t. \quad \dot{x}(t) = f(x(t),u(t),p) \quad (6) \\ x_{\min} \le x \le x_{\max}; \quad p_{\min} \le p \le p_{\max}; \quad t \in [t_L, t_K] \end{matrix}$$

The second term represents the prediction errors within the horizon and the first term represents the arrival cost (the penalization of a change of the estimates of the initial values of the states and of the parameters). Note that only the initial values of the states and the parameters are free parameters of the optimization problem because no state noise is assumed within the horizon, which is equivalent to the assumption of a dynamic model that is perfect in its structure. The absence of state noise on the horizon is compensated by the simultaneous estimation of key model parameters which is an appropriate assumption since uncertainties are mostly due to model errors and not to disturbances. From the solution $x(t_L)$ and p of the optimization problem, the deterministic model is simulated forward to obtain the current estimated state x_K. The MHE takes upper and lower bounds on the states and on the parameters into account. The means $\bar{x}(t_L)$ and $\bar{p}$ and the covariance P_L in the arrival cost are determined by a smoothed Extended Kalman Filter that is implemented using QR-decompositions in order to guarantee positive definite matrices despite possible numerical errors [5]. In order to enable a smooth gradient calculation with respect to the simulated measurements which are subject to jumps due to the periodic movement of the ports, virtual measurements at constant positions at the outlet of each chromatographic column are included in the mapping of h. In order to account for the actual existence of real measurements at the considered time point k, the corresponding components on the diagonal of the measurement weight V_k^{-1} are set to σ_v^{-1} while nonexisting measurements have zero entries on the diagonal of V_k^{-1}. A zero weight can be interpreted as infinite measurement noise. The last two entries of V_k are the variances of the measurements at the internal measurement position (recycle) which are not shifted.

3.1. Multiple-Shooting Real-Time Iteration Scheme for MHE

The moving horizon optimization problem is solved by the multiple shooting methods that subdivides the time horizon into subintervals and formulates autonomous initial value problems on each individual subinterval. To retain the original problem, the subproblems are coupled by continuity conditions to guarantee the continuity of the state trajectories. The computational requirements are largely reduced by applying the *real-*

time iteration scheme for the multiple shooting method introduced by [1] that updates all relevant sensitivity matrices that are necessary to solve the optimization problem before the most recent measurement η_K is available. Another important feature is that the next optimization problem is initialized well at the current solution such that the number of iterations can be reduced to one.

3.2. Results (start-up scenario)

The separation of the enantiomer mixture EMD-53986 into the pure components is considered. The parameters of the SMB model were taken from [6].The measurements are corrupted by noise with a standard deviation of *0.025 g/l*. No cross-correlations between the state noises and between the state noises and the parameters were assumed. The same noise variances were assumed for each state. The tuning of the moving horizon estimator was performed by varying the covariances of the state variables and of the free parameters. The weighting matrix W incorporates a state standard deviation of 0.00433 *g/l* and a parameter standard deviation of 0.0316 for H^2_A and 0.0265 for H^2_B: $W^{0.5}=diag(0.0043,\ldots,0.0043,0.0361,0.0265)$. The initial weight P_0 is set to 0.005 W. The chosen state and parameter noises represent a compromise between the smooth estimation of the states and a quick adaptation of the parameters. The sampling time of the estimator is 1/10 of the period length. The moving horizon length is five sampling intervals (half a period). In the simulation scenario, the reference model and the model of the estimator are initialized with empty columns.The output, parameters, and states are reconstructed correctly, as can be seen by figures 2 to 4. The estimation of the parameters does not interfere with the reconstruction of the states. The MHE estimator can be applied online, as can be seen from Fig. 3. The CPU times are below the sampling rate at all sampling points. The CPU times of the MHE are around 19 s on a standard PC (Intel Xenon CPU 2.8 GHz, 4.0 GB RAM), the maximum and minimum values being 25.0 s

t=0.0 min, (2,6,8) t=0.97 min, (2,6,8) t=4.37 min, (2,6,8) t=6.32 min, (3,7,8)

t=9.23 min, (3,7,8) t=14.09 min, (4,8) t=18.95 min, (1,5,8) t=38.39 min, (1,5,8)

Fig. 4: Start-up scenario: real and estimated concentrations; measurements at the outlet of the columns indicated in brackets

4. Conclusion

In this paper, a moving horizon state estimation scheme that successfully reconstructs the states and key parameters was described and applied to a high-order nonlinear process with discrete switching of the inputs, the Simulated Moving Bed process. The integration of the presented moving horizon scheme in an advanced control scheme is subject of ongoing research.

Channel Blockage Detection of Microreactors Using Pressure Sensors

Yasuyuki Kaburagi, Masaru Noda and Hirokazu Nishitani

Graduate School of Information Science, Nara Institute of Science and Technology, 8916-5 Takayama, Ikoma 630-0192, Japan

Abstract

Blockage in microreactors is a serious problem that limits their practical usage. A proper diagnosis of blockage is indispensable to ensure these machines operate effectively and stably. We describe two systems, A and B, that can locate channel blockage using pressure sensors. System A uses a computational fluid dynamic (CFD) simulation, and system B uses a simple pressure balance model to construct databases for channel blockage diagnosis. The results of case studies showed that system A can identify the blockage location accurately using fewer pressure sensors than microchannels. System B can also identify the blockage location in many cases, but several misdiagnoses occur. In addition, we describe a method that estimates the degree of blockage in a microchannel. Simulation results showed that our method can estimate the degree of blockage precisely using the pressure sensor that is closest to the blocked location identified by systems A or B.

Keywords: Microreactor, Channel blockage diagnosis, Support vector machine, Computational fluid dynamics, Pressure balance model

1. Introduction

Microreactors have received both industrial and academic attention as a new type of production technology for specialty chemicals that are difficult to produce with conventional reactors. Blockage in the microchannels of microreactors is a serious problem that limits their practical usage. It changes the flow pattern in the microreactor and degrades the product quality. Detecting and identifying the blockage location is indispensable for ensuring more effective and stable operation in these microreactors.

Kano *et al.* (2007) proposed a blockage diagnosis system for a stacked microreactor that uses temperature sensors. The system uses the temperature differences at sensor locations between normal and abnormal operating conditions to identify the blockage location. When the channel blockage does not affect the temperature in the microchannels due to a high surface/volume ratio, which is one of the characteristics of microreactors, the system may not work. Also, they did not address how to estimate the degree of blockage after identifying the location.

This paper describes two blockage diagnosis systems that use pressure sensors instead of temperature sensors. One uses a computational fluid dynamic (CFD) simulation, and the other uses a simple pressure balance model for constructing a database for a channel blockage diagnosis. We also describe a method for estimating the degree of blockage after the location is identified. A CFD simulation was also used in this study to generate the validation data for our systems in case studies.

2. Microreactor

A microreactor generally consists of three parts, namely, an inlet manifold for flow distribution, parallelized microchannels for the reaction, and an outlet manifold for mixing, as shown in Fig. 1. The industrial scale production using a microreactor requires a high number of parallelized microchannels because each one provides only a small amount of product. The blockage in the microchannel causes poor uniformity in the residence time distribution between them, which may make product quality worse.

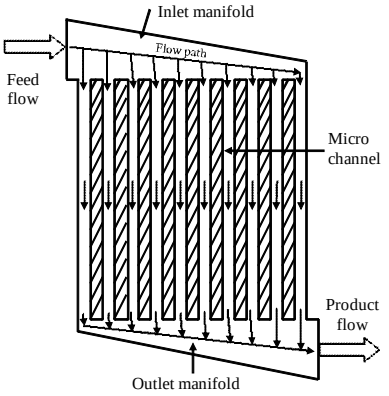

Fig. 1 Structure of microreactor

This study introduces the following assumptions for developing a blockage diagnosis system of a microreactor:

(1) Pressure sensors are set up at the inlets of microchannels. The total number of sensors, N_C, and their locations, $s \in S$, are given in advance.

(2) Channel blockage occurs in only one microchannel at a time.

3. Blockage diagnosis system A based on CFD simulation data

When channel blockage occurs in a microreactor, the pressure distribution changes. If the pressure distribution has certain patterns due to the blockage location, comparing measured pressure-distribution data with the prepared pressure distribution data when channel blockage occured can identify the blockage location.

In this study, we used a CFD simulation to execute a number of simulations for preparing pressure distribution data at sensor locations under various degrees of blockage in each microchannel. The pressure distribution data calculated by the CFD simulation are used as a training data set for a support vector machine (SVM) to construct a discriminate function for identifying the blockage location.

The detailed procedure for building System A is as follows. We assume that pressure distribution data vector $\tilde{P}_N$ consisting of measured pressure $\tilde{p}_{N,s}(s \in S)$ in a normal operating condition is known. Here, $\tilde{p}_{N,s}$ denotes the pressure data measured at sensor location s without any blockage, and S is the set of sensor locations.

(1) Calculate pressure data vector $\hat{P}_{B,i,x}$ consisting of $\hat{p}_{B,i,x,s}(s \in S)$ for some degrees of blockage $x \in X$ in microchannel i using the CFD simulation. Here, $\hat{p}_{B,i,x,s}$ denotes the calculated pressure data at sensor location s under x% blockage in microchannel i (i = 1,…,N_C). X is the set of degrees of blockage for which pressure data is calculated using the CFD simulation.

(2) Calculate the pressure difference vector $\Delta\hat{P}_{i,x}$ by Eq.(1).

$$\Delta\hat{P}_{i,x} = \hat{P}_{B,i,x} - \tilde{P}_N \quad (i = 1,..., N_C, x \in X) \tag{1}$$

(3) Construct a discriminate function using the SVM. The database of blocked channel i and pressure difference data $\Delta\hat{P}_{i,x}$ $(i = 1,..., N_C, x \in X)$ are used as a training data set for the SVM.

The blockage location is identified through the following procedure:

(1) Obtain actual pressure data vector $\tilde{P}_B$ consisting of $\tilde{p}_{B,s}(s \in S)$.

(2) Calculate pressure difference data vector $\Delta\tilde{P}$ using Eq.(2)

$$\Delta\tilde{P} = \tilde{P}_B - \tilde{P}_N \tag{2}$$

(3) Identify the blockage location using the discriminate function of the SVM.

4. Blockage diagnosis system B based on pressure balance model

A CFD simulation is a powerful tool for estimating the states in a microreactor when channel blockage occurs, but it is a time-consuming and costly process. Commenge *et al*. (2002) proposed a pressure balance model (PBM). Figure 2 shows an example of compartments defined in the PBM. The PBM consists of a simplified description of pressure and material balances in compartments. They applied this model to estimate states such as the flow rate and pressure drop in each microchannel instead of using a CFD simulation.

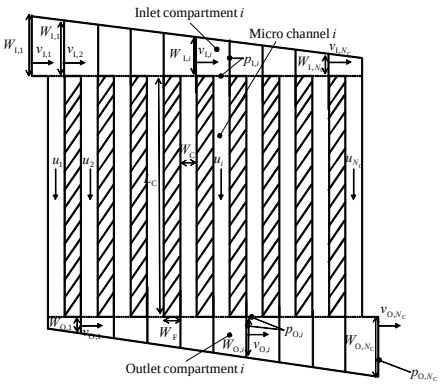

Fig. 2 Pressure balance model

This section describes a simple blockage diagnosis system, B, that is based on the pressure balance model. System B uses correlations between the pressure data vector calculated using the PBM under 50% blockage in each microchannel and the measured pressure data vector at the sensor locations. The procedure for building the database for system B is as follows:

(1) Calculate pressure data vector $\overline{P}_{B,i}$ consisting of $\overline{p}_{B,i,50,s}(s \in S)$ under 50% blockage in microchannel i (i = 1,…,N_C) using the PBM.

(2) Calculate pressure difference data vector $\Delta\overline{P}_i$ using Eq.(3).

$$\Delta\overline{P}_i = \overline{P}_{B,i} - \tilde{P}_N \quad (i = 1,..., N_C) \tag{3}$$

The blockage location is identified through the following procedure:

(1) Obtain actual data vector $\tilde{P}_B$ consisting of $\tilde{p}_{B,s}(s \in S)$.

(2) Calculate pressure difference data vector $\Delta\tilde{P}$ using Eq.(2)

(3) Identify microchannel i^*, which has the highest correlation between $\Delta\tilde{P}$ and $\Delta\overline{P}_i$ as the blocked microchannel. The correlation R_i is defined using Eq.(4).

$$R_i = \frac{(\Delta\tilde{P} - \Delta\bar{\tilde{P}})^T (\Delta\bar{P}_i - \Delta\bar{\bar{P}}_i)}{\left\|\Delta\tilde{P} - \Delta\bar{\tilde{P}}\right\| \left\|\Delta\bar{P}_i - \Delta\bar{\bar{P}}\right\|} \tag{4}$$

Here, all elements of $\Delta\bar{\tilde{P}}$ and $\Delta\bar{\bar{P}}_i$ are the means of all elements of $\Delta\tilde{P}$ and $\Delta\bar{P}_i$, respectively. The superscript *T* denotes the transpose, and $\|\cdot\|$ denotes 2-norm.

5. Estimation method of degree of blockage

After the location of the blockage is identified, the degree is estimated through the following procedure.

(1) Obtain pressure data $\tilde{p}_{B,i^{**}}$ at sensor location i^{**}, which is the closest location to microchannel i^* identified by systems A or B as the blocked location.

(2) Determine $\bar{W}_C^*$, which minimizes the objective function *J* given using Eq.(5).

$$J = \left| \tilde{p}_{B,i^{**}} - \bar{p}_{B,i^{**}}(W_C^*) \right| \tag{5}$$

Here, W_C^* is the width of microchannel i^*. $\bar{p}_{B,i^{**}}$ is the pressure data at sensor location i^{**} calculated using the PBM.

(4) Determine the degree of blockage (*BD*) of microchannel i^* using Eq.(6).

$$BD = \left(1 - \frac{Z_C \cdot \bar{W}_C^* \cdot \bar{u}_{B,i^*}}{Z_C \cdot W_C \cdot \bar{u}_{N,i^*}}\right) \times 100 \ [\%] \tag{6}$$

Here, Z_C and W_C are the original depth and width of each microchannel. $\bar{u}_{B,i^*}$ and $\bar{u}_{N,i^*}$ denote the flow rate in microchannel i^* with and without blockage calculated using the PBM, respectively.

6. Case study

Systems A and B were applied to the blockage diagnosis problems of a microreactor with 10 microchannels. The geometric parameters in Fig. 2 and the operating conditions of the microreactor are summarized in Table 1. The following four types of pressure sensor configurations were implemented as different case studies. In this study, Fluent version 6.1™ (ANSYS Japan) was used to generate validation data for our systems.

Configuration 1: N_S=10, S = {1, 2, 3, 4, 5, 6, 7, 8, 9, 10}
Configuration 2: N_S=5, S = {1, 3, 5, 7, 9}
Configuration 3: N_S=4, S = {1, 4, 7, 10}
Configuration 4: N_S=3, S = {1, 5, 9}

Eighty cases of CFD simulations were executed to obtain pressure distribution data under eight degrees of blockage: 4.8%, 9.1%, 18.5%, 36.4%, 44.8%, 52.9%, 70.8%, and 79.1% in each microchannel. The results of the CFD simulation were used as a training data set to construct a discriminate function of the SVM.

The diagnosis results of system A are summarized in Table 2. The identified number of the blocked microchannel is shown in Table 2 for ten blockage locations, for three

degrees of blockage (8.6%, 27.3%, and 61.4%), and for four sensor configurations. System A perfectly identified the blockage location using only four pressure sensors (Configuration C). Four misdiagnoses, including failure to diagnose, occurred when the degree of blockage was 8.6% and when sensor configuration D was used. These simulation results proved the usefulness of system A.

System B was also applied to the aforementioned blockage diagnosis problem. Table 2 shows that system B identified the blockage location in many cases, but several misdiagnoses occurred. A misdiagnosis tends to occur when the degree of blockage is low and when the pressure sensor interval is high. This is due to a mismatch of the PBM and the model used in the CFD simulation.

Table 3 shows the estimation results of the degree of blockage. The results show that our method can estimate the degree of blockage with less than 2.1% error.

Table 1 Geometric parameters and operation conditions of microreactor

Name	Parameter	Value	Unit	Name	Parameter	Value	Unit
Number of channel	N_C	10	-	Inlet manifold	$W_{I,1}$	5.0	mm
Channel width	W_C	100	μm		$W_{I,Nc}$	1.4	mm
Channel depth	Z_C	100	μm	Outlet manifold	$W_{O,1}$	1.4	mm
Channel length	L_C	20	mm		$W_{O,Nc}$	5.0	mm
Width of fin	W_F	284	μm	Inlet velocity	$v_{I,1}$	0.01	m/s
Viscosity	M	0.1	Pa·s	Outlet pressure	$p_{O,Nc}$	101.3	kPa

7. Conclusion

Two blockage diagnosis systems, A and B, that use pressure sensors were described. Simulation results showed that system A can diagnose the blockage location successfully using only four pressure sensors against ten microchannels, even when the degree of blockage is low. Though system B can also identify the location of blockage in many cases, several misdiagnoses occurred. The diagnosis performance of system B is worse than that of system A, but it will be useful when CFD simulation is not available.

When some experimental data under abnormal operating conditions are obtained, those data can be used as a part of a training data set for constructing a discriminate function of system A. An optimal integration of experimental data and CFD simulation data is a next problem to be discussed.

Our blockage diagnosis system and the estimation method for the degree of blockage are very useful for detecting early blockage and for identifying the blocked microchannels. In this study, we focused on a microreactor with many microchannels, but our methods can very easily be applied to various types of micro-devices when pressure distribution data can be calculated under abnormal operating conditions.

Abstract

PETROBRAS has defined Real Time Optimization (RTO) as a "High Sustainability" technology for downstream operations, due to its high economic return. Since 2001, RTO tools are being tested within the Company, either using in-house process simulators or, sometimes, using available commercial ones. This paper presents an overview of the PETROBRAS experiences on RTO, showing applications on Distillation and Fluidized Catalytic Cracking (FCC) units. Alternatives based on Sequential-modular simulators, along with reduced models (Kriging models and neural nets), as well as Equation-oriented based simulators / optimizers have been explored. The project scopes vary from covering only the Reactor / Regenerator section of a FCC unit up to a whole Crude distillation unit, including the preheat train, all distillation towers and the heat and material integration. Some of these RTO applications have been running close loop for almost 6 months, with proved expressive economical benefits. Based on the knowledge acquired during all these years, some of the future development needs for the improvement of RTO technology will be presented and discussed, as a guide for future research projects.

Keywords: real time optimization, industrial application, sequential modular simulator, equation oriented simulator.

1. Introduction

RTO technology is a powerful tool for the continuous search of the most profitable way to run petroleum and petrochemical process units. Some of the major Oil Companies, as ExxonMobil, Shell and BP to name a few, have specific groups to study it and use it to improve their business [1] [2]. Cutler and Perry [3] state that despite being a hard and complex task, its potential benefits are relevant and might provide profit increases around 6 to 10% when allied to Advanced Process Control (APC).

The task of an RTO application is to make the best of an existing process unit, adjusting its process variables for every new change of external conditions, like operational variables, feed compositions and process constraints. The RTO benefits are usually

associated with the maximization of products and minimization of the specific energy consumption and other resources, depending on the following factors [4] :

- Market availability;
- Safety and environmental constraints
- Products prices and feed costs
- Product specifications

This paper focuses on the use of RTO technologies in the optimization of petroleum downstream process units. The next section provides an overview of the structure and mechanism of RTO systems. Section 3 describes PETROBRAS experience on the development and use of in-house and commercial RTO solutions. On section 4 this paper is concluded with the discussion of the key aspects to the achievement of successful implementations.

2. RTO structure, mechanism and characteristics

Though many implementation structures are possible, RTO has been usually used as a connection between the tasks of production planning & scheduling and process control [4] [7] [8] for petroleum and petrochemical applications. The central figure of an optimization application is the mathematical model. It is expected to represent the process behavior on a wide range of operating conditions with good accuracy. It is required not only to guarantee that the predicted potential profitability matches that of the real process, but also because when the optimal solution is implemented the process constraints must not be violated. Most RTO systems used nowadays are based on rigorous, steady-state, first principles mathematical models.

The good performance of an RTO system depends on a reliable mathematical model and on reliable input data. In order to obtain that, many procedures must be executed before the economic optimization problem can be solved [4] [6] [8]:

a) Gross Error Detection
b) Steady-state Detection
c) Data Reconciliation
d) Parameter estimation.

Once that a reconciled data set and a fitted model have been obtained, the process optimization can be performed. The optimization problem usually consists of maximizing the operational profit (or minimizing costs) subject to a set of constraints. On most situations the optimization problem is posed as a non-linear programming (NLP). Most commercial applications are based on variations of the SQP (Successive Quadratic Programming) algorithm. This algorithm is also used to solve the previous Data Reconciliation and Parameter Estimation problems.

3. Real Time Optimization within PETROBRAS

Since 2004, RTO has been classified by PETROBRAS and its Strategic Downstream Committee as a “High Sustainable” technology. It means that RTO is seen as a key technology to improve PETROBRAS performance and profit, and therefore significant effort and resources will be spent on this subject. PETROBRAS implementations on RTO covered a wide range of alternatives, focusing both on profitability and on the search of the best way to deliver the technology:

- Fluid Catalytic Cracking (FCC) and Crude Distillation Units (CDU)
- proprietary and commercial process models and RTO systems
- Sequential Modular (SM) and Equation Oriented (EO) approaches [6]

3.1. First experiences

The first RTO initiatives were taken using PETROBRAS' in-house process simulator for FCC, with a small scope covering only the reactor/regenerator section. The

proprietary process model used is based on a Sequential Modular (SM) approach, many difficulties were found (see next section). Nevertheless, we were able to test the technology as well as our engineers to take a step further.

3.2. Distillation Unit / SM approach (2004)

This implementation took place at the Crude Distillation Unit (CDU) and the two Solvents Units of RECAP refinery [6].

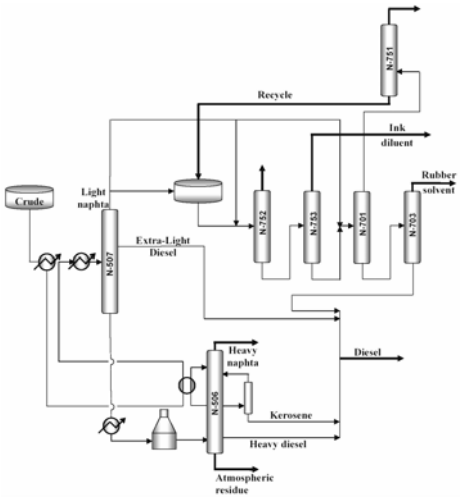

Figure 1 - Scheme of the CDU and the Solvents Units of RECAP/PETROBRAS.

The process model was built using PETROX, a proprietary sequential-modular process simulator from PETROBRAS. The simulation comprises 53 components and pseudo-components and 64 unit operation modules, including the 7 distillation columns and a recycle stream. All modules are built with rigorous, first-principles models.

For optimization applications, PETROX was linked to NPSOL, an SQP optimization algorithm. Procedures for Steady-state and Gross error detection, Data Reconciliation, Parameter Estimation and Economic Optimization were implemented. The economic optimization problem consisted of the maximization of the operational profit, constrained by limits related to product specifications, safety constraints, feed rate and performance parameters. The whole optimization problem involves 19 decision variables and 21 constraints.

Most of the reported problems of optimization based on sequential-modular models were observed in this application:

- Low computational efficiency, due to slow recycle loops and the numerical derivatives, that imply running the SM model several times. These derivatives are also inaccurate, which slows down the optimization process even more.
- Lack of reliability. The SM model is computed many times, and must converge always. If a single failure happens during the optimization, all the effort is lost.

In order to minimize these problems, a lot of effort must be spent on the conception, customization and tuning of the SM model. However, that is no guarantee of success. When the Data Reconciliation and Parameter Estimation problems were implemented, the same problems were observed.

3.2.1. Metamodel approach

In order to overcome some of these shortcomings, a metamodel approach has been studied. Metamodels or surrogate models [5] [6] are reduced models whose parameters are obtained with data that is generated with rigorous, first principles models. In this work, an optimization procedure was developed, combining metamodels and rigorous models with a Sequential approximate optimization (SAO) algorithm. The optimization problem is solved based on the metamodel, that is updated with data obtained from the rigorous model throughout the optimization procedure. The RECAP optimization problem was addressed with this approach, with kriging models and neural nets used as metamodels. Accurate results have been obtained with considerable reduction of the computational effort on most of the studied cases.

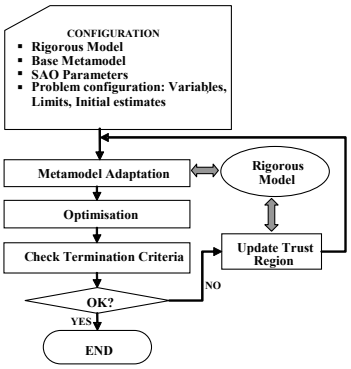

Figure 2 - SAO strategy applied to the metamodel-based optimisation.

3.3. Distillation Unit / EO (2005 to 2006)

This was the first EO RTO project PETROBRAS implemented. After an International Bid, where 3 well-known companies were invited to submit their proposals, we've decided to contract AspenTech and its AspenPlus Optimizer. The project scope included all 3 preheat trains as well as Pre-flash, Naphtha Stabilizer, Atmospheric, Vacuum and Pre-vacuum distillations towers. The unit was fully energy and mass integrated modeled on the RTO software, which allowed us to study the implications that changes on the preheat train, like feed distribution, has on the Atmospheric tower, for instance. Or to study the best pumparound heat removal distribution along this tower and its effects on the preheat train. In order to do that, all pumparounds were modeled as external streams from the tower and not as an internal model within its model (see Figure 3), as it is common on SM simulators.

The system is running on open loop since 2007. PETROBRAS intends to close loop this year after making model tuning adjustments in order to incorporate the new atmospheric trays and other unit improvements. Nevertheless, by keeping the system running open loop (around 9 runs / day), we were able to improve our knowledge of the system itself, how to overcome non convergence problems and gain expertise on how to maintain such a real time, strong data and instrumentation dependent system as well as evaluate potential benefits (around 13 000,00 dollars / day).

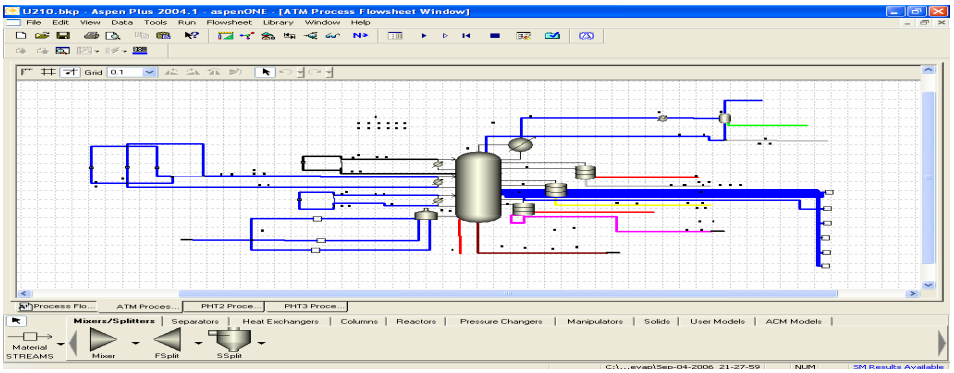

Figure 3 - Aspen Plus Optimizer Screenshot - Atmospheric tower

3.4. FCC Unit / EO (2007 to 2008)

Following the success on the distillation unit, PETROBRAS moved forward to implement an RTO on another very important unit. Again, after an international bid where the same 3 well known companies were invited to be on, we've decided to use Invensys and its ROMeo, as part of our intend to test all the available technology. The project scope included the Reactor / Regenerator section, Main Fractionator and Gas Recovery Plant. Again the unit was fully energy and mass integrated modeled.

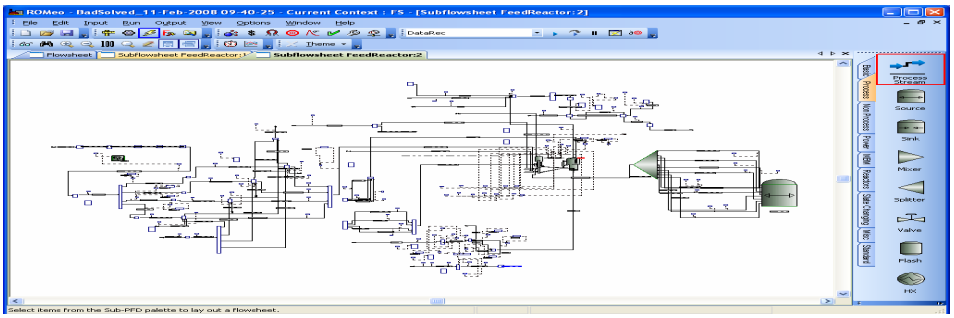

Figure 4 - ROMeo screenshot - Reactor/Regenerator Section.

The system is running on closed loop (around 8 runs / day) since June/08 with most of the independent variables active. On average, around 60% of the successful runs are being accepted by Operations and targets are being sent to Advanced Control. PETROBRAS has evaluated an average gain of US$ 0.12 / bbl of FCC feed for this application, by comparing the unit performance with and without RTO.

A few comments on both projects:

- **Lack of instrumentation on preheat train (FCC)** – implied on simplifications, which has impacts on Main Fractionator heat balance and, thus, must be evaluated from time to time
- **Low feed lab analysis frequency** – There is a need for a better way to estimate feed characterization
- **Non-convergence problems** - Mainly, due to instrumentation faulty and/or out of service heat exchanger or other piece of equipment. Although there is a kind

of standard procedure to deal with them, it is not possible to automate it. So each problem must be solved on a case to case, hands-on basis.

These facts enforce the need for a fully dedicated RTO engineer for each application, not only to assess its results and make sure they are being implemented, but to keep the system running despite of the many daily issues the application faces.

4. Conclusions

4.1. Successful implementations

A key aspect to a successful RTO application, is the good integration among different corporate teams, like Process analysis, Production and Planning Program, Optimization and Automation, IT, Instrumentation, Laboratory, Production. A long-term plan must also be done to assure that the acquired benefits are kept and expanded, with APC and RTO experts dedicated to the on-line applications after their implementations. The process model must be updated throughout the process unit life cycle. The problem constraints and the optimization results must be continuously evaluated. The advanced and regulatory control systems are the ways by which the RTO optimal solutions are implemented. Therefore, they are essential to a successful RTO as well.

4.2. Modeling approach

PETROBRAS experiences showed that the Open-equation approach is more suitable for RTO, when compared to the Sequential-modular process models, specially when process unities of higher complexity are addressed.

4.3. Future Developments

PETROBRAS automation staff is now working to apply RTO technologies to other process technologies. Another ongoing initiative is the simultaneous application of RTO to more than one process unit.

Embedded Control for Optimizing Flexible Dynamic Process Performance

Jeonghwa Moon, Seonbyeong Kim, Gerardo Ruiz and Andreas A. Linninger

Laboratory for Product and Process Design, Department of Chemical Engineering, University of Illinois at Chicago. Chicago, IL 60607, USA.

Abstract

High performance processes require design that operates close to design boundaries and specifications while still guaranteeing robust performance without design constraint violations. In order to safely approach tighter boundaries of process performance, much attention has been devoted to integrating design and control in which dynamic controllability as well the design decisions are taken simultaneously. However rigorous methods solving design and control simultaneously lead to challenging mathematical formulations which easily become intractable numerically and computationally. This paper introduces a new mathematical formulation to reduce this combinatorial complexity of integrating design and control. We will show substantial reduction in the problem size can be achieved by embedded control decisions within specific designs. This embedded control decisions avoid combinatorial explosion of control configuration by using a full state space model that does not require pairing of control variables and loops. The current capabilities of the methodology will be demonstrated using a realistic reactor-column flowsheet.

Keywords: Design and control integration, process and operational uncertainty, design and analysis of dynamic flexibility.

1. Introduction

The aim of integration of process design and control is finding best design decision considering economics and dynamic controllability simultaneously. During the last 30 years, several methodologies have been developed for the integration of design and control (Vassilis et al., 2004; Ramirez & Gani, 2007; Seferlis P., & Georgiadis M.C., 2004). In spite of their progress in integration of design and control field, the available methodologies still offer insufficient insight to the problems. Recently, we proposed a new method, *embedded control optimization approach* (Malcolm et al, 2007). This integrated design method can operate satisfactorily under adverse input conditions, while delivering products within desired quality specifications. In this paper, this embedded control optimization methodology is reviewed and enhanced to incorporate full state space estimator for better the dynamic process performance. A case study of designing reactor-column flowsheet is considered as a more realistic example for this methodology. In this case study, we will illustrate the ability of performing design and control integration with rigorous mathematical techniques.

2. Methodology

2.1. Problem decomposition

The conceptual problem of the integration of process design and control is a stochastic infinite dimensional mixed integer dynamic optimization problem which is extremely challenging for existing mathematical programming techniques. To overcome intractability of original problem, Pistikopoulos and co-workers proposed problem decomposition algorithms (Mohideen et al., 1996). In their problem decomposition, the main design optimization problem is solved in discretized sampling space; rigorous flexibility tests in a second stage ensure the dynamic feasibility over the entire uncertain space. If current candidate designs are not feasible in critical scenarios, these critical scenarios incorporate into the sampling space and main problem is solved again with additional augmented scenario. The final optimal designs can be achieved by repeating this iterative process. This framework is also used in our algorithm.

2.2. Embedded control optimization

Even though, the problem decomposition substantially reduces the problem size, it still remains a challenge due to combinatorial complexity of the non polynomial hard search space. Specifically, introduction of control decisions such as the insertion of feedback loops, or pairing of manipulated and control variables causes combinatorial explosion in the possible integrated design and control realizations. We therefore propose to separate the design decisions from the control decisions as shown Figure 1. At the master level, we fix design decisions such as reactor sizes, and residence time that govern dynamic process performance. No control decisions are made at this level. Once the main design decisions are specified, we assess the dynamic performance of process by using a simplified, yet reasonably competitive control schemes based on full state space identification and least square regulation. Optimal control action is calculated with relative ease based on linear state space models which are obtained dynamically in each time step. In order to keep the model consistent with the nonlinear process dynamics, the process identification is repeated in each time step. The detailed description is found elsewhere (Malcolm et al., 2007).

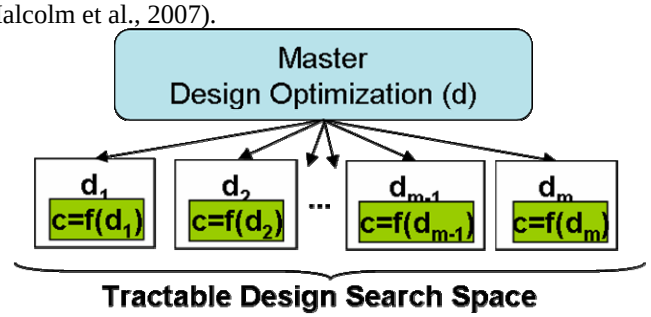

Figure 1 Proposed embedded control optimization structure. It optimizes control choice with given design.

3. Flexible design of reactor column

This section demonstrates the effectiveness of embedded control optimization by designing a reactor-column flowsheet process with uncertain reaction coefficients. This is similar to processes introduced and studied by Luyben (2007). The aim of this case study is to determine optimal design specifications with reasonable control for

dynamically flexible operations. This task of design and control integration should be done simultaneously with reasonable computational effort.

3.1.1. Process description.

This flowsheet has one reaction and one distillative separation column, as shown in ***Figure 2***. The precursor *A* enters the reactor to be converted into the product *B* with an exothermic irreversible first order reaction.

$$A \xrightarrow{k_0} B \qquad \textbf{(1)}$$

The reaction cannot be driven to full conversion, because this operation would require too high temperature causing the product *B* to be destroyed. In addition, this high temperature might violate safety constraints and lead to reactor explosion. To control temperature in reactor, it is equipped with a cooling jacket. Its effluent *F* is directed to the continuous distillation column in order to separate the product *B* from unreacted raw material *A*.

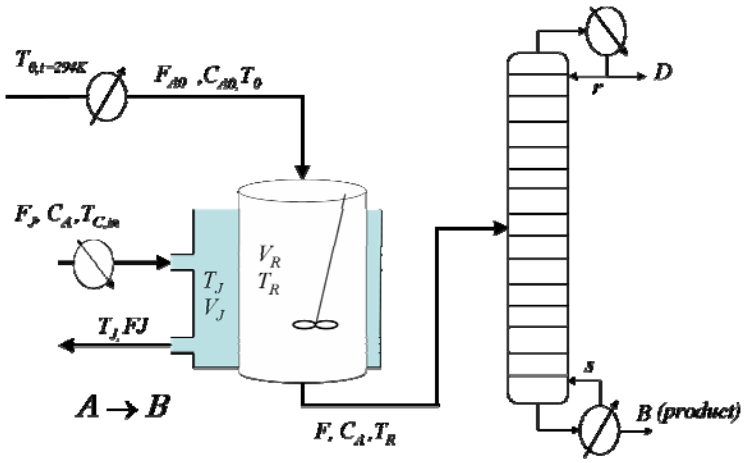

Figure 2 Reactor-column flowsheet. This is composed of a reactor and a column. The reactor is surrounded by a cool jacket.

3.1.2. Design & manipulated variables.

Reactor diameter (D_R) and length (L_R), and heat transfer area (A_J) are treated as design variables. Also the number of stages (*Ns*), feed stage, and column diameter (N_f) are design variables of the column,. For manipulated variables, we select input feed temperature (T_0), coolant temperature (T_J), reflux ratio (*r*), and reboil ratio (*s*). The values of the design variables and manipulated variables need to be determined to insure safe operation within desired quality standards, under any operating conditions and in the presence of uncertain reaction conditions.

3.1.3. Operational constraints.

For safe operation, this process needs to satisfy three constraints at all times.

For the safety, reactor temperature (T_R) should never exceed 385K,

$$T_R < 385 \qquad \textbf{(2)}$$

For the product quality, we enforce the mole fraction of component *A* (x_A) of final product B should be less than 0.05.

$$x_A < 0.05 \quad \textbf{(3)}$$

For minimum process productivity, the conversion ratio (χ) should be greater than 0.7.

$$\chi > 0.7, \quad \chi = 1 - \frac{C_A}{C_{A0}} \quad \textbf{(4)}$$

Thus, control variables are T_R, x_A, and χ. Among these constraints, the safety constraint needs to be enforced dynamically for all time periods of possible scenarios, as opposed to merely the steady state which is the sole concern in classical flexibility analysis. A certain design specification does not satisfy safety constraint in dynamic state, even though it does not have any violations in steady state. Therefore, we need to consider the dynamic flexibility for the optimal dynamic process performance. Productivity and quality constraints are soft constraints, which lead to performance losses that cost money, but need not to be enforced rigorously for all time intervals.

3.1.4. Uncertainty scenarios.

We wish to investigate the impact of two main uncertain parameters, associated with chemical reactions. The first parameter is preexponental factor k_0, and the second is heat of reaction λ. Their nominal values and variance are illustrated in **Table 1**.

Table 1 Nominal values and expected deviation of uncertain parameters

	θ^N	$\Delta\theta^+$	$\Delta\theta^-$	var
k_0	20.75e6	2.07e6	2.07e6	10%
λ	-17.43e3	-1.74e3	-1.74e3	10%

As a first attempt to perform the stochastic optimization, we chose 10 samples in the uncertain space of reaction conditions using Latin hypercube method, and evaluated the probabilities of each parameter set to calculate expected cost.

We now wish to rigorously determine the design and manipulated variables in the manner that, with every realization of the reaction conditions and all variability in the dynamic performance by uncertainty, the process does not violate the constraints and produces product *B* in desired purity limit.

3.2. Identification test

In order to employ the embedded control optimization, our methodology dynamically performs of adaptive state space identification. This repeated identification is to convert highly nonlinear process model into a simple linear state representation in open loop. With this simplified linear model, the linear regulator can find optimal control moves. The performance of process in response to step change in feed rate as well as the impact of sinusoidal disturbance is show in **Figure 3**. We have now identification phase which is occurring until time step of 40,000. In each step, there is a little change because the process is operated with approximately constant conditions, only in sinusoidal disturbances slightly impacts processes. However, a big impact occurs at t=40,000, in which the flow rate is suddenly increased to double. Now dynamics of whole process is changed and we need to adjust to new state space. This is done very satisfactorily, as shown **Figure 3**. The blue lines represent nonlinear data from mathematical model; red lines represent predicted data by identifier. Even though model is linear, because it is updated in every time step, it can maintain reasonable predictability even in a transition phase.

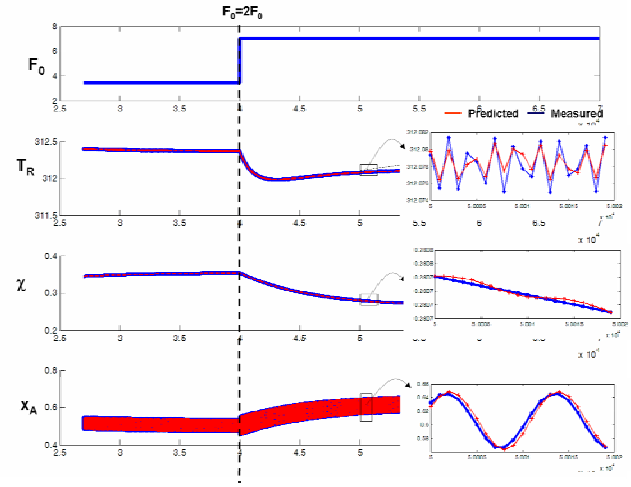

Figure *3* Performance test of identifier. This figure shows sequential least identification method predicts dynamic system behavior well, even in dynamic transition phase.

3.3. Control performance of there different designs

Next, we tested controllability of several designs under specific disturbance scenarios. Dynamic controllability of three reactors with different volumes of 12, 23, 143m^3 were investigated in response to dramatic increase of the feed rate. The doubling feed occurs at t=40,000.

Case 1: Small reactor, V_R=12m^3. When doubling the input feed, this small reactor is loosing the controllability- the control is not capable of handling this upset to process conditions as shown in **Figure 4**. The reactor temperature drops and reaction conversion declines, and product quality is violated.

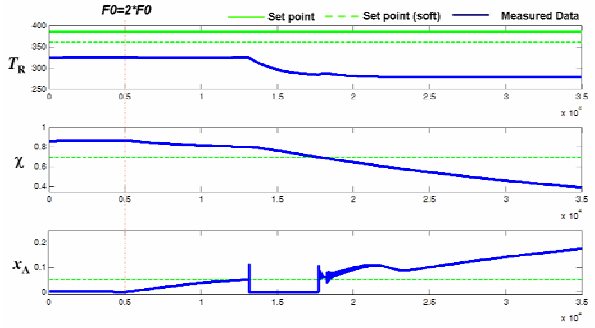

Figure *4* Control performance with VR=12m^3. It fails to keep the values of two control variables (χ, x_A) under the set points.

Case 2: Middle reactor, V_R=23m^3. We tested controllability of a middle size reactor. With this design specification, the controller rejected the disturbance well. The quality constraint was violated briefly in the instance of the disturbance inception, but the controller quickly removed this quality issue and kept values of all process variables under the set points. This design handles disturbance very well with simple control scheme.

Case 3: Large reactor, V_R=143m^3. Finally we tested larger reactor size. Our model demonstrated that the feed flow disturbances do not affect the process dynamics much in this over-dimensioned design. So the large reactor is very robust against the disturbance, but it is not competitive because of cost. It turned out that middle reactor generated more profit than the large reactor. Moreover, large reactors exhibit sluggish response and slow servo performance when set points are changed to adjust to different product specifications. This example supports the notion that arbitrary overdesign of equipment is not a solution to ensuring dynamic process flexibility of high performance processes.

3.4. Optimal integrated design with control

The previous analysis of different design demonstrated the trade off between controllability and servo performance. When considering also costs and profits what would be the best integrated design and control? For maximizing the performance, while at the same time planning flexible operation, we performed the design optimization under uncertainty as follows. For capital configuration, we consider the reactor, the column and the heat exchangers. Also we consider energy consumption for input feed temperature, cooling temperature, the reboiler and condenser, as operating cost. Also, we consider product prices to calculate total annual profit. The master level of this problem is to maximize total profit. To solve optimal design problem, Nelder-Mead simplex method is used in master level of our methodology. We found the best optimal design after 34 iterations.

4. Conclusions & future work

This paper describes conceptual framework for integrating of design and control developed by our group. Our methodology is to recast integrated design and control problem into solvable mathematical programming formulation. The case study described to show suitability of our methodology. In future, more challenging flowsheets will be examined. Also we wish to improve the quality of identification for highly nonlinear processes using more advanced identification such as subspace identification method or nonlinear model predictive control. However these advanced algorithms are more expensive, the trade off between accuracy and performance of algorithms need to be considered.

Abstract

This paper summarizes the results of a comparison including three different fault detection and isolation (FDI) methods for dynamic systems. The techniques studied have recently been proposed in the literature and are Dynamic Principal Component Analysis (DPCA), Canonical Variate Analysis (CVA) and Subspace Model Identification (SMI). The aim of this study is to contrast the performance of each method in detecting and isolating incipient fault conditions. Utilizing real data from a debutaniser distillation tower, this study yields that the observer approach based on an identified SMI model is most sensitive for fault detection but performs poorly in isolating the fault condition. This method failed to correctly diagnose the fault condition using fault isolation approach. In contrast, DPCA offered a correct picture of this event using variable reconstruction and contribution charts, whilst CVA only yielded satisfactory results using variable reconstruction. For this study, it is therefore concluded that both approaches have complementary strengths and weaknesses.

Keywords: Subspace Methods, Fault Detection and Isolation, Chemical Process

1. Introduction

Based on the ever growing requirement for safe and reliably operating processes in the chemical industry, fault detection and isolation has received considerable attention over the past decades. The research literature has shown two main approaches: (i) data driven multivariate statistical techniques (Chiang *et al.*, 2001; MacGregor *et al.*, 2005) and the use of model-based state-space systems (Isermann, 2005). These approaches yielded similar fault detection and isolation methods. Given the large number of variables that are typically recorded in complex chemical, the use of mechanistic first principal models is difficult in practice, which has led to significant research activities on data-driven methods.

The aim of this article is to investigate the potential of utilizing model-based methods based on the observer design for fault detection and isolation. The required model is provided by subspace model identification, a data driven methodology that has been extensively studied over the past decade (Verhaegen, 1994; Van Overschee and De Moor, 1996). This data-driven and model-based methodology is contrasted with competitive multivariate methods for dynamic systems. Chiang *et al.* (2001) summarized that DPCA and CVA are such methods that identify a dynamic monitoring model in a reduced dimensional latent variable space.

For DPCA and CVA, process monitoring is based on the use of univariate statistics and fault isolation relies on variable reconstruction (Qin and Li, 2001) and contribution charts (Miller *et al.*, 1998). In a similar fashion to the univariate fault detection indices of DPCA and CVA, the paper proposes the use of the T^2 and SPE statistics on the basis of the estimated states and the output estimation error, respectively, for the model-based approach.

To examine the utility of the model- and observer-based approach with DPCA and CVA, the article summarizes the results of an industrial process. The objective of this study is to contrast the performance of each method in detecting fault conditions and in diagnosing the recorded event.

2. Fault Detection and Isolation Methods

This section briefly reviews DPCA, CVA and the proposed model- and observer-based approaches for FDI.

2.1. Dynamic Principal Component Analysis (DPCA)

DPCA (Chiang *et al.*, 2001) relies on a time series arrangement of a set of recorded process variables. An eigendecomposition of the covariance matrix of this augmented variable set forms then the basis for constructing a model plane and a complementary residual subspace. The retained components of this eigendecomposition relate to the most dominant eigenvalues of this decomposition and span the model plane. The residual subspace is consequently spanned by the discarded eigenvectors. Geometrically, the orthogonal projection of the augmented data vector, z, onto the model plane and the residual subspace is $\hat{z} = PP^T z$ and $\tilde{z} = (I - PP^T)z$, respectively, such that the following equality holds $z = \hat{z} + \tilde{z}$.

2.2. Canonical Variate Analysis (CVA)

Similar to DPCA, CVA performs FDI in a model plane and a residual subspace defining state sequences, x, (Chiang *et al.*, 2001). CVA relies on augmented vectors that include time lagged values of the process input and output variables. More precisely, the lagged terms are time-series arrangements of the output variables that relate to future, f, and past measurements and an arrangement of the input variables for past measurements. The state sequences are the first *d* dominant canonical variates, $\hat{x} = J_d p = U_d^T \Sigma_{pp}^{-1/2} p$, where U_d is a matrix storing the first *d* columns of U, $\Sigma_{pp}^{-1/2} \Sigma_{pf} \Sigma_{ff}^{-1/2} = U \Sigma V^T$. Moreover, p is a vector storing the past time-series arrangements of the input and output variables and the different Σ are covariance and cross-covariance matrices. The residual vector of the state-space model in term of the past is given by the *r* remaining state variables, $\tilde{x} = J_r p$.

2.3. Subspace Model Identification (SMI)

The state space model that the observer-based FDI scheme requires is provided by an SMI technique. Based on the numerically stable and efficient QR and SVD decompositions, the MOESP algorithm (Verhaegen, 1994) has gained attention. In addition, Chen (1999) reported that the subspace identification offers various practical advantages, mainly for industrial process systems, over the classical realization from input/output identified models (Chen, 1999). This algorithm relies on future and past arrangements of the input and output variables to form a total of four block Hankel matrices, where the samples are stored row wise. These matrices are then stacked prior

to the application of a QR decomposition. Together with a subsequent SVD decomposition, the quadruple of state space matrices, A, B, C and D can be extracted from the R-matrix of the QR decomposition and the left singular vectors of the SVD decomposition.

2.4. Observer Designs

The observer-based approach for FDI traditionally uses process variables to estimate output variables through a state-space model in a closed-loop design. The provided output estimation error can then be monitored as residuals (Patton and Chen, 1997). As the design of such observers may offer degrees of freedom, many approaches have been proposed to tackle uncertainties and disturbances issues. This paper uses the traditional Luenberger state observer designed by pole placement.

2.5. Univariate Statistical Fault Detection Indices

For fault detection, two traditional univariate statistics are employed for multivariate statistical process monitoring, the Hotelling's T^2 statistic:

$$T^2 = t^T \Lambda^{-1} t \tag{1}$$

which follows an F-distribution and a squared prediction error:

$$SPE = r^T r \tag{2}$$

for which approximate distributions have been proposed in Box (1954). In Equation 1, t denotes an uncorrelated mean-centered variable set and Λ, its covariance matrix.

Table 1 shows the definition of these statistics for each method.

Table 1 – Fault Detection Indices

Technique	**Principal Subspace**	**Residual Subspace**
Based on DPCA	$t^T \Lambda^{-1} t$	$\tilde{z}^T \tilde{z}$
Based on CVA	$\hat{x}^T \Lambda^{-1} \hat{x}$	$\tilde{x}^T \tilde{x}$
Based on observer	$\hat{x}^T \Lambda^{-1} \hat{x}$	$e^T e$

The work in reference Nomikos and MacGregor (1995) allows the determination of confidence limits for each of these statistics with a significance of 0.01 for example.

2.6. Fault Isolation Indices

This task relates to the determination of which process variables are mostly affected by a detected fault condition. The research literature has proposed two different concepts: (i) the use of contribution chart (Kourti and MacGregor, 1996) and (ii) variable reconstruction (Dunia and Qin, 1998). These methods are readily applicable for DPCA (Qin and Li, 2001) and CVA (Lee *et al.*, 2006). The observer-based method relies on the use of generalized observers, as discussed in Isermann (2005). More precisely, each output variable is reconstructed in turn by eliminating the associated column from the observer setting and using the remaining output variables. Table 2 summarizes the isolation indices for each method in which *a* implies "affected", *i*

denotes the *i*th process variable and * represents a vector reconstructed by excluding the *i*th process variable.

Table 2 Isolation Indices

	Variable Contribution		**Variable Reconstruction**
Technique	*Principal Subspace*	*Residual Subspace*	*Residual Subspace*
Based on DPCA	$t_a\lambda_a^{-1}p_{a,i}z_i$	$\tilde{z}_i^T\tilde{z}_i$	$\frac{\tilde{z}_i^{*T}\tilde{z}_i^*}{\tilde{z}^T\tilde{z}}$
Based on CVA	$\hat{x}_a j_{a,i} z_i$	$\tilde{x}_a j_{a,i} z_i$	$\frac{\tilde{x}_i^{*T}\tilde{x}_i^*}{\tilde{x}^T\tilde{x}}$
Based on observer	-	$e_i^T e_i$	$\frac{e_i^{*T}e_i^*}{e^Te}$

3. Industrial Application Example

This section presents a debutaniser process used to contrast the performance of each method in detecting and isolating a fault condition. The process is designed to purify a mixture of hydrocarbons into butane from a fresh feed which is product of a depropaniser distillation. Therefore, the fresh feed is not steady and can interfere in the top and bottom temperatures by an incipient change. The recorded fault data set contains a small drop in the fresh feed followed by a larger one, which some minutes later affects all the temperatures of the process. In such undesired conditions, the concentration of the head-product is altered, increasing the concentration of pentane. In order to manage the quality of this process, it is required a dynamic model and a fast FDI method.

The industrial data were recorded at a sampling interval of 30 seconds, including 8000 samples describing normal operation conditions for the training data set and 4744 samples containing the fault condition for the testing data set. The input variables are: the reflux flow (u_1), fresh feed flow (u_2) and fresh feed temperature (u_3); and the output variables are: mid-tray temperature (y_1), top-tray temperature (y_2), butane product flow (y_3), bottom-tray temperature (y_4) and inlet temperature (y_5).

4. FDI Results using DPCA, CVA and Observer-Design

This section summarizes the application of the presented fault detection and isolation methods to the recorded data sets. The subspace methods, CVA and MOESP, relied on 2 block rows, whilst for the DPCA, Parallel Analysis showed that the number of principal components does not change with the number of lag variables from 5 lag variables on. Table 3 gives the number of selected components for each method, where for CVA and MOESP it was selected according to the Scree test (Chiang et al., 2001). The observer design was based on the selection of poles inside the unit circle.

For fault detection, three parameters were used to assess the performance of each method: type I error (false alarm rate), type II error (misdetection rate) and the detection delay. Table 3 also summarizes the fault detection results and indicates that the observer-based approach outperformed the statistical-based ones in the last two parameters. Ideally, the methods should have values around 1% for the type I error due to the confidence limit chosen. Such result can be explained due to the fact that the observer-based approach has a well-defined dynamic structure, which guarantee quick and accurate responds compared to CVA-based approach. Regarding to DPCA-based

approach, which dynamic structure is based on an ARX model, the detection delay was significant once the influence of the lag variables (fault-free) in the moment of the fault can be high.

Table 3 - Fault Detection Results

			Type I Error (%)		**Type II Error (%)**		**Detection Delay (min)**	
Method	*l*	*n*	T^2	*SPE*	T^2	*SPE*	T^2	*SPE*
DPCA	5	7	0.7	1.3	20.7	24.8	57	51.5
CVA	1	5	0.4	2.3	27.4	22.4	84.5	50.5
OBS	1	5	0	0.1	5.4	14.4	27	34

Next, the performance of each method for fault isolation was contrasted. Table 4 summarizes the results of each method using contribution charts and Table 5, using variable reconstruction approach. Letters *a* and *b* in Tables 4 and 5 stands for the first and the second fault detection indices, respectively.

The fault isolation step via contribution charts showed divergent results among the methods. DPCA-based approach presented the best description of the fault since the residuals were able to detect the minimal increasing in the fresh feed, and the T^2 contributions could reveal the most affected variable. From this result, the root cause of the fault can be clearly identified and the fault diagnosis can be correctly performed as a trouble in the feed stream. CVA-based approach had similar result compared to DPCA only for the model subspace. However, the "faulty" variable (u_2) was missed in such way that impaired the correct fault diagnosis. Finally, the observer-based approach was unable to make a reasonable description of the fault since the proposed fault detection index for the state variables (OBSa) does not allow a kind of contribution and the residuals are restrictive only to the output variables.

Table 4 - Fault Isolation Results Via Variable Contribution

	Variable Contribution							
Methods	u_1	u_2	u_3	y_1	y_2	y_3	y_4	y_5
DPCAa	40.3	3.8	46.2	**734.2**	64.4	34.2	6.1	43.8
DPCAb	16.3	**66.6**	1.5	20.5	1.1	17.5	0.3	2.3
CVAa	0.9	1	4.9	**49.8**	0.5	2.3	21.8	8.4
CVAb	3.7	2.8	4.3	54.7	**157.1**	2.7	37.4	27.9
OBSa	-	-	-	-	-	-	-	-
OBSb	-	-	-	1576	576	263	359	**4626**

The variable reconstruction approach also had good results compared to the contribution charts, concerning the statistical methods. On the other hand, the bank of generalized observers did not show any improvement. Although this approach can make an analysis of the input variables as well as the output variables, the results of these industrial data sets showed that it does not work well. The observers designed for the input variables monitoring were able to predict correctly the output variables so that the influence from the input variables was not significant and the fault isolation turned out to be impractical.

Table 5 - Fault Isolation Results Via Variable Reconstruction

	Variable Reconstruction							
Methods	u_1	u_2	u_3	y_1	y_2	y_3	y_4	y_5
DPCAb	0.89	**0.52**	0.96	0.87	0.98	0.84	1.00	0.94
CVAb	44.80	**32.98**	45.05	36.13	42.71	44.75	34.31	42.48
OBSb	0.000	0.000	0.000	0.019	**0.005**	0.009	0.009	0.010

5. Conclusions

This paper studied the performance of the most traditional fault detection and isolation methods in a chemical process. In order to make a reasonable comparison, univariate statistics for the state variables and the output estimation errors of the observer-based approach were proposed. Results from a real process data showed a very accurate detectability in the case of the observer-based method. The dynamic structure of such method can be handled by pole placement allowing different types of respond. For the fault isolation step, only statistical-based methods were able to make a good description of the fault. Therefore, none of the methods showed a significant advantage in both fault detection and isolation steps simultaneously. A hybrid approach unifying the strengths of such methods will be the focus of future works.

Abstract

The full potential of a novel continuous reactor is addressed via the relationship between process design, the ability in handling the constraints and the optimisation framework. A Model Predictive Controller is developed to maximise the yield under hard input and state constraints. Simulations show that the designed control system gives high reaction yield and ensures that the temperatures inside the reactor are within a predefined limit. The challenges of an efficient start-up phase and the transition to the optimal operating point are also investigated by means of an event-driven approach.
Keywords: Process Intensification, process control, MPC, HEX reactor start-up

1. Introduction

The synthesis of fine chemicals and pharmaceuticals are generally carried out in a batch or semi-batch processes due to flexibility and versatility of the equipment over the continuous counterpart [Roberge *et al.*; 2005]. However, poor transfer of heat generated from reactions limits the application of batch equipment to products of low volumes and short life-times.

A new concept of small-scale continuous reactor, the Variable Channel Reactor (VCR) is being developed by AM Technology. The VCR is well incumbent under the umbrella of process intensification, as it simultaneously tolerates high reactant concentrations whilst minimising solvent usage. It is evident that reaching the optimal operating point when starting from a cold, empty reactor is a non-trivial matter.

Here we propose a control and event-driven start-up strategy with the objective of optimising the reactant conversion with constraints on both control and state variables.

2. The Variable Channel Reactor

The VCR is a modular construction of reactor plates. Through initial process design, inherent control of the temperature profile is achieved by altering the geometry of the channel along the process fluid flow path, as seen in Figure 1. The reaction power is thus controlled by varying the volume to heat transfer area. In this paper, a simple second order exothermic reaction is considered where C is the product of interest.

$$A + B \longrightarrow C + \text{heat}$$

The VCR assembled as multiple consecutive channels may, from a modelling point of view, be approximated as a 1-D continuous tubular reactor with injections of reactant B along the reactor with cooling jackets around the tube. Initial experiments indicate perfect mixing conditions after a few channels, implying that the Arrhenius law can be used for modelling the reaction kinetics. From first principles, partial differential equations (PDEs) of the distributed system are discretised into elements which characterise the states of reactor temperature T and concentration C of components i.

The spatial derivatives are approximated with a first order backward finite difference method (BFDM) to a system of ordinary differential equations (ODEs);

Material balance: $$\frac{\partial C_i}{\partial t} = -\bar{v} \cdot \frac{1}{L} \cdot \frac{\partial C_i}{\partial z} + D \cdot \frac{1}{L^2} \cdot \frac{\partial^2 C_i}{\partial z^2} + \sum_{j=1}^{\text{NoReac}} \left(v_{i,j} \cdot r_j \right) \qquad i=1,\ldots, \text{NoComp}$$

Energy balance: $$\bar{\rho} \cdot \bar{C}_P \cdot \frac{\partial T}{\partial t} = -\bar{\rho} \cdot \bar{C}_P \cdot \bar{v} \cdot \frac{1}{L} \cdot \frac{\partial T}{\partial z} + k \cdot \frac{1}{L^2} \cdot \frac{\partial^2 T}{\partial z^2} + Q - Q_{rxn}$$

where, $$Q = \frac{S}{H} \cdot U \cdot (T_{wall} - T) \; ; \qquad Q_{rxn} = \sum_{j=1}^{\text{NoReac}} (\Delta H \cdot r)$$

Reaction rate: $$r_j = A_j \cdot \exp^{\left(-E_a / R \cdot T\right)} \cdot \prod_{i=1}^{\text{NoComp}} C_i^{a_{i,j}} \qquad j = 1,\ldots, \text{NoReac}$$

The terms Q and Q_{rxn} refer to the heat removal rate of the reactor element and the heat generation rate from the reaction respectively. The assumption of constant wall temperatures, T_{wall}, considers the VCR as 'defacto' isothermal. It is worth noting that the derived model is highly nonlinear due to temperature influence on the reaction rate.

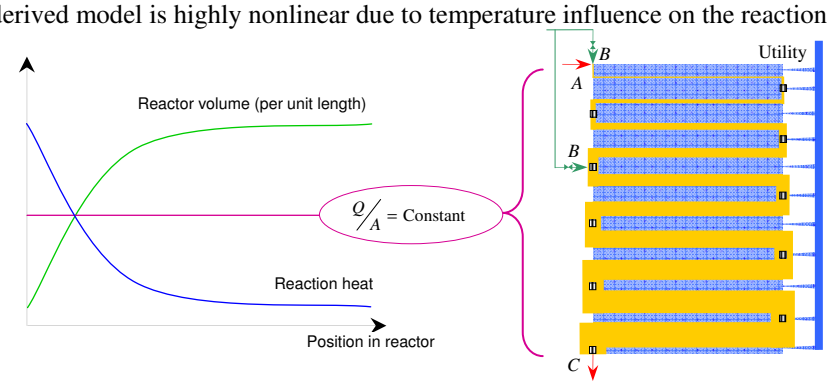

Figure 1. *Left:* The VCR concept. *Right:* A schematic of the VCR, with reactant and utility flows, i.e. 0.25 g/s and 290 g/s respectively. Temperature probes are within the vertical channels.

3. Process Operation

The main focus is on the number and locations of the injections and the cooling zones, as these significantly affect reactor performance and control conditions [Fogler; 1992]. Steady state temperature and conversion profiles are plotted for an exothermic reaction in Figure 2. Reactant *B* is distributed with 60% at the inlet and 40% in channel 9 (positioned at 40% along the reactor's length). The cooling capacity also changes with the latter injection. A maximum temperature, T_{max}=30 °C is in place to avoid product degradation above this limit and which inadvertently limits production capacity.

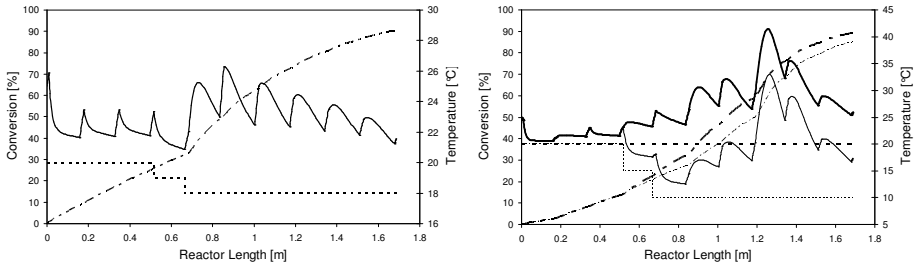

Figure 2. *Left:* Simulated process temperature profile (solid), conversion (dash-dot) and cooling (dashed) with injection at two sites giving a temperature maxima of T=26.3 °C. *Right:* Same as *left*, but here five injections are used with one (thick) and two (thin) cooling zones.

The importance in accurately representing the uncertainty in parameters such as reaction kinetics, micro-mixing conditions, heat transfer capacity as well as nonlinearities in the process dynamics, is crucial to give confidence in the model output [Shah *et al.*; 1999].
The overall control objective is an optimisation of the reactant conversion, γ, defined as the ratio between the amount of product formed to a theoretical conversion of 100%.

$$\max_{u\in U} \gamma(x,u,d) = \frac{C_C}{C_A + C_C} \quad \text{so that} \quad Wx \le \Omega$$

where x are the state variables; temperatures and concentrations along the reactor, u are the three control signals, U is the admissible control set, d are exogenous disturbances with the state constraints defined as W and Ω.

4. The control strategy and design

The configuration indicated in Figure 2 is applied for simplicity, i.e. two injections of reactant *B* and two cooling zones. In this paper, three main control signals will be investigated; the injection flow of reactant *B*, u_1, and the inlet temperature of both cooling utilities, u_2 and u_3. To guarantee stoichiometric balance, the total flow rate of reactant *B* is fixed (at 0.25 g/s) and the control signal u_1 denotes the fraction injected at the first point. The remainder, $(1-u_1)$ is injected at the second point. The total flow rate of reactant *B* is thus constant at all times as are all other inputs.
Two control approaches are available for the VCR; decentralised and centralised. In decentralised control, control loops are designed independently with automatic modes to give feedback such as PID controllers. In centralised control, the feedback control is based on a multivariable process model. As a result all control inputs and measurements are computed simultaneously. An accurate process model is thus required to implement centralised control, whereas decentralised control does save on modelling effort and is easier to tune. The centralised controller in most cases improves control performance, due to its ability to consider the cross-couplings between control inputs.

4.1. Model Predictive Control

The reaction used in the simulations is the preparation of *cis*-5-norbornene-endo-2,3-dicarboxylic anhydride, a fast Diels-Alder exothermic single liquid-phase reaction. The kinetic reaction parameters at ambient temperature are; A_j=1.1·10^5 L/(mol·s), E_a=35700 kJ/kmol and ΔH=−96600 kJ/kmol.
A linear MPC controller is developed based on notations from Maciejowski [2002] and Morari *et al.* [2004]. The nonlinear model is linearised around a working point (x^0,u^0) and is sampled with h=1 s to a discrete-time system. The VCR is discretised in 20 elements. There are six states within each element, the reactor and two utility temperatures, with the concentrations of the reactants and product, giving the linear model 120 states.
The controlled outputs z are chosen to be the outlet concentrations of the two reactants. The cost function to be minimised is employed from Maciejowski [2002] and the reference trajectories are set to r=[0 0]^T, corresponding to γ=100%.

$$V(k) = \sum_{i=1}^{H_p} \left\| \hat{z}(k+i|k) - r(k+i|k) \right\|_{Q(i)}^2 + \sum_{i=0}^{H_u-1} \left\| \Delta\hat{u}(k+i|k) \right\|_{R(i)}^2$$

The temperatures inside the reactor are subjected to hard constraints due to product degradation, $T_i \le T_{max}$=30 °C, where T_i is the temperature in the i:th element of the model. There are also constraints on the control signals, $0.1 \le u_1 \le 0.9$ and 5 °C $\le u_2; u_3 \le$ 30 °C, with the changes $|\Delta u_1| \le 0.1$ and $|\Delta u_2; \Delta u_3| \le 1$.
The prediction and control horizons are set to H_p = 200 and H_u = 10 respectively, as a

result the prediction time is $H_p \cdot h$=200 seconds. The weighting matrices for the controlled variables Q and the control actions R are chosen as Q=$10^{-5}\cdot\mathbf{I}$ and R=[1000 0; 0 1; 0 1], so to remain below the temperature constraint of 30 °C.
The VCR is subjected to an unmeasured inlet disturbance d namely the inlet concentrations. The temperatures of the reactor walls, the inlet and outlet cooling utilities are the available state measurements, y.
The MPC controller and the nonlinear model are implemented in Matlab and gPROMS. An extended Kalman filter (EKF) is designed from a tutorial given by Dochain [2003]. The filter calculates the gain matrix $P(\hat{x})$ as the solution of the dynamical Riccati matrix equation, thus minimising the variance of the estimation error. R_1 and R_2 are the variances of the process and measurement noise, respectively.

$$\frac{\mathrm{d}\hat{x}}{\mathrm{d}t} = -f(\hat{x},u,d) + K(\hat{x})(y-\hat{y}) \qquad ; \qquad K(\hat{x}) = \frac{P(\hat{x})C_y^T}{R_2}$$

$$\frac{\mathrm{d}P}{\mathrm{d}t} = -\frac{PC_y^T \cdot C_y P}{R_2} + PA^T(\hat{x}) + A(\hat{x})P + R_1$$

4.2. Event-driven start-up control
Upon start-up, temperatures within the VCR should guarantee that a reaction starts and that the reactants are consumed, for example at the first reactant B injection point T_1. To satisfy these two conditions, the start-up sequence is divided into four modes, schematically shown in Figure 3. With an open-loop start-up control procedure, it is possible to find the best operating point, whilst obeying the temperature constraints, However, this is difficult to isolate a suitable route in taking the process from initial rest, through to start-up to optimal operation. Therefore an event-driven start-up as described in Figure 3 is implemented with feedback control. For each step of the start-up, the already developed MPC controller due to its multivariable nature and its capacity to handle state constraints is applied.

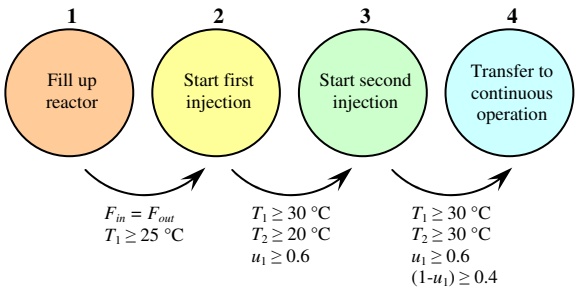

Figure 3. A finite state machine illustrates the steps during start-up.

5. Simulation results

The process starts at rest in a non-optimal working point. The rejection property of the EKF and the MPC controller is tested with a ramp increase of 5% in the concentration of both reactants during t=50-100 s, see Fig. 4 and 5. This increase increases the heat released from reaction and the associated risk of violating the temperature constraint.
The signal u_1 increases from 0.6 to 0.65 within the first 50 seconds, and thus redistributing reactant B from the second injection. Temporary changes in stoichiometry cause a drop in the product yield during the first 70 s. The flow from the second injection point, i.e. 40 % along the reactor length, to the exit is around 20 s which

explains the time delay. The MPC controller optimises conversion by increasing the temperatures inside the reactor by increasing the cooling temperature u_2 and u_3 by 0.8 °C and 1.5 °C, respectively. However, since the cooling temperature has a limited impact on the reactor temperature in the first part of the reactor, the reactant injection distribution was used to increase the temperature there. After t=50 s, the temperatures throughout have reached the prerequisite constraint of 30 °C. To maximise the yield, the temperatures are kept just below this constraint level, which indeed is the main limitation to the reactor's performance.
During the disturbance, the disturbance rejection property of the EKF and the MPC controller reacts by decreasing u_1 that is, redistributing more reactant *B* to the second injection and increasing the cooling rates, see Figure 5. With the estimation, the MPC controller can ensure that the temperature constraints are only slightly violated during the ramp and afterwards in steady-state the temperatures stay on the constraint. This is the main advantage of multivariable model-based control [Qin and Badgwell; 2003].

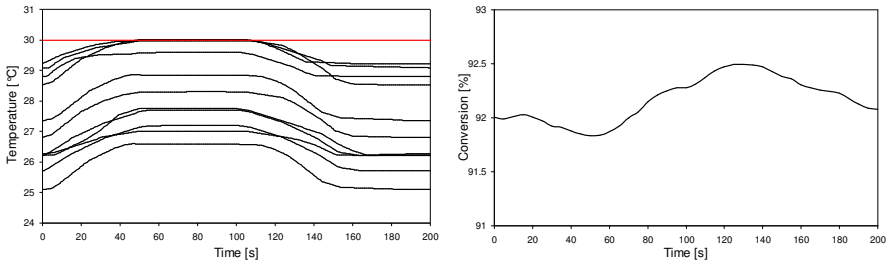

Figure 4. *Left:* Temperatures within each channel containing temperature probes whilst being under a ramp disturbance. *Right:* Outlet conversion under the 5% ramp disturbance.

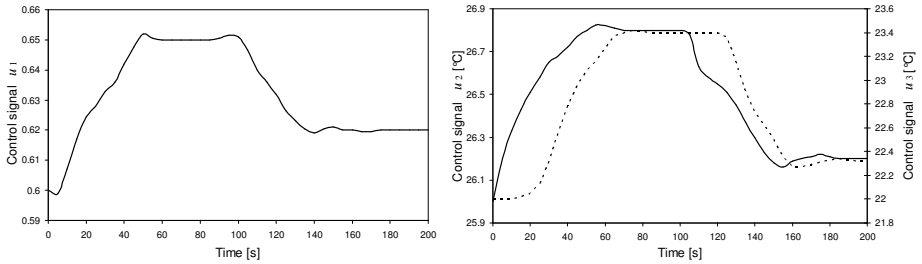

Figure 5. Control signals for the VCR. *Left:* Injection flow of reactant *B*, u_1. *Right:* Cooling utilities to the channels 1-7, u_2 (solid; right axis); and to channels 9-21, u_3 (dashed; left axis).

The closed-loop start-up control procedure is simulated with the non-linear process model is shown in Figure 6. The switch between step 1 and 2 in Figure 3 occurs at t=0, with reactant *A* is flowing through the reactor at steady-state.
Reactant *B* is injected to a channel 1 at t=0 s. As the inflow increases to its outflow the controller increases the utility to follow the temperature reference. After 3 seconds, the temperature at the first injection has reached 26 °C, meaning the reaction has started.
At t=22 s the controller switches from step 2 to 3. The inlet flow rate at the injection point in channel 9 is now included as a control variable. The temperature reference of 20 °C is tracked, and as the second feed increases, the cooling is intensified.
At t=36 s transition between step 3 and 4 occurs. At this step, the controller switches from start-up mode to continuous operation mode. The MPC now aims to optimise for product conversion, by increasing the reactor temperature to the highest allowable temperature before product degradation. In turn, some of reactant *B* is redistributed from

the second injection to the first, which decreases the need of cooling and saving energy. The transfer to optimal operation in step 4 allows the reactor to reach a conversion of 92% at the outlet, compared to 90.6% after step 3.

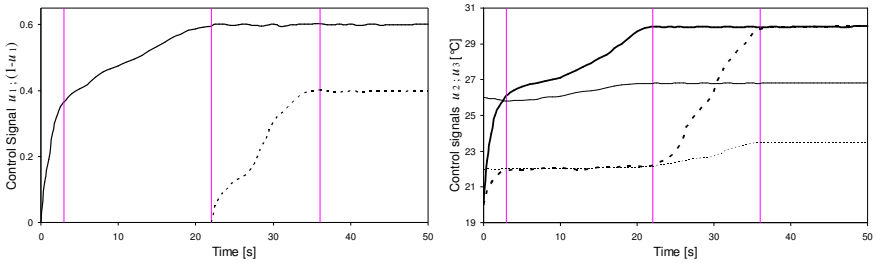

Figure 6. *Left:* During start-up, control signal of injection flow of reactant *B*, u_1 (solid) and 1- u_1 (dashed). *Right:* Temperatures of cooling utilities, u_2 (thick solid); and, u_3 (thick dashed), with temperature profiles within channels 1 and 9, T_1 (thin solid) and T_9 (thin dashed) respectively.

6. Conclusions

The concept and operation of the Variable Channel Reactor (VCR) has been presented. A combination of good mixing and high heat transfer capacity makes the VCR suitable for exothermic reactions and process intensification. The flexible configuration with cooling zones and multiple injections give possibilities for improved process control.

A centralised control is chosen over a decentralised approach, since it takes advantage of multiple inputs multiple outputs (MIMO) models, and offers explicit handling of input and state constraints. Thus, a linear MPC controller is designed, using the injection flow of reactant *B* and the inlet temperatures of cooling utilities to maximise conversion whilst obeying temperature constraints for improved product quality. An extended Kalman filter (EKF) was applied for estimation of unmeasured concentrations. Disturbance estimation was used to reduce the impact from variations in the feed concentrations. The simulations show that high reaction yield can be achieved, without violating the safety constraints. The disturbance and parameter estimation in the EKF increases the robustness of the process control system. By reducing the impact from external disturbances, the risk of unnecessary shutdowns is decreased.

The MPC controller was then applied to the start-up of the VCR which transfers the process from initial state to an operating point. Multiple steady states and multiple inlet ports along the reactor form a process with challenging dynamics. Safe and robust start-up is achieved through an event-driven sequence, i.e. divided into several steps, each associated with a transition condition that needs to be satisfied. The rule of thumb is that the feed of reactant *B* should only begin when the temperature is favourable for the reaction to start. This reduces the sensitivity to uncertainties and aids for good control.

Abstract

The objective of this work is to present the development of a strategy to monitor and control the organic solvent-water interface level on the MDIF® (a mixer-settler based on phase inversion) process. This is one of the most important variables for this equipment. However, the measurement of the organic solvent-water interface level (in line) is still a hard task. There are few sensors able to measure it in laboratory scale systems due to dimensional compatibility. In the present study, a sensor for detecting the organic solvent-water interface level was developed based on the acquisition and treatment of images obtained dynamically through a camera (webcam). In addition, a control strategy was implemented in feedback mode in order to maintain the referred interface level in a desired condition. A control and data acquisition program was built in Compaq Visual Fortran language to perform the following tasks: acquisition and treatment of images for identification of water-solvent interface; decisions and implementations of control signals; and recording of data in files. Some experimental runs in open-loop were carried out using the MDIF® and random pulse disturbances were applied on the input variable (water outlet flow). The responses of interface level permitted the process identification by transfer models. From these models, the parameters for a PID controller were tuned by direct synthesis and tests in closed-loop were performed. Preliminary results for the feedback loop demonstrated that the sensor and the control strategy developed in this work were suitable for level control.

Keywords: MDIF®; process control; image-based sensor; interface level.

1. Introduction

The process imaging use with applications in process engineering has increased significantly more recently. Process information can be extracted from images to estimate important variables as part of a control scheme. Regarding the image sensors, there are three applications field with interest in image detection techniques and analysis: communication and entertainment; medical, security and scientific; and industrial sectors. In the particular case of the chemical process industry, the imaging technology can be found in a significant range of applications, such as: in three dimensional multiphase flow; in the development and control of combustion systems; in detection and measurement of particulate size and shape, mixture uniformity, amount of fluidization, process efficiency, and various factors related to product quality; in particle separation by flotation cells and columns; in thermal imaging for monitoring flow profiles, and so on (Scott and McCann, 2005). Although this technology is already in industrial use, it is still an area in development. The main objective of this work is to present a based-image sensor developed to measure, and subsequently to control, the organic solvent/water interface of a system mixer-settler based on phase inversion (MDIF®) (Fernandes Jr. et al., 2006). The idea is to promote a safer and more efficient

operation for this continuous liquid-liquid separator which is used to treat continuously wastewater of oil industries.

2. Experimental Unit - MDIF®

MDIF® (a mixer-settler based on phase inversion) is a continuous system composed basically by three sections: mixing, settling and separation (Hadjiev et al., 2004). As shown in Figure 1, in a mixing chamber (1), the water contaminated with oil (2) is put in contact with an organic solvent (3) by agitation in order to extract the oil from the water. When this mixture passes through a perforated plate (4), water drops (5) are formed and carry small oil droplets internally (6). The water, which is originally the continuous phase, becomes the dispersed phase (as drops), while the organic solvent that is added to extract the oil becomes the continuous phase of the system. The water drops descend toward to the settling chamber (7) filled with organic solvent, allowing a transfer of the oil droplets from the water drops to the continuous phase (organic solvent). In the separation section (8), the water drops coalesce and form a dense phase (treated water) containing oil in acceptable accordance with the environmental legislation in force, which, in Brazil, establishes maximum total oil and grease (TOG) of 20 mg/L. An important variable during the MDIF® operation is the organic solvent-water interface level (9) in the separation section. In order to measure this interface level, it was developed an image-based sensor, which consists on image detection by a camera (webcam) (10) and its treatment by computational routine. Using a feedback control loop, this measurement is compared to the desired level and a control action is taken according to the PID law, via computational program (11). This action is sent to manipulate the water outlet flow through a control valve (12). The interface level control is essential both to avoid the dragging of the solvent during the water removal and improve the extraction efficiency of the oil by the solvent.

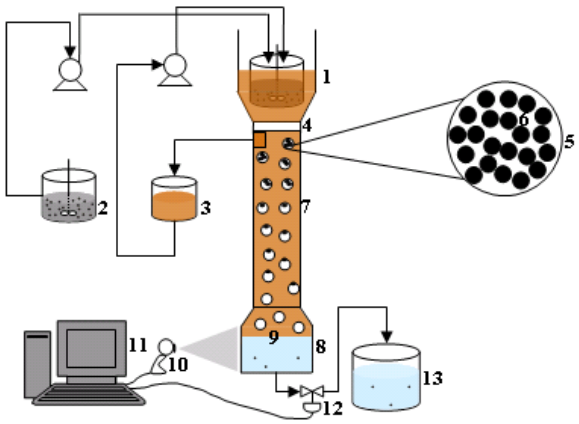

Figure 1 – MDIF® schematic representation.

3. Development of a image-based sensor

The image-based sensor was developed with the objective of detecting the organic solvent/water interface level in the MDIF® separation section. As it mentioned previously, the oil-water interface level control on the separation chamber is extremely important by two reasons: first, with regard to security and quality - the organic solvent-water interface level must be kept far from the outlet to avoid dragging organic to the treated water; second, regarding to the process performance - the organic solvent -water interface level must not ascend in the settling chamber to avoid reducing the residence time of the drops. Moreover, as the MDIF® is in laboratory scale, it is difficult to find an interface sensor with reliable dimensions to this system, and conventional level

sensors are not applied on interface detection. In this study, the image capture was carried out by a simple camera (webcam) and the interface level was estimated using a computational routine, according to the following steps:

1. The camera shows images in real time in preview mode and a static image is captured in grey scale every 3 seconds.
2. Color arrays with 200 discretization points at vertical direction from captured image are obtained in four horizontal positions and a mean is taken, as shown in the Figure 2.
3. From the color arrays mean, a theoretical curve (sigmoid function), represented by the Equation 1, is fitted dynamically through a parameters estimation method based on Particle Swarm Optimization (PSO) (Kennedy and Eberhart, 1995). The first derivative of this curve is used to compute the interface level through the calculation of maximum point. This approach allows to signalize the colors transition between organic solvent phase and water phase (Figure 3).

In this method, the theoretical curve used to fit the color data of the image is given by the expression:

$$f(x) = [a - (a - b).e^{-p_1.e^{-p_2.x}}] \quad (1)$$

where a, b, p1 and p2 are parameters; x indicates the image vertical coordinate; and f(x) is the resultant color in gray scale (0-255).

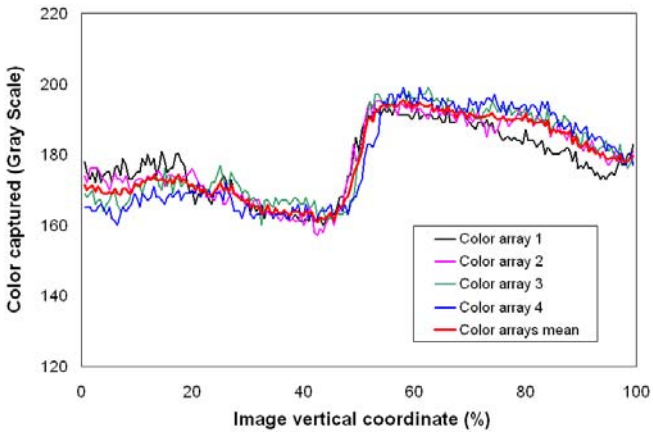

Figure 2 – Color spectra measured from the image in gray scale.

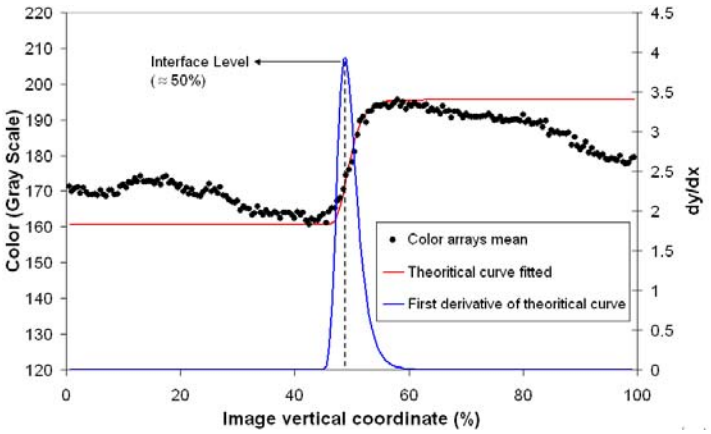

Figure 3 – Sigmoidal fitting with the color spectra mean and its first derivative.

4. Process identification and control strategy

In order to identify the dynamic model capable to describe the behavior of the MDIF® process regarding the interface level, some experiments were performed in open loop from different initial steady state. By applying random pulse disturbances with different magnitude and duration, it was possible to analyze the interface level response from the reaction curves for distinct operational conditions of flowrate. In Figure 4, it can be seen one of studied cases where an attempt of reaching the process identification was led using two transfer models: first-order and second-order functions. The parameters for each function were estimated using the Particle Swarm Optimization method (Kennedy and Eberhart, 1995). The fitted curves allow to show that the models presented a similar behavior. Therefore, it is not possible to discriminate the better model which describes the process (Figure 4). In spite of this, the transfer functions were used to find the PID (proportional-integral-derivative) controller parameters in feedback structure by direct synthesis approach (Ogunnaike and Ray, 1994), admitting a first-order closed-loop trajectory (q) with time constant (τc) of 1.0 minute. The Table 1 lists the adjusted functions for the experiment presented in Figure 4 and the parameters obtained by direct synthesis for PI and PID controllers.

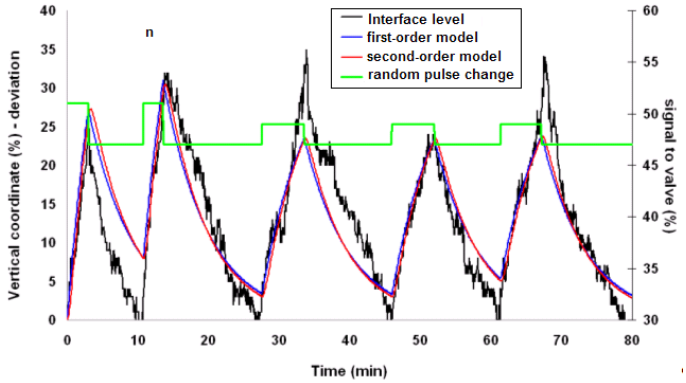

Figura 4 – Dynamic curve for the interface level as response to random pulse changes – experimental and approximate curves.

Tabela 1 – Transfer functions and tuning for feedback PID controller

First-order trajectory: $q(s) = \frac{1}{(s+1)}$

System	Approximate Model	Parameters			Controller
		Kc	τ_D	τ_I	
First-order	$G(s) = \frac{18.1}{(6.32s+1)}$	0.35		6.32	PI
Second-order	$G(s) = \frac{17.84}{(5.78s+1)(0.34s+1)}$	0.34	0.32	6.12	PID

A control and data acquisition program was implemented with the Compaq Visual Fortran compiler (CVF 6.5) as shown in Figure 5. In this program, the following tasks are accomplished: acquisition and treatment of images for detecting the interface level; decisions and implementations of control signals based on PID controller; and recording of all data in file. In addition, as displayed in the program window (Figure 5), the users

can notice the interface level in real-time and to operate the process in manual control mode, if necessary. Other important fact is that the control strategy can be modified in order to improve the controller. In this preliminary study, only PID controller was implemented in this program. However, other control schemes can be adapted easily as routines for the program.

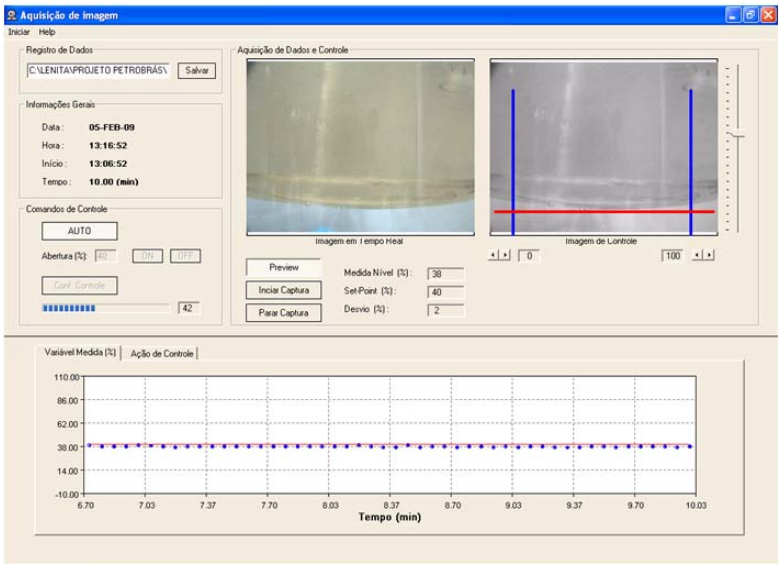

Figure 5 – Main window of the program implemented to monitor and control the MDIF® process.

5. Results and Discussion

In order to investigate the response of the closed-loop system to step changes in the set-point and in the input disturbances (Ogata, 1997), some experiments were carried out with the MDIF® process. For reason of space limit in this document only two experiments are presented here. The particular case of the set-point response for the interface level using the PID controller tuned by direct synthesis (Table 1) is shown in Figure 6. It is possible to note that the PID controller provides a response with short rise time and without offset. Although the response has presented short overshoot and damped oscillations, the controller has demonstrated satisfactory for MDIF® process.

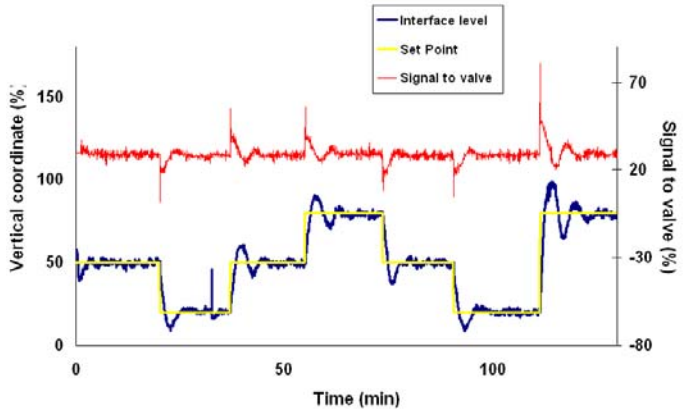

Figure 6 – Closed-loop set-point change responses for the interface level using the PID controller tuned by direct synthesis, as shown in Table 1.

In the case of response to input disturbance, the experiments were performed applying step perturbation at the process water feed through manipulating the pump flowrate. As shown in Figure 7, the step changes were done at time values signalized by dashed lines with magnitude represented by the green points. The response for this case provides overshoots when the changes are implemented. As larger the perturbation, more intense it is the overshoot. Even so, the controller is able to bring back the system to the desired set-point without offset. So, the controller presented suitable results regarding the regulatory control condition.

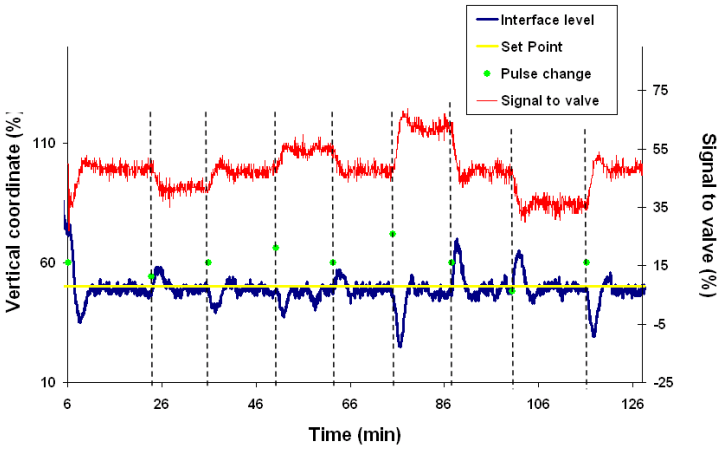

Figure 7 – Closed-loop response to the input disturbance using the PID controller tuned by direct synthesis, as shown in Table 1.

6. Conclusions

The results and analysis obtained showed that the strategy of image detection and treatment was able to measure the organic solvent/water interface level from image color spectra for the MDIF® system. The procedures to the process identification and PID controller design resulted in a closed-loop scheme that provided satisfactory responses both to servo and regulatory control. As this is a preliminary study, other controller tuning rules could be tested in order to enhance the control performance. From a practical point of view, the image-based sensor presented here may be applied as part of a control system used in other processes, where the control of interface level is required.

Dynamic degrees of freedom for tighter bottleneck control

Elvira Marie B. Aske[a,b], Sigurd Skogestad[a]

[a]*Department of Chemical Eng.ineering, Norwegian University of Science and Technology, 7491 Trondheim, Norway.*
[b] *StatoilHydro, Reaserch & Development, 7005 Trondheim, Norway.*

Abstract

To realize maximum throughput, tight control of the bottleneck unit(s) is necessary. Dynamic degrees of freedom can be used to obtain tighter bottleneck control. Here, "dynamic" means that the degree of freedom has no steady-state effect on plant operation, like most inventories (levels). Nevertheless, temporary changes of inventories can allow for dynamic changes in the flow through the bottleneck that keeps the process closer to its bottleneck constraint and increase the throughput.

Keywords: Throughput maximization, bottleneck, inventory, ratio control

1. Introduction

In many cases, prices and market conditions are such that optimal operation is the same as maximizing plant throughput. In this case, the optimum lies at constraints, and in order to maximize throughput, the flow through the bottleneck(s) should be at its maximum at all times (Aske *et.al*, 2008). If the actual flow through the bottleneck is not at its maximum at any given time, then this gives a loss in production that can never be recovered. Tight bottleneck control is therefore important for maximizing throughput and avoiding losses.

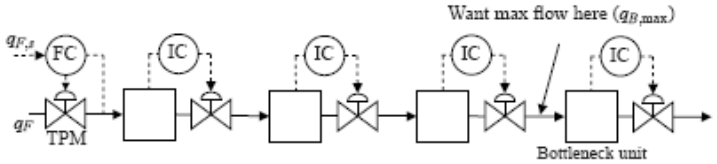
In existing plants, the most common approach for controlling the throughput is to set the feed flow at the inlet of the plant and use inventory control in the direction of flow (Price et al., 1994). One reason for this is that most of the control structure decisions are done at the design stage (before the plant is built), where one usually assumes a fixed feed rate. However, tight bottleneck control requires that the throughput manipulator (TPM) is located close to the bottleneck (Skogestad, 2004). The term "close to the bottleneck" means that there is a short effective delay from the input (TPM) to the output (bottleneck flow).

Ideally the TPM should be located at the bottleneck, but this may not be desirable (or even possible) for other reasons. First, if the TPM is moved, the inventory loops must be reconfigured to ensure self-consistency (Aske and Skogestad, 2009). Second, there may be dynamical reasons for avoiding a so-called on-demand control structure with inventory control opposite the direction of flow (Luyben, 1999). Third, if a bottleneck(s) moves in the plant due to disturbances, then single-loop control requires relocation of TPM and reconfiguration of inventory loops. Thus, in practice one is often left with a fixed throughput manipulator, usually the feed rate. This usually leads to a large effective delay ("long loop") because the bottleneck is usually located inside the plant, and this leads to an economic loss because of a large required back off from the bottleneck constraints.

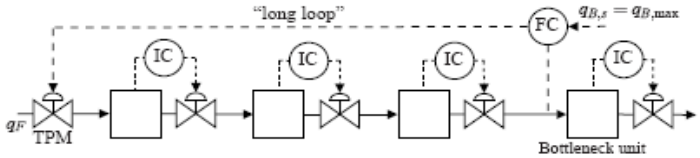
There are also related issues in business systems for using inventories as degree of freedom. Supply chains are sometimes modelled as continuous processes and Schwartz *et al.* (2006) used simulation to study decision policies for inventory management.

2. Alternative strategies for bottleneck control

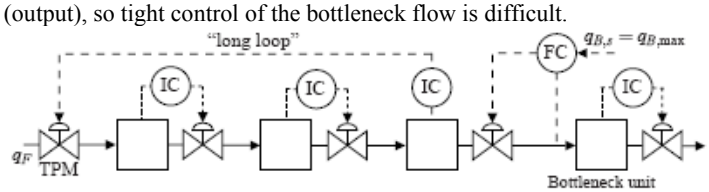
Assume that the objective is to maximize the flow through the bottleneck and that the feed rate is available as a degree for freedom (TPM). Figure 1 show four ways of achieving this using simple single-loop control structures.



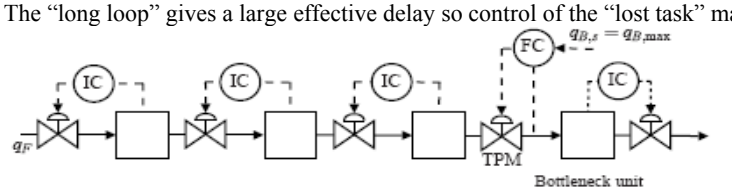
(a) **Traditional configuration** (manual control of feed rate). The feed rate is the degree of freedom for manipulating throughput (TPM), and inventory control is in the direction of flow. To maximize the flow through the bottleneck, the operators change the feed valve manually based on information about the plant operation and experience.



(b) **Alternative 1: Single-loop control of bottleneck flow using the feed rate.** *Problem:* The "long loop" gives a large effective delay from the feed flow (input) to the bottleneck flow (output), so tight control of the bottleneck flow is difficult.



(c) **Alternative 2: Move TPM from feed to bottleneck**. This achieves tight control of the bottleneck flow. The inventory loops are not reconfigured, so the feed rate now needs to take over the "lost task" which in this case is control of the inventory upstream of the bottleneck. *Problem:* The "long loop" gives a large effective delay so control of the "lost task" may be poor.

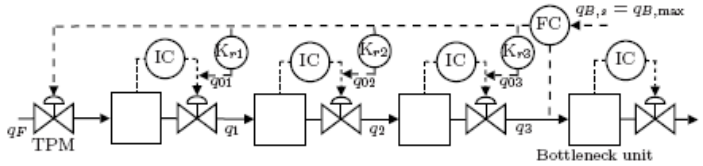


(d) **Alternative 3: Reconfigure inventory control**. The TPM is moved to the bottleneck and at the same time all the upstream inventory loops are reconfigured to be in the opposite direction of flow. Tight bottleneck control (of both flow and local inventory) may be achieved. *Problem:* Reconfiguration of inventory loops is usually very undesirable from a practical point of view.

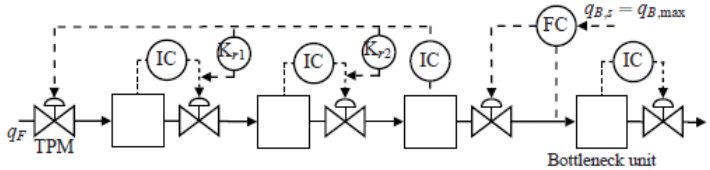
Figure 1: Simple single-loop control structures for maximizing bottleneck flow in serial process. IC stands for inventory controller (e.g. level controller).

In summary, none of the alternatives in Figure 1 are desirable. To improve control and keep the flow through the bottleneck closer to its maximum at all times, we would like to have additional degrees of freedom, and the only ones that are normally available are the inventories (holdups) in the buffer tanks, which can be used to make

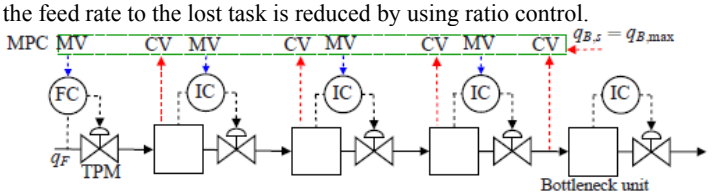
dynamic flow changes. The word ”dynamic” is used because most inventories have no steady-state effect on plant operation.
The main idea is as follows: To change the flow through the bottleneck, for example, to increase it, we temporarily reduce the inventory in the upstream holdup volume. However, this inventory needs to be kept within bounds, so if we want to increase the bottleneck flow permanently, we need to increase the flow into this part of the process and so on, all the way back to the feed (throughput manipulator). The simplest (but not generally optimal) approach is to use a “ratio” control system where all flows upstream the bottleneck are increased simultaneously by the same relative amount. The idea is illustrated in Figure 2.



(a) **Alternative 1D: Single-loop plus ratio control.** The idea is to control the bottleneck flow by simultaneously changing all the flows upstream of the bottleneck by the same relative amount. The advantage is that the effective delay from the feed to the bottleneck may be significantly reduced and even eliminated in some cases. However, the dynamic flow changes are counteracted by the inventory controllers. In particular, note that the feed flow is the only degree of freedom that has a steady-state effect on the bottleneck flow. The strategy may also be viewed as a “ratio feedforward controller” from the feed flow to the downstream flows.



(b) **Alternative 2D: Move TPM to bottleneck and add ratio control to “lost task”**. The TPM is moved to the bottleneck and the “lost task” (inventory upstream the bottleneck) is controlled by the feed rate. The use of ratio control is the same as for Alternative 1D. The effective delay from the feed rate to the lost task is reduced by using ratio control.



(c**) Alternative 4: Multivariable controller**. A multivariable controller (e.g. MPC) uses the feed rate and the inventory controller set points as manipulated variables (MVs). The controlled variables (CVs) are the bottleneck flow and inventory constraints.

Figure 2: Structures for controlling bottleneck flows that use inventories as dynamic degrees of freedom (with no reconfiguration of the inventory loops). Alternative 1D is studied in this paper. IC stands for inventory controller (e.g. level controller) and K_{ri} is a constant gain (ratio controller).

The most obvious is to adjust the inventory set point I_s, but it is more direct in terms of flow changes to adjust the bias q_0. The two approaches are not very different, because a change in q_0 can equivalently be implemented as a set point change by choosing $I_s = -q_0/K(s)$, where $K(s)$ is the feedback controller. In this paper, we choose to use the bias q_0 as the dynamic degree of freedom for ratio control. The important point to note is that

there are no dynamics in K_r. This means that all the flows q are changed simultaneously when q_F changes.

3. Example: Four distillation columns in series

Consider four distillation columns in series, as shown in Figure 3. The four columns represent the liquid upgrading part of a gas processing plant and consist of a deethanizer, a depropanizer, a debutanizer and a butane splitter. Assume that the butane splitter is the bottleneck unit. The throughput is manipulated at the feed to the first column. The idea is to use the column inventories (sump or condenser drum holdup) as dynamic degrees of freedom to obtain tighter bottleneck control.

The distillation column models are implemented in Matlab/Simulink. Each of the four columns is modelled as multicomponent distillation with one feed and two products, constant relative volatilities, no vapor hold-up, constant molar flows, total condenser and liquid flow dynamics represented by the Francis weir formula. All columns use the "LV-configuration" where distillate (D) and bottoms flow (B) are used for inventory control (M_D and M_B). To stabilize the column composition profile, all columns have temperature control in the bottom section by manipulating the boilup. The column inventories M_D and M_B are controlled with P-controllers with gain $K_c = 1/\tau_V$. Here we use "smooth" level control where we set $\tau_V = V_{tank}/q_{out}$ (Skogestad, 2006) where q_{out} is the flow out of the volume (D or B). The temperature controllers (TC) are tuned with SIMC PI-tuning (Skogestad, 2003) with $\tau_c = 0.5$ min.

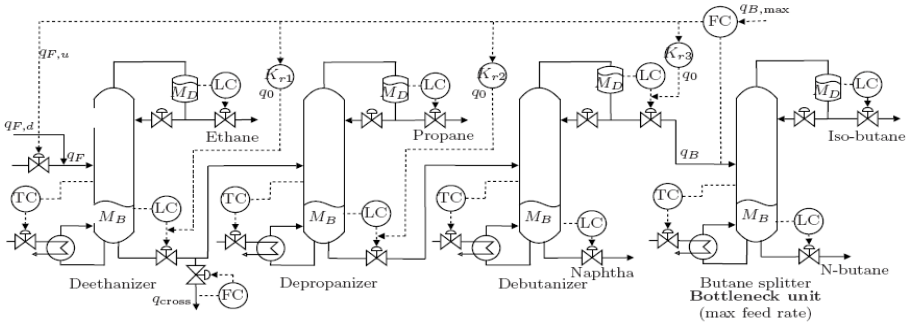


Figure 3: Distillation process: Four columns in series, here shown with throughput controlled by using single-loop with ratio control (Alternative 1D).

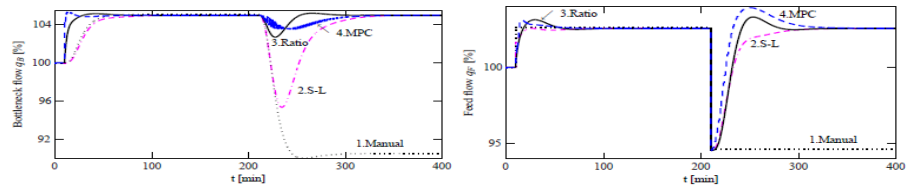
Two disturbances are considered. First, at *t = 10 min*, we make a 5% increase in the bottleneck flow set point ($q_{B,s}$). Second, *at t = 210 min*, there is an 8% unmeasured decrease in the feed rate to the deethanizer (q_F). The net feed flow is $q_F = q_{F,u} + q_{F,d}$, where $q_{F,u}$ is the flow contribution from the controller (initially $q_{F,d} = 0$ and $q_F = q_{F,u} = 100$, but then $q_{F,d} = -8$ at *t = 210*).

Four different control structures are tested for maximizing throughput:

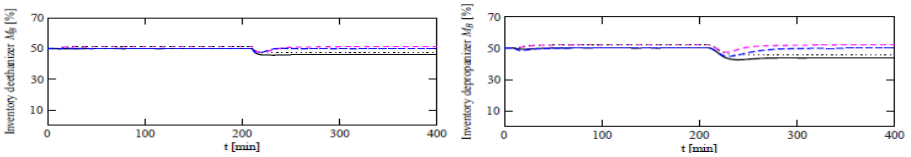
1. **Manual:** Traditional (manual) control of the throughput. We assume that a skilled operator can immediately change the feed rate to the value corresponding to the new bottleneck flow set point. However, we assume that the operator does not notice the unmeasured feed flow disturbance, so no adjustment is therefore done for the feed rate disturbance.
2. **Single-loop:** Single-loop control where the bottleneck flow is controlled using the feed rate (Alternative 1).We want smooth tuning to avoid overshoot and "aggressive" use of the feed valve. Therefore, the bottleneck flow controller (FC) is tuned with SIMC tunings with $\tau_c = 3\theta$ for smooth tuning (Skogestad, 2006).

3. **Single-loop with ratio:** Use of the inventories as dynamic degrees of freedom by adding a bias (q_0) to the inventory controller outputs as in Figure 3 (Alternative 1D). In this case there is no effective delay and the bottleneck flow controller (FC) is tightly tuned with a short integral time, which are typical FC tuning parameters.
4. **Multivariable:** MPC with the feed rate and the inventory set points as MVs and the bottleneck flow and level constraints as CVs (Alternative 4). The built-in MPC toolbox in Matlab is used and tuned with a low penalty on the use of inventories (MV moves) and a high penalty on the deviation from the bottleneck flow set point (CV set point).

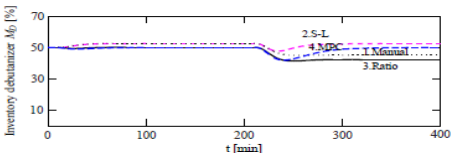
The four control structures are evaluated in terms of how tightly the bottleneck flow (q_B) is controlled in spite of disturbances. The resulting bottleneck flow (q_B), the net feed flow (q_F) and the inventories used as dynamic degrees of freedom (deethanizer M_B, depropanizer M_B and debutanizer M_D) for the four different control structures are displayed in Figure 4. The bottleneck control is significantly tighter with ratio control and MPC where inventories are used as dynamic degrees of freedom. The inventories are quite tightly controlled with surprisingly small variations. This follows because the disturbances introduced here are small compared to what the IC's are tuned to handle.



(a) Response in bottleneck flow q_B (CV) (b) Responses in feed flow q_F (MV)



(c) Responses in deethanizer bottoms level M_B (d) Responses in depropanizer bottoms level M_B



(e) Responses in debutanizer distillate level M_D

Figure 4: Bottleneck control of the distillation process for four different control structures. 1) Manual control (dotted), 2) Single-loop control (dash-dotted), 3) Single-loop with ratio (solid), 4) MPC using both feed rate and inventories as MVs (dashed).

4. Summary: Implications for design of inventory tanks

The effect of using inventories as dynamic degrees of freedom on the design of inventory tanks is summarized. The derivations are given in details in Aske (2009).

4.1. Tank size

A desired change in tank throughput ΔqB results in a volume variation ΔV and we have

$$|\Delta V| = \tau_G \cdot |\Delta qB| \quad (1)$$

where τ_G is the time constant for "refilling" the tank. In practice, τ_G is the time for the flow rate into V to reach 63% of its steady-state change following a step in flow rate out of the (closest) upstream inventory. This is for the normal case when the TPM is upstream the bottleneck; the same formula applies also when it is downstream. For design purposes, the flow change $|\Delta q_B|$ is the (steady-state) flow change through tank resulting from the largest expected throughput (bottleneck flow) change.

Equation (1) is useful for sizing the tank (inventory volume). In words, the expected volume variation for an inventory used for bottleneck control is approximately the expected variation in flow through the unit multiplied by the time constant for the flow dynamics for "refilling" V from the upstream inventory.

4.2. Level control tuning

The level control tuning involves the closed-loop time constant (τ_V) for the level control loop in the inventory tank. We get

$$|\Delta V| = \tau_V \cdot |\Delta q_d| \quad (2)$$

where Δq_d is the flow rate change through the tank in question. Equation (2) can be used to tune the level controller, and then gives the well-known formula for smooth (averaging) level control. To see this, note that for a nominally half-full tank we must require $|\Delta V_{peak}| < 0.5\ V_{tank}$ to avoid overfilling or emptying. If we furthermore assume that the maximum expected change in flow through the tank is 50% of the nominal flow, then $q_d = 0.5\ q$. This gives $\tau_V < V_{tank}/q$, which is the well-known value for smooth level control, (e.g. Skogestad (2006)).

A Global Optimization Approach for the Estimation of Domains of Attraction

Luis G. Matallana, Aníbal M. Blanco, J. Alberto Bandoni
PLAPIQUI (UNS - CONICET), Camino "La Carrindanga" – km 7
(8000) Bahía Blanca, ARGENTINA

Abstract

In order to completely characterize an asymptotically stable equilibrium point, some information about the size and shape of its Domain of Attraction is required. In this contribution a global optimization approach is proposed to estimate domains of attraction of general nonlinear dynamic systems. The technique is illustrated by a two states system that presents a very rich nonlinear behavior and is then applied to a typical continuous stirred tank reactor.

Keywords: Nonlinear dynamic systems, Domains of attraction, Global optimization

1. Introduction

The Domain of Attraction (DOA) of an asymptotically stable equilibrium point represents the portion of the state space where trajectories that converge to the equilibrium point originate. For the general nonlinear case, the DOA is a complicated set that does not admit analytical representation. Many techniques have been proposed so far to address the estimation of DOAs. In particular, the Lyapunov stability theory provides the basis of a family of techniques whose rationale is to approximate the DOA by a level set of a Lyapunov function. Several approaches have been proposed to identify the best level set of a given Lyapunov function by solving an optimization model. This problem is very challenging for the general case since the resulting optimization model is nonlinear semi-infinite. Formulations that make use of results on deterministic global optimization were recently proposed (Hachicho, 2007). The technique allows the identification of the best possible level set of a rational Lyapunov function that constitutes an estimation of the DOA of the equilibrium under study for nonlinear dynamic systems of polynomial type. In this contribution, an extension of the formulation presented in Hachicho (2007) is proposed. An optimization model is formulated, which includes additional constraints to avoid possible dummy solutions and makes use of a global optimization approach to address nonlinear systems of the general type.

2. Estimation of DOAs

Consider the following autonomous nonlinear dynamic system:

$$d\mathbf{x}/dt = \mathbf{f}\left(\mathbf{x}(t)\right) \tag{1}$$

being the origin of the state space, $\mathbf{x} = \mathbf{0}$, an asymptotically stable equilibrium point. The DOA of the origin is defined by the set of initial conditions $\mathbf{x}_0$, such that the trajectories initiated at $\mathbf{x}_0$ (denoted by $\mathbf{x}(\mathbf{x_0}, t)$) converge to the origin as time increases:

$$\mathrm{DOA}(\mathbf{0}) = \left\{\mathbf{x}_0 : \mathbf{x}(\mathbf{x_0}, t) \to 0 \text{ as } t \to \infty\right\} \tag{2}$$

Consider that a function $V(\mathbf{x})$ exists such that:

$$V(\mathbf{x}) \succ 0 \text{ in } \mathrm{R}(\mathbf{0}) \tag{3a}$$

$$dV(\mathbf{x})/dt \prec 0 \text{ in } \mathrm{R}(\mathbf{0}) \tag{3b}$$

where R(**0**) is a region around the origin. Equation (3a) means that $V(\mathbf{x})$ is positive definite in region R(**0**) and (3b) that its time derivative is negative definite in that region. If (3a) and (3b) hold for system (1) then $V(\mathbf{x})$ is known as a Lyapunov function of (1). Let $V(\mathbf{x}) = c$ be the level set of $V(\mathbf{x})$ at value c, this is, the projection on the state space of $V(\mathbf{x})$ at value c. Consider the region S(**0**)={**x**: $V(\mathbf{x}) - c \leq 0$} is contained in R(**0**):

$$\mathrm{S}(\mathbf{0}) \subset \mathrm{R}(\mathbf{0}) \tag{4}$$

then S(**0**) belongs to the DOA of the origin and can be considered an estimation of DOA(**0**). A powerful technique based for the design of "maximal" Lyapunov functions has been proposed in Vannelli and Vidyasagar (1985). A maximal Lyapunov "candidate" is a rational function with the following structure:

$$V(\mathbf{x}) = \frac{N(\mathbf{x})}{D(\mathbf{x})} = \frac{\sum_{i=2}^{n} R_i(\mathbf{x})}{1 + \sum_{i=1}^{n-2} Q_i(\mathbf{x})} \tag{5}$$

Where $N(x)$ and $D(x)$ are polynomials defined through the $R_i(\mathbf{x})$ and $Q_i(\mathbf{x})$ homogeneous functions of degree i and n ≥ 2. If the system of nonlinear equations is represented in terms of a series of homogeneous functions of degree i, $F_i(\mathbf{x})$:

$$\frac{d\mathbf{x}}{dt} = \mathbf{f}[\mathbf{x}(t)] = \sum_{i=1}^{\infty} F_i(\mathbf{x}) \tag{6}$$

a Lyapunov function can be obtained by the procedure proposed in Vannelli and Vidyasagar (1985) and then an estimation S(**0**) of DOA(**0**) can be calculated by finding the largest positive value of c that verifies (4). The calculation of the maximum level set of a given Lyapunov function can be stated as:

$$\begin{aligned} &\max_{c,\mathbf{x}} \; c \\ &s.t. \;\; V(\mathbf{x}) = c \qquad \text{a)} \\ &\qquad \dot{V}(\mathbf{x}) \prec 0 \qquad \text{b)} \end{aligned} \tag{7}$$

In order to handle the negative definiteness constraint (7b), Hachicho (2007) proposed to reformulate problem (7) as:

$$\begin{aligned} &c = \min_{\mathbf{x}} \; V(\mathbf{x}) \\ &s.t. \;\; \dot{V}(\mathbf{x}) = 0, \quad \mathbf{x} \neq \mathbf{0} \end{aligned} \tag{8}$$

The rationale behind problem (8) is to find the minimum level set of function $V(\mathbf{x})$ which is contained in the level set $dV(\mathbf{x})/dt = 0$. The solution of algebraic model (8) is a single point in the state space, which corresponds to the tangential contact of level sets $V(\mathbf{x}) = c$ and $dV(\mathbf{x})/dt = 0$. In order to graphically illustrate this situation consider dynamic system (9) and Lyapunov function (10).

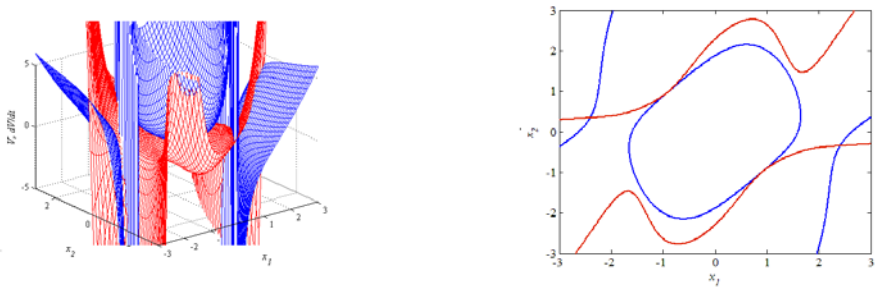
$$\begin{aligned}\frac{dx_1}{dt} &= -x_2 \\ \frac{dx_2}{dt} &= x_1 - x_2\left(1-x_1^2\right)\end{aligned} \tag{9}$$

$$\begin{aligned}N(\mathbf{x}) &= 0.593x_1^2 - 0.364x_1x_2 + 0.437x_2^2 - 0.1253x_1^4 + 0.2885x_1^3x_2 - 0.0537x_1^2x_2^2 \\ &\quad + 0.0581x_1x_2^3 - 0.0196x_2^4 \\ D(\mathbf{x}) &= 1 - 0.0001x_1 + 0.0001x_2 - 0.2685x_1^2 + 0.3217x_1x_2 - 0.1163x_2^2\end{aligned} \tag{10}$$

In Fig. 1a) it is shown the Lyapunov function and its time derivative. In Fig. 1b) the level sets of interest are depicted. The closed curve $V(\mathbf{x}) = 2.2086$ (blue line) contained in the level $dV(\mathbf{x})/dt = 0$ (red line) constitutes the desired solution of problem (8) for the system under study (9)/(10). It should be noted that, due to symmetry, there are two points in the state space for the same $V(\mathbf{x}) = c$ for this system. Since both solutions are equivalent regarding the resulting estimation only one of them is reported.

3. Proposed Approach

Problem (8) is a nonlinear optimization model and therefore it may have many local solutions. A local solution may not correspond to a proper estimation of the DOA for the system under study. Consider for example the different solutions of problem (8) for system (9)/(10) shown in Fig. 2. In Fig. 2 (a to d) different level sets for the Lyapunov function are shown in blue line. In all cases the level set of the time derivative at value zero is shown in red line. The solution depicted in Fig. 2 a) is a solution of problem (8) with a value of c lower than that of the desired estimation (Fig. 1 b)). The solution corresponds to an intersection between the level set $V(\mathbf{x}) = 0.1$ and the level set $dV(\mathbf{x})/dt = 0$. It can be noticed that the intersection takes place far from the origin and therefore a very small portion of the level set of $V(\mathbf{x})$ is in fact an estimation of the actual DOA (the small circle around the origin). The solution of Fig. 2 b) verifies tangential contact between the level sets. The situation is pretty the same as in the previous case. The tangency between level sets takes place far from the origin and the estimation of the DOA is also poor. It can be observed in this case, that although the constraints of problem (8) hold, as well as a tangency condition, both $V(\mathbf{x})$ and $dV(\mathbf{x})/dt$, verify a transition of definiteness in an intermediate portion of the state space. Particularly $V(\mathbf{x})$ is positive definite in the small circle around the origin, then becomes negative definite in an intermediate region and recovers positive definiteness far from the origin. Similarly $dV(\mathbf{x})/dt$ is negative definite close the origin, becomes positive definite in an intermediate region and recovers negative definiteness far from the origin. While the small circle is an estimation of the DOA since it is fully contained in the region of negative definiteness of $dV(\mathbf{x})/dt$, the fact that the actual solution occurs beyond the transition of definiteness of the functions is clearly undesirable. Figs. 2 c) and d) are also solutions of problem (8) that present tangency between the level sets $V(\mathbf{x}) = c$ and $dV(\mathbf{x})/dt = 0$. However, none of them are actual DOAs since the level sets of $V(\mathbf{x})$ are not fully contained in the region of negative definiteness of $dV(\mathbf{x})/dt$. Since all solutions of Fig. 2 are valid solutions of problem (8) but none is the desired estimation of the actual DOA, they are considered dummy solutions of for system (9)/(10). From the above qualitative description it can be concluded that for a certain level set $V(\mathbf{x}) = c$ be an optimal estimation of the DOA, it should verify the following conditions:



a) Surfaces:
$V(\mathbf{x})$ (blue), $dV(\mathbf{x})/dt$ (red)

b) Level sets:
c = 2.2086, x_1 = -0.9079, x_2 = 0.9887

Fig. 1: Lyapunov function and time derivative for system (9)/(10)

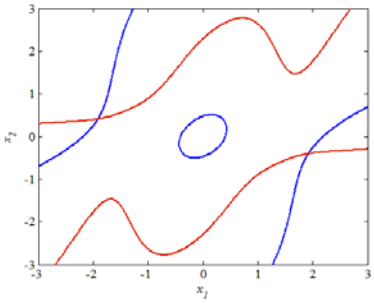
1. The level sets $V(\mathbf{x}) = c$ and $dV(\mathbf{x})/dt=0$ should verify tangential contact
2. The solution should belong to the portion of the state space around the origin, previous a transition of definiteness of $V(\mathbf{x})$ and $dV(\mathbf{x})/dt$ takes place
3. Provided that conditions 1 and 2 hold, the level set $V(\mathbf{x}) = c$ should be the global minimum

Condition 1 helps in avoiding dummy solutions such as the one in Fig. 2a). Condition 2 ensures that solutions of the type of Fig. 1b) are preferred over a solution like the one of Fig. 2b). Finally, the global minimum condition 3 favors the solution of Fig. 1b) over the tangential solutions of Figs. 2 c) and d). While problem (8) explicitly implies global optimality (condition 3), neither condition 1 nor condition 2, are considered. Therefore, dummy solutions such as those of Fig. 2 may result from problem (8). The proposed formulation is presented in Eq. (11) where ε is an auxiliary variable. While condition 1 can be straightforwardly imposed as a geometric constraint (11 b), condition 2 does not posses obvious mathematical expressions to be included within the optimization problem. In this contribution it is proposed to include a strict positive constraint on the denominator of function (5) to account for condition 2 (11 c). In Fig. 3 it is shown in gray the region determined by $D(\mathbf{x}) > 0$. Such condition contains the desired solution (Fig. 3 a) but excludes the dummy solution shown in Fig. 2b as can be appreciated from Fig. 3b).

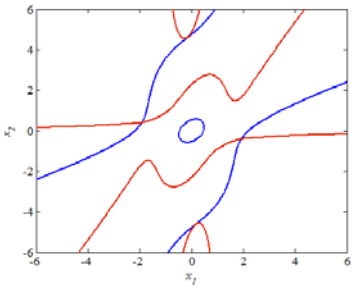
$$
\begin{aligned}
& c = \min_{\mathbf{x}} \; V(\mathbf{x}) \\
& s.t. \;\; \dot{V}(\mathbf{x}) = 0, \quad \mathbf{x} \neq \mathbf{0} && \text{a)} \\
& \nabla\left(V(\mathbf{x}) - c = 0\right) = \varepsilon \nabla\left(\dot{V}(\mathbf{x}) = 0\right) && \text{b)} \\
& D(\mathbf{x}) > 0 && \text{c)}
\end{aligned}
\tag{11}
$$

4. Application Example

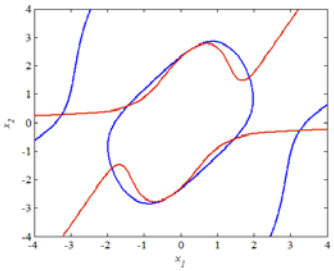
Formulation (11) is applied in this section to the determination of the DOA of a typical continuous stirred tank reactor. Consider the dynamic system of a typical CSTR described by mass and energy balances (12). Definitions and data are provided in Table 1. An estimation of the DOA of the steady state is calculated by solving problem (11) with Lyapunov function (13) ($x \equiv C_A$, $y \equiv T$).



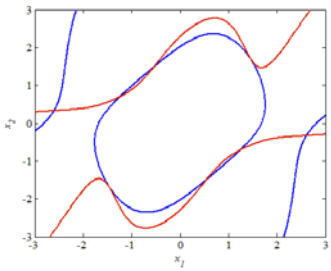
a) c = 0.1, x_1 = -1.9183, x_2 = 0.4052



b) c = 0.1287, x_1 = 0.1505, x_2 = -4.6180

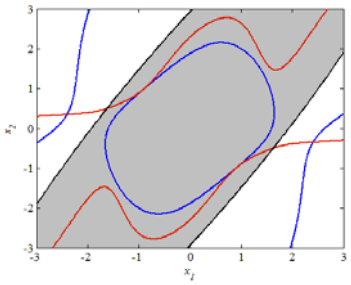


c) c = 4.7652, x_1 = -0.2962, x_2 = -2.5906

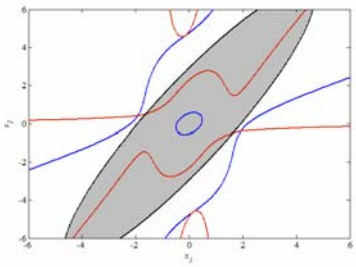


d) c = 2.8, x_1 = -1.4649, x_2 = -1.6832

Fig. 2: Dummy solutions for system (9)/(10)



a) Desired solution included



b) Dummy solution excluded

Fig. 3: Region D(**x**) > 0

$$\frac{dC_A}{dt} = \frac{F}{V}\left(C_{Af} - C_A\right) - k_0\, exp\left(\frac{-\Delta E}{RT}\right)C_A$$
$$\frac{dT}{dt} = \frac{F}{V}\left(T_f - T\right) + \left(\frac{-\Delta H}{\rho C_P}\right)k_0\, exp\left(\frac{-\Delta E}{RT}\right)C_A - \frac{UA}{V\rho C_P}\left(T - T_j\right) \quad (12)$$

$$N(x,y) = 325.4977x^2 + 71.4479xy + 4.2514y^2 + 69.4087x^3 + 22.9472x^2y + 2.1447xy^2 + 0.0404y^3 + 1.7325x^4 + 0.7648x^3y + 0.0591x^2y^2 0.0008xy^3 + 0.0005y^4$$
$$D(x,y) = 1 + 0.7341x + 0.0809y + 0.0877x^2 + 0.0195xy + 0.0007y^2 \quad (13)$$

Table 1: Nomenclature and data

Symbol	Description	Value
C_A	Concentration of A in reactor	2.3589
T	Reactor temperature	368.0629
k_0	Pre-exponential factor	9703*3600 h^{-1}
$-\Delta H$	Reaction heat	5960 kcal/kgmol
ΔE	Activation energy	11843 kcal/kgmol
ρCp	(Density)(heat capacity)	500 kcal/(m^3°C)
UA/V	(Hat transfer coefficient)(Area)/(Reactor Volume)	150 kcal/(m^3°C h)
R	Ideal gas constant	1.987 kcal/(kgmol K)
F/V	Residence time	1 h^{-1}
C_{Af}	Feed Concentration	10 kgmol/m^3
T_f	Feed Temperature	298 K
T_j	Jacket temperature	298 K

The problem was solved in the GAMS platform with the global optimization solver BARON (GAMS, 2008). The level sets of the Lyapunov function and its time derivative are shown in Fig. 4. The obtained estimation is the closed curve in blue around the equilibrium. $dV(\mathbf{x})/dt=0$ is shown in red and region $D(\mathbf{x}) > 0$ in gray.

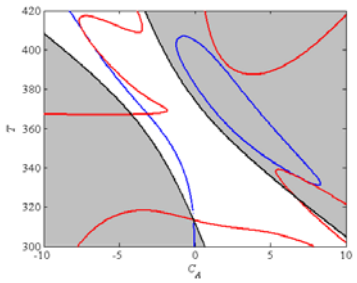


Fig. 4: Level sets $V(\mathbf{x}) = 639.5575$ and $dV(\mathbf{x})/dt = 0$ for system (12)/(13)

5. Conclusions

A global optimization formulation was proposed to estimate DOAs of stable equilibriums of systems of dynamic equations based on Lyapunov functions. In order to avoid potential dummy solutions, a tangency condition and a constraint on the denominator of $V(\mathbf{x})$ were added to previously published global optimization approaches. The rationale behind the proposed methodology was qualitatively described by means of a very rich example and also applied to a classic chemical engineering system.

Probabilistic modelling and stochastic dynamic optimization for managing abnormal situations in plant-wide operations

Yu Yang, Jong Min Lee

Chemical and Materials Engineering, University of Alberta, Edmonton, Alberta, T6G 2G6, Canada

Abstract

This study proposes a novel dynamic real-time optimization framework that detects abnormalities at their onset and calculates a new operating condition to contain their further development. The proposed approach utilizes operational data and constructs a probability transition matrix that describes transition probabilities among representative operating modes under uncertainties. A quantitative measure of risk is defined to strike a balance between risk and profit in decision making. An integrated plant example consisting of a reactor, a storage tank, and a separator with a recycle loop is presented to demonstrate the efficacy of the approach.

Keywords: self organizing map, approximate dynamic programming, real-time optimization, plant-wide control.

1. Introduction

With an ever increasing need for improving process efficiency and product quality in today's complex manufacturing environment, real-time optimization (RTO) is considered an essential technique for the operation of complex chemical plants. Steady-state model-based RTO has been the most popular technique due to its simplicity (Cutler and Perry, 1983). However, steady-state RTO may leave significant room for performance improvement because it ignores the dynamic degrees of freedom such as unused capacity of a buffer tank and provides infeasible operating strategies during certain time periods. On the other hand, full-scale dynamic plant-wide models were used for rigorous online dynamic optimization based on a nonlinear programming method (Biegler et al., 2001). This approach may not be scalable to practical plant-wide optimization problems due to its excessive computational requirements.

One common difficulty associated with the model-based methods is obtaining a reliable plant-wide dynamic model in the form of algebraic/differential equations, apart from its relevance to online optimization. Another key issue of a model-based approach is that uncertainties from various sources can seriously degrade the performance. For example, model uncertainty can lead to RTO solutions that are far from the true plant optimum, or even an infeasible solution with respect to actual process constraints. Furthermore, once such solutions implemented and early symptoms go unnoticed, abnormal situations may arise and lead to significant periods of off-spec products or plant shutdowns.

Dynamic programming (DP) offers a unified approach to solving dynamic optimization problems under uncertainty (Bertsekas, 2005). The DP algorithm decomposes a

stochastic dynamic optimization problem into a sequence of single-period sub-problems that are solved recursively backward in time. Central to the methodology is the "value" function, which is obtained via solving Bellman's equation. Since DP algorithms compute and store a table consisting of one value per state, the size of a state space typically grows exponentially in the number of state variables, referred to as the curse of dimensionality.

Recently, the approach of approximate dynamic programming (ADP) has received much attention in the community of operations research (Si et al., 2004) and has been introduced to process systems engineering field (Lee and Lee, 2006). In most ADP methods, the value table is constructed only for a small subset of states and a function approximator is used to estimate values for unvisited states. The sample points are determined by running simulations with some known or random policies. The goal of this contribution is to develop a novel ADP-based RTO framework suitable for a large-scale plant under uncertainty.

2. Background

2.1. Markov Decision Processes and Dynamic Programming

Markov decision process (MDP) is a general modeling framework for multistage optimal control problems under uncertainty. At each of a series of discrete time steps, the state of a system (x_t) is observed and used to select an action (u_t), which then causes the system to change state and emit a numerical reward, $r(x_t, u_t)$. In general, the system dynamics is probabilistic for systems under uncertainty:

$$p_t(x_{t+1} | x_t, u_t) \tag{1}$$

which gives the probability of being in state x_{t+1} at time t+1 when the system is in state x_t and the decision u_t is implemented at time t.

The objective is to find a policy that maximizes the total reward received. The trade-off between immediate and delayed reward is handled by a discount factor $\gamma < 1$. Then the *value* of following a policy π from a state x is defined as the expectation of the sum of the subsequent rewards, each discounted geometrically by its delay:

$$V^{\pi}(x) = E\left\{ \sum_{t=0}^{\infty} \gamma^t r\left(x_t, u_t\right) \middle| x = x_0 \right\} \tag{2}$$

An optimal policy, π^*, achieves $V^{\pi^*}(s) \geq V^{\pi}(s)$ $\forall \pi, s$. DP involves iteratively solving the following Bellman equation:

$$V^*(x_t) = \max_{u_t} E\left\{ r(x_t, u_t) + \gamma V^*(x_{t+1}) \right\} \tag{3}$$

Once V^* is obtained, the optimal decision is easy to find through the following single-stage optimization

$$u_t^* = \arg\max_{u_t} E\left\{ r(x_t, u_t) + \gamma V^*(x_{t+1}) \right\} \tag{4}$$

2.2. Approximate Dynamic Programming

In ADP, the optimal (or *nearly optimal*) value function is obtained by iteratively improving the initial estimate of optimal value function based on a set of sampled state points visited by simulation or real-operation. One of the simplest methods in ADP is temporal difference learning of order 0 (TD(0)), which simply performs an update as follows:

$$\tilde{V}(x_t) \leftarrow r(x_t, u_t) + \gamma \tilde{V}(x_{t+1}) \tag{5}$$

where $\tilde{V}$ is approximation of the optimal value function.

Another advantage of ADP in solving the Bellman equation is that it can be extended to the case where transition probability or process model is unknown. This is possible by encoding the optimal value function with state and action pair as follows:

$$Q^*(x_t, u_t) = E\left\{ r(x_t, u_t) + \gamma \max_{u_{t+1}} Q^*(x_{t+1}, u_{t+1}) \right\} \tag{6}$$

The optimal value function and the optimal action-value function have the relationship of $V^*(x) = \max_u Q^*(x, u)$. The optimal decision given x_t is simply obtained by solving

$$u_t^* = \arg\max_{u_t} Q^*(x_t, u_t) \tag{7}$$

3. Proposed RTO Framework

3.1. Construction of Markov Chain Model

The first step in the proposed approach is to model underlying behavior of plant-wide dynamics under uncertainties as a series of "representative" discrete states evolving over time without any predetermined equations. In order to characterize such representative states, we cluster process data using self-organizing map (SOM) (Kohonen, 2001). SOM creates an ordered set of states in one or more dimensions. This offers topological structure of data, which means data points that are closer to each other in high dimensional space will be projected to the neighboring clusters (or nodes) in low dimensional space.

Once the historical data set is divided into representative nodes, the probability transition matrix P and one step reward are computed. It is assumed that each unit can take a finite number of set-point values. Under a particular action vector u (i.e., a particular set of set points), the transition probability from a discrete node i to j is estimated as

$$P_{ij}^u = \frac{N_{ij}^u}{\sum_{k=1}^{n_T} N_{ik}^u} \tag{8}$$

where N_{ij}^u is the number of switches from the states belonging to the node i to those belonging to j under action u and n_T is the total number of discrete nodes. The one step reward R_{ij}^u, the reward incurred during the transition from i to j under action u, is estimated as

$$R_{ij}^u = \frac{\sum_{x_{ij}} r(x_{ij}, u)}{M} \tag{9}$$

where x is the state point that made a transition from node i to j under action u and M is the total number of transitions.

A special node, F, is also designed to represent "failure states" such as shutdown, reaction termination, or constraint violation. This node behaves like an absorbing state,

meaning that the system stays at the same state with probability of one. A negative one step reward should be assigned to this node due to the loss of performance.

Once the representative states and their transition probabilities are obtained, the optimal value for each cluster is obtained by iteratively solving the Bellman equation:

$$V^*(i) = \max_u E\left\{R_{ij}(i,u) + \gamma V^*(j)\right\} \tag{10}$$

3.2. Model Refinement

A group of data points with distinctive values from the majority of data points inside each node can occur, which will degrade the performance of RTO. In order to identify such "outliers," Q value of each process state and action pair is first estimated using

$$Q(x_t, u_t) = r(x_t, u_t) + \gamma V^*(j) \tag{11}$$

where j is a representative node containing x_{t+1}. The outliers are defined as the data points with Q values falling outside $[Q_1\text{-}1.5(Q_3\text{-}Q_1), Q_3\text{+}1.5(Q_3\text{-}Q_1)]$ (Tukey, 1977). Q_1 and Q_3 denote the first and the third quartiles, respectively.

As the outliers are detected successively in each node, simple hyper-spheres are constructed to represent the area of outliers for fast classification in real-time applications. The center of each hyper-sphere is the current outlier, and the radius is the distance between that outlier data and its nearest "normal" data. Since the probabilistic model is not valid for outliers any more, a model-free approach is employed to estimate a new value for each outlier. Once the radius and centroid of hyper-sphere is defined, the data points belonging to the area are counted and their action-values $Q(x, u)$ are computed by the following model-free update scheme:

$$Q(x_t, u_t) \leftarrow Q(x_t, u_t) + \alpha\left\{r(x_t, u_t) + \gamma Q(x_{t+1}, u_{t+1}) - Q(x_t, u_t)\right\} \tag{12}$$

where α is a step-size parameter less than 1. The model refinement step can be performed both off-line (i.e., using the historical data only) and online (i.e., when the optimizer is put to work). The transition matrix, optimal value for each node, and action-values for outliers are updated online as a new observation is available at each time step.

3.3. Quantitative Risk Term

The proposed method designs a special node, F, to represent failure states and assigns a negative value V_F. The policy derived from the learned value and action-value functions with V_F will strike a balance between total reward and the risk of entering undesirable states. In this work, V_F is assigned by

$$V_F = \frac{(D+1)\underline{r} - D\overline{r}}{\gamma(1-\gamma)} \tag{13}$$

where D is a user-specified parameter, $\underline{r}$ and $\overline{r}$ are lower and upper bounds of single-stage reward, respectively. The detailed discussion on how to derive Eq. (12) is provided in Yang and Lee (2009).

4. Case Study

An integrated process studied in Tosukhowong et al. (2004) is considered to illustrate the efficacy of the proposed framework. The process is composed of a CSTR, a storage tank, and a flash tank with a material recycle stream as shown in Fig. 1. A fresh feed

stream F_0 consisting of pure component 1 is fed to the reactor, where two irreversible reactions take place to produce the desired product 2 and undesired product 3. Detailed model descriptions can be found in Tosukhowong et al. (2004).

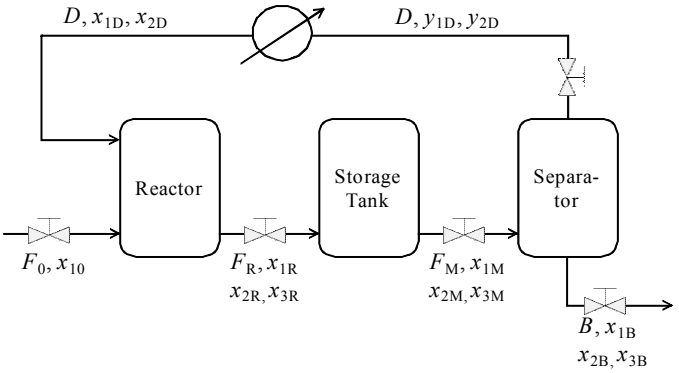

Figure 1. Schematic of the reaction-storage-separation network.

Three proportional-only (P) controllers are designed to control liquid level of each unit, and inappropriate assignment of a set point trajectory to each unit may lead to instability or significantly reduced performance under uncertainty in the inlet flow and kinetic parameters. Use of more sophisticated local controllers than P-controller may enhance the plant-wide performance. However, the question here is how to improve the plant-wide performance given the existing local controllers by coordinating operating conditions of each unit.

The objective of plant-wide optimization is to maximize the production of desired product formulated as

$$\max \sum_{t=1}^{\infty} 0.9^{t-1} B(t) x_{2B}(t) \tag{14}$$

The time interval of dynamic optimization is set as 40 minutes as suggested in Tosukhowong et al. (2004). In each episode of simulation, a sequence of random set points was used for each unit for six hours. Every 100-200 minutes, F_0 and the kinetic parameters were alternating between upper and lower bounds ($1.45 \leq F_0 \leq 1.85$, $0.01 \leq k \leq 0.03$) with their nominal values 1.667 and 0.0167, respectively.

From the data, the SOM structure with 7×3 was selected considering the number of outliers. With the 21 clusters, the single-stage reward and the transition matrices were calculated. V_F was estimated as -1478 with γ and D set as 0.9 and 4, respectively.

For comparison with steady state RTO and dynamic RTO proposed in Tosukhowong et al. (2004), 300 episodes of simulation scenarios different from the training ones were executed. As inappropriate set points will lead to total drainage of storage tank and plant shutdown, the ratio of failing optimization are compared in Fig. 2. Fig. 3 shows one of the sample realizations in the test. The production of x_{1B} is interrupted (a negative value) at 250th sample time under the dynamic RTO.

5. Conclusions

The proposed approach is based on a Markov chain model and approximate dynamic programming and provides a more robust and risk-averse policy compared to other

deterministic model-based approaches. This method can be applied to any dynamic optimization problems when a process model is difficult to obtain, which is likely for large-scale problems, and uncertainties affect operations significantly.

Abstract

A robust nonlinear model predictive control (NMPC) algorithm is developed based on a multi-scenario formulation. The uncertainties are characterized by different scenarios so that the calculated control action is feasible over the entire uncertainty region. We show that this multi-scenario formulation is Input-to-State practically Stable (ISpS), and can be easily extended to the recently proposed advanced-step NMPC (as-NMPC), which is able to reduce the online computational delay. We demonstrate the advantages of this strategy on a large-scale air separation unit.

Keywords: NMPC, Robust strategy, large-scale applications

1. Introduction

Nonlinear model predictive control (NMPC) has recently received a great amount of attention, especially for energy and chemical processes that require dynamic real-time optimization (D-RTO). Moreover, a recent vehicle for D-RTO deals with advanced-step Nonlinear Model Predictive Control (as-NMPC) (Zavala & Biegler, 2008), which incorporates very large dynamic optimization problems and can reduce the on-line feedback delay to only a few CPU seconds, even with industrial-size first principle dynamic models.

On the other hand, ensuring stability of closed-loop systems with faults and model mismatch remains an important problem in NMPC. While nominal stability and feasibility have been extensively addressed in the past decades (Magni & Scattolini, 2007, Limon et al, 2008), NMPC with asymptotic stability does not guarantee robust stability and large unmeasured disturbances can lead to poor performance for D-RTO. In these cases, robust design strategies are necessary to account for uncertainties explicitly in the controller formulation. A well known strategy to guarantee the robust stability is the min-max NMPC formulation, which computes the best control policy based on the worst expected realization of the uncertainties. However this formulation dramatically increases the computational cost of the on-line NMPC problem, despite some recent remedies (Diehl et al, 2008, Fontes & Magni, 2003). Moreover, since the control action is based on the worst case, the performance is compromised, e.g. output variables present large offset.

In this work, we propose a robust NMPC design strategy based on multi-scenario NLP formulation and extend it to as-NMPC. The robust stability can be established through the recent input-to-state practical stability (ISpS) framework (Limon et al, 2008). Section 2 presents the multi-scenario formulation for NMPC and as-NMPC and analyze their robust stabilities; section 3 shows that the proposed method is suitable for real world systems by considering a large-scale air separation unit with plant-model mismatches; section 4 concludes the paper.

2. NMPC based on Multi-scenario formulation and Stability Analysis

2.1. Multi-scenario Formulation

In this work, the dynamics of an uncertain plant will be described by the following discrete-time model,

$$x(k+1) = f(x(k), u(k), \phi(k)),\ k \geq 0 \tag{1}$$

where $x(k) \in \mathfrak{R}^{n_x}$ is a system state vector, $u(k) \in \mathfrak{R}^{n_u}$ is a control variable vector and $\phi(k) \in \mathfrak{R}^{n_\phi}$ is an uncertainty signal which models disturbances and plant-model mismatches at time steps $k > 0$. For the sake of clarity, we only consider the state-independent uncertainty signals in this work, i.e. $\phi(k)$ does not depend on $x(k)$ and $u(k)$. However with slight modification of notations, the analysis here can be extended to the case with state-dependent uncertainties. In general, the control and state of the plant are required to fulfill the constraints, e.g. $x(k) \in \mathbb{X},\ u(k) \in \mathbb{U}$, and only the partial information of the uncertainty $\phi(k) \in \mathbf{\Omega}$ is available, e.g. its feasible region Ω. Without losing generality, we assume that the given plant (1) has an equilibrium point at the origin, i.e. $f(0,0,0) = 0$.

Given $x(k)$, the current state value at time step t_k, the NMPC formulation can be described in the following discretized form:

$$\min_{z(j),v(j)}\ J(x(k)) := F(z(N)) + \sum_{j=0}^{N-1} \varphi(z(j), v(j), \theta(j)) \tag{2a}$$

$$s.t.\ z(j+1) = f(z(j), v(j), \theta(j)),\ z(0) = x(k) \tag{2b}$$

$$z(j) \in \mathbb{X},\ z(N) \in \mathbb{X}_f,\ v(j) \in \mathbb{U},\ \theta(j) \in \mathbf{\Omega},\ j = 0, \ldots N-1 \tag{2c}$$

where N is the finite time horizon, $\theta \in \Omega$ is the uncertainty parameter in the controller. The computed control $v(j) \in \mathfrak{R}^{n_u}$ and predicted state $z(j) \in \mathfrak{R}^{n_x}$ are enforced to satisfy the constraints $v(j) \in \mathbb{U}$, $z(j) \in \mathbb{X}$, $z(N) \in \mathbb{X}_f$. The cost function $J(x(k))$ at t_k comprises stage cost $\varphi(\cdot,\cdot,\cdot)$ and terminal penalty cost $F(\cdot)$. When the solution sequence $(z^*(l), v^*(l))$ is available, the first control $u(k) = v^*(0)$ is injected into the plant. In general, $x(k+1)$ is different from the predicted value because of the plant-model mismatches, (e.g.$\theta \neq \phi$). At the next time step t_{k+1} when $x(k+1)$ is measured or estimated, we move the time horizon one step further and solve problem (2) again.

If the presence of uncertainties does not cause any loss of feasibility (e.g. no constraints), the NMPC (2) enjoys inherent robustness (Magni & Scattolini, 2007). However if the constraints are enforced and uncertainties are present, the calculated control v from (2) may be infeasible for the plant (1). To avoid this difficulty, we solve a multi-scenario problem:

$$\min_{z_l(j),v(j)}\ V(x(k)) := \sum_{l=1}^{M} w_l J_l(x(k))$$

$$= \sum_{l=1}^{M} w_l \left\{ F_l(z_l(N)) + \sum_{j=0}^{N-1} \varphi(z_l(j), v(j), \theta_l) \right\} \tag{3a}$$

$$s.t.\ z_l(j+1) = f(z_l(j), v(j), \theta_l),\ z_l(0) = x(k),\ l = 1, \ldots M \tag{3b}$$

$$z_l(j) \in \mathbb{X},\ z_l(N) \in \mathbb{X}_f,\ v(j) \in \mathbb{U},\ \theta_l \in \mathbf{\Omega},\ j = 0, \ldots N-1, \tag{3c}$$

with M different uncertainties $\theta_l, l \in 1, \ldots, M$, where l is the index of scenarios and w_l are weights for each scenario, satisfying $0 \leq w_l \leq 1,\ \sum_{l=1}^{M} w_l = 1$. In addition, consider $B_{\delta l}$ as M closed balls, $B_{\delta l} \triangleq \{\vartheta_l \in \Omega | |\vartheta_l - \theta_l| \leq \delta_l\},\ \forall l \in 1 \ldots M$, centered around q_l with radius δ_l. The balls $B_{\delta l}$ are defined such that an NMPC formulated with

θ_l as nominal model parameter is robustly stable within this ball. We will prove that the control sequence $v(\cdot)$ calculated from (3) remains feasible and stable for all the uncertainty regions $B_{\delta_l}, \forall l$. If $\phi(j) \in \bigcup_{l=1}^{M} B_{\delta l}, \forall j$, then the closed-loop system is robustly stable.

2.2. Robust Stability Analysis

For the analysis of the robust stability of multi-scenario NMPC, we make use of the regional input-to-state practical stability (ISpS) property developed in Limon et al, 2008. Here, we only summarize key definitions and results.

Definition 1. *Given a set $\Gamma \subseteq \Re^{n_x}$, including the origin as an interior point, the system (1) is said to be ISpS in Γ w.r.t ϕ, if Γ is a robust positive invariant set for (1) and there exist a $\mathcal{KL}$ function β, a $\mathcal{K}$ function γ and a constant $c \geq 0$ such that,*

$$|x(k)| \leq \beta(|x_0|, k) + \gamma(|\phi_{(k-1)}|) + c, k \geq 0, \ \forall x_0 \in \Gamma, \ \phi(k) \in \mathbf{\Omega} \tag{4}$$

with $|\phi_{(k-1)}| \triangleq sup_{k\geq 0}\{|\phi(k-1)|\}$. Moreover, a function $V(\cdot)$ is an ISpS-Lyapunov function for system (1) in Γ if there exist $\mathcal{K}$ functions α_1, α_2, α_3, σ and constants $c_1, c_2 \geq 0$ such that:

$$\alpha_2(|x|) \leq V(x) \leq \alpha_2(|x|) + c_1, \ \forall x \in \Gamma$$
$$\triangle V(x, \phi) = V(f(x, u, \phi)) - V(x) \leq -\alpha_3(|x|) + \sigma(|\phi|) + c_2, \forall x \in \Gamma, \ \forall \phi \in \mathbf{\Omega} \tag{5}$$

Lemma 1. *If (1) admits an ISpS-Lyapunov function in Γ, then it is ISpS in Γ w.r.t ϕ.*

In order to deal with the multi-scenario formulation, the common robust stability assumptions (Magni & Scattolini, 2007, Zavala & Biegler 2008, Limon et al, 2008) are modified as follows.

Assumption 1 *(Assumptions for Multi-scenario Formulation and Robust Stability)*

a) There exists a constant $c_3 \geq 0$, that the terminal penalty $F_l(\cdot)$ satisfy $\alpha_F(|x(k)|) \leq F_l(x(k)) \leq \gamma_F(|x(k)|) + c_3, \ \forall l, \ \forall x \in \mathbb{X}_f \subseteq \Gamma, \ \alpha_F(\cdot)$ and $\gamma_F(\cdot)$ are $\mathcal{K}$ functions.

b) There exists a local control law $h_f(z_l(N))$ defined on $\mathbb{X}_f \subseteq \Gamma$, such that $f(z_l(N), h_f(z_l(N)), \theta_l) \in \mathbb{X}_f, \forall z_l(N) \in \mathbb{X}_f$, and $F_l(f(z_l(N), h_f(z_l(N)), \theta_l)) - F_l(z_l(N)) \leq -\varphi(z_l(N), h_f(z_l(N)), \theta_l), \ \forall l$.

c) $\alpha_p(|x(k)|) \leq \varphi(x(k), u(k), \theta(k)) \leq \alpha_q(|x(k)|) + c_4, \forall \theta(k) \in \mathbf{\Omega}$, for some constant $c_4 \geq 0$ with $\alpha_p(\cdot)$, $\alpha_q(\cdot)$ as $\mathcal{K}$ functions.

d) Given $u(k)$ and $z_l(k+1) = f(x(k), u(k), \theta_l)$ for each scenario l, there exist future mismatches at the next sampling time:

$$\epsilon_l(x(k+1)) := J_l(x(k+1)) - J_l(z_l(k+1)) \ \forall l \tag{6}$$

with $\mathcal{K}$ functions α_4, σ_2 and positive Lipschitz constants L_ϵ such that $|\epsilon_l(x(k+1))| \leq L_\epsilon(\alpha_4(|x(k)|) + \sigma_2(|\theta_l - \phi(k)|))$.

e) For a constant $c_5 \geq 0$, $\mathcal{K}$ functions α_5 and $\theta_l \in \Omega, \ \forall l$, there exists a constant $K \geq 0$ such that:

$$\sum_{l=1}^{M} w_l \Big[-\varphi(x(k), u(k), \theta_l) + K(\alpha_4(|x(k)|) + \sigma_2(|\theta_l - \phi(k)|)) \Big]$$
$$\leq -\alpha_5(|x(k)|) + \sigma_1(|\phi(k)|) + c_5 \tag{7}$$

Robust stability of multi-scenario NMPC can now be established by the following theorem.

Theorem 1 *(Robust ISpS stability of Multi-scenario NMPC) If the plant uncertainty parameter vector lies in the union of balls centered around the uncertainty parameters in the controller, i.e.* $\phi(j) \in \bigcup_{l=1}^{M} B_{\delta l}, \forall j$*, then under Assumption 1, with* $K \geq L_\epsilon$*, the cost function* $V(x(k)) = \sum_{l=1}^{M} w_l \big[F_l(z_l(N)) + \sum_{j=0}^{N-1} \varphi(z_l(j), v(j), \theta_l)\big]$ *is an ISpS-Lyapunov function for plant (1) in* Γ *and the resulting closed loop system is ISpS stable.*

Proof. First let $u(k)$ be the first element of the control sequence calculated from (3) based on $x(k)$ at t_k, There exists a $\theta_{min}(k) \in \mathbf{\Omega}$ so that $\varphi(x(k), u(k), \theta_l) \geq \varphi(x(k), u(k), \theta_{min}(k)), \forall \theta_l \in \mathbf{\Omega}$ for the fixed $x(k)$ and $u(k)$, then

$$\begin{aligned} V(x(k)) &= \sum_{l=1}^{M} w_l \left\{ F_l(z_l(N)) + \sum_{j=0}^{N-1} \varphi(z_l(j), v(j), \theta_l) \right\} \\ &\geq \sum_{l=1}^{M} w_l \sum_{j=0}^{N-1} \varphi(z_l(j), v(j), \theta_l) \\ &\geq \sum_{l=1}^{M} w_l \varphi(x(k), u(k), \theta_{min}(k)) \geq \alpha_p(|x(k)|) \end{aligned} \tag{8}$$

the last two inequalities follow from letting $j = 0$ and Assumption 1.c).

Then we consider the multi-scenario NMPC with horizon N+1, its objective function is

$$V(x(k), N+1) = V(x(k), N) + \sum_{l=1}^{M} w_l \big[- F_l(z_l(N)) +$$

$$F_l(f(z_l(N), h_f(z_l(N)), \theta_l)) + \varphi(z_l(N), h_f(z_l(N)), \theta_l)\big] \leq V(x(k), N) \tag{9}$$

the inequality is from Assumption 1.b). So that

$$\begin{aligned} V(x(k), N+1) &\leq V(x(k), N) \leq \ldots \leq V(x(k), 0) \\ &= \sum_{l=1}^{M} w_l F_l(x(k)) \leq \gamma_F(|x(k)|) + c_3 \end{aligned} \tag{10}$$

the last inequality is from Assumption 1.a).

Finally, we are able to compare the cost function $V(x(k+1))$ and $V(x(k))$ from the two neighboring problems with horizon length N,

$$\begin{aligned} &V(x(k+1)) - V(x(k)) \\ &= \sum_{l=1}^{M} [w_l J_l(z_l(k+1))] - V(x(k)) + V(x(k+1)) - \sum_{l=1}^{M} [w_l J_l(z_l(k+1))] \\ &= \sum_{l=1}^{M} w_l [J_l(z_l(k+1)) - J_l(x(k))] + \sum_{l=1}^{M} w_l \epsilon_l(x(k+1)) \end{aligned} \tag{11}$$

From Assumption 1.b), we know $J_l(z_l(k+1)) - J_l(x(k)) = F_l(f(z_l(N), h_f(z_l(N)), \theta_l)) - F_l(z_l(N)) + \varphi(z_l(N), h_f(z_l(N)), \theta_l) - \varphi(x(k), u(k), \theta_l) \leq -\varphi(x(k), u(k), \theta_l), \forall l$. Consequently

$$\begin{aligned} &V(x(k+1)) - V(x(k)) \leq \sum_{l=1}^{M} w_l [-\varphi(x(k), u(k), \theta_l) + \epsilon_l(x(k+1))] \\ &\leq \sum_{l=1}^{M} w_l \Big[- \varphi(x(k), u(k), \theta_l) + L_\epsilon(\alpha_4(|x(k)|) + \sigma_2(|\theta_l - \phi(k)|)) \Big] \end{aligned} \tag{12}$$

where (12) follows from Assumption 1.d). With $K \geq L_\epsilon$ and Assumption 1.e),

$$V(x(k+1)) - V(x(k)) \leq -\alpha_5(|x(k)|) + \sigma_1(|\phi(k)|) + c_5 \tag{13}$$

The desired result follows as (8), (10) and (13) allow *x(k)* and *V* to satisfy (4) and (5). ?

Note from the analysis, the robust stability is guaranteed when $\phi(j) \in \bigcup_{l=1}^{M} B_{\delta l}, \forall j$, we also see that the it will improve if the majority of the uncertainty parameters in the controller are close to that in the plant. In practice, since the plant uncertainty parameter is unknown, the multi-scenario NMPC can be initiated with a few guessed parameters, if the controller appears to be unstable, more scenarios should be added to make sure that the plant uncertainty ϕ is in the neighborhood of one uncertainty parameter θ_l, hence the robust stability is achieved.

2.3. Multi-scenario for as-NMPC

Although the multi-scenario formulation can improve robust stability, it may introduce large computational delay online. In order to reduce the online computational delay, we modify the algorithm of the advanced-step NMPC (Zavala & Biegler, 2008) to incorporate the multi-scenario formulation, as follows:

1. Background calculation: at t_k, predict the future state $z_l(k+1)$ with $x(k)$ and $u(k)$ for each scenario *l*. Solve problem (3) with $z_l(k+1)$ as the initial condition for each scenario *l*. The NLP solver takes a Newton step, which can be expressed as:

$$K(z_l(k+1))\triangle s = -\varphi(z_l(k+1)) \tag{14}$$

where s is the solution vector and Δs represents the Newton step from the current solution towards the new point, $K(\cdot)$ and $\varphi(\cdot)$ are the KKT matrix and KKT condition at current solution, respectively.

2. Online update: at t_{k+1}, obtain $x(k+1)$ and use (14) to get the updated solution: $K(z_l(k+1))\triangle s = -\varphi(x(k+1))$. Extract control action $u(k+1)$ and inject into plant.

3. Iterate: set $k \leftarrow k+1$, and go to step 1.

Note that the KKT matrix in (14) has already been factorized in solving (14), so only a single back-solve is required in Step 2; this is at least two orders of magnitude faster than solving the optimization problem (3). Along the same lines, we can derive a similar but weaker ISpS property for multi-scenario as-NMPC, where the online update leads to only a small deterioration of the stability property.

3. Simulation examples

We now revisit the large-scale air separation unit reported in Huang et al, 2009 with plant-model mismatches. In this work, we modify the ASU model to introduce a tray efficiency, which is considered as an uncertain parameter. In this simulation, we assume that the true value of tray efficiency is $\alpha = 0.8$ and the ASU starts from a nominal steady-state. The oxygen (POX) and nitrogen production (PNI) rate set-points are reduced by *30%* through a ramp change from $t = 30$ to $t = 60$ minutes, while temperatures (Tl30 & Th15) are required to remain constant to control the product purities. After this, they undergo a ramp increase from $t = 1000$ to $t = 1030$ back to their original values. The NMPC formulation with $\alpha = 0.9$ or $\alpha = 1$, and multi-scenario NMPC with two scenarios $\alpha = 0.9$ and $\alpha = 1$ yield infeasible control actions. Hence, we choose equally weighted three scenarios with $\alpha_1 = 0.8$, $\alpha_2 = 0.9$ and $\alpha_3 = 1$ in the multi-scenario as-NMPC. Figure 1 shows that it is able to track the output variables with stable control actions and product purities are satisfied. Moreover multi-scenario as-NMPC yields nearly the same performance as the ideal multi-scenario NMPC. Without plotting results, the same NMPC formulation is robustly stable for cases where tray efficiency equals to 0.85, 0.95 and 1. After discretization, the optimization problem with three scenarios leads to a NLP contains 350,940 variables and 350,700 constraints. The simulation was done on an Intel Quad Core @ 2.4GHz server running Linux. For each horizon, IPOPT took 20-30 CPU minutes for the background calculation, while

sensitivity update took around 2 CPU seconds. Note online computation time is reduced by at least 600 times with virtually no loss in performance.

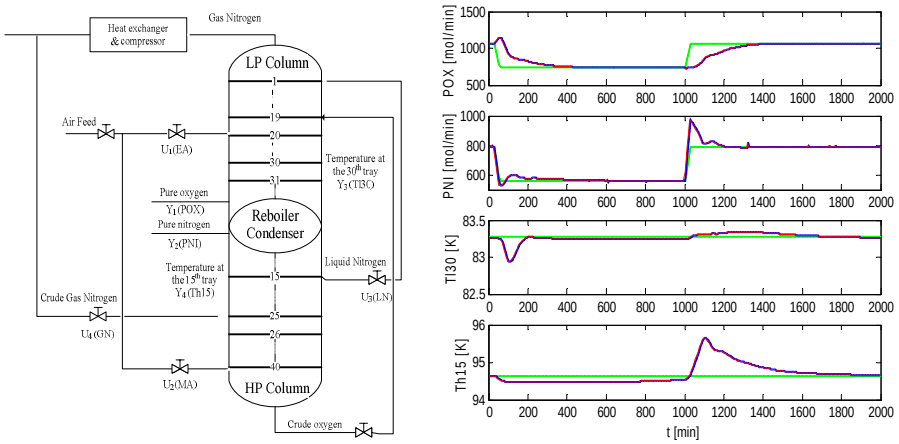

Figure 1. ASU flowsheet and output variable profiles. Dash-dotted- lines are setpoints, superimposed dashed and solid lines are multi-scenario NMPC and as-NMPC, respectively.

4. Concluding Remarks

In this study a robust NMPC strategy based on multi-scenario formulation is presented. This strategy solves multiple problems with different uncertainty parameters to guarantee the satisfaction of constraints. We establish the input-to-state practical stability of this formulation for both NMPC and as-NMPC. The advantages of the proposed method are demonstrated by simulation of a large-scale ASU. In addition the multi-scenario as-NMPC presents nearly the same performance as the NMPC counterpart, but dramatically reduces the online computation delay. For the future work, we propose to study the strategies that allow the background solution taking more than one sampling time while still providing instantaneous on-line update. Besides parallel computing with distributed computer cluster will be studied to future reduce the background computational effort. Moreover we will explore methods to reduce the number of scenarios needed to guarantee the robust stability, e.g. back-off constraints.

Abstract

Moving horizon estimation (MHE) is increasingly being used for state estimation in model predictive control schemes. Approximation of the arrival cost in MHE formulation is an open issue in this domain. In this work, we propose to use a constrained particle filter for estimating the moments of the prior probability density function of the initial state and approximating the arrival cost. The efficacy of the proposed approach is illustrated in a simulation case study on a benchmark problem.

Keywords: Moving Horizon Estimation, Arrival Cost, Constrained Ensemble Kalman Filter

1. Introduction

Moving horizon estimation is a preferred approach for state estimation particularly when used in connection with model predictive control schemes (Zavala and Biegler, 2008). The main advantage of MHE is that it can handle bounds on state and parameter estimates or irregular measurements in a systematic manner. Moreover, it provides a unifying framework for state estimation in systems described by differential algebraic equations or hybrid systems. Recent focus of research in this area has been on development of computationally efficient algorithms for on-line implementation (Zavala and Biegler, 2008). An important aspect of MHE formulation is estimation of the arrival cost. In a recent review paper, Bakshi and Rawlings (2006) have indicated that best choice of the arrival cost remains an open issue in the domain of MHE research. As the true arrival cost is difficult to determine, it is often estimated using linearization approximation as in the extended Kalman filtering (EKF) formulation. This method of approximating the arrival cost, however, does not consider the bounds on state estimates in a systematic manner.

Recently, a new class of recursive Bayesian filtering technique, called particle filtering, has attracted attention of many researchers (Rawlings and Bakshi, 2006). The objective of the recursive Bayesian state estimation problem is to find the mean and variance of the random state variable using its probability density function conditioned on the past measurements. While dealing with nonlinear systems, the exact analytical solution to the recursive propagation of the posterior density is difficult to obtain. Thus, it becomes necessary to develop approximate and computationally tractable sub-optimal solutions to the sequential Bayesian estimation problem. The particle filter is a numerical method for implementing an optimal recursive Bayesian filter through Monte-Carlo simulation. Thus, even when the state estimation error has multimodal and non-Gaussian distributions, a particle filter formulation can accurately estimate its moments. Ensemble Kalman filter (EnKF) developed by Evenson (2003) is a form of particle filter that retains the computational simplicity of EKF without requiring linearization or

normality of the conditional density function. However, as proposed, EnKF formulation cannot deal with bounds on states or parameters. Recently, Prakash et al. (2007) have developed constrained version of ensemble Kalman filter (C-EnkF), which provides a systematic and statistically consistent approach to deal with bounds on the state estimates. In the present work, we exploit this feature of C-EnKF for approximating the arrival cost in the MHE formulation. The efficacy of the proposed approach is illustrated by conducting simulation studies on a benchmark problem in the state estimation literature.

2. Review of MHE and C-EnKF

2.1. Preliminaries

Consider a nonlinear system represented by the following nonlinear state space equations:

$$\mathbf{x}(k) = F\left[\mathbf{x}(k-1), \mathbf{u}(k-1)\right] + \mathbf{w}(k-1) \tag{1}$$

$$\mathbf{y}(k) = H\left[\mathbf{x}(k)\right] + \mathbf{v}(k) \tag{2}$$

In the above process model, $\mathbf{x}(k) \in R^n$ is the system state vector, $\mathbf{u}(k) \in R^m$ is known system input, $\mathbf{w}(k) \in R^p$ is the state noise with known distribution, $\mathbf{y}(k) \in R^r$ is the measured state variable and $\mathbf{v}(k) \in R^r$ is the measurement noise with known distribution. The index k represents the sampling time. The operators $F[.]$ and $H[.]$ represent the nonlinear process model and nonlinear measurement model, respectively. It is further assumed that the initial state of the system $\mathbf{x}(0)$ is a random vector with known probability distribution.

2.2. Moving Horizon Estimation

In most physical systems, states/parameters are bounded, which introduces constraints on state/parameter estimates. One major limitation of recursive nonlinear filters is that these formulations cannot handle such constraints. Moving horizon estimation (MHE) (Bakshi and Rawlings, 2006) formulation provides a systematic approach to handling of bounds on states/parameters or any other algebraic constraints. The MHE problem can be stated as (Bakshi and Rawlings, 2006)

$$\underset{\mathbf{x}(k-N:k)}{Min} \; \Pi\left[\mathbf{x}(k-N)\right] + \sum_{i=k-N+1}^{k} \left\{\log\left[p\left(\mathbf{w}(i-1)\right)\right] + \log\left[p\left(\mathbf{v}(i)\right)\right]\right\} \tag{3}$$

$$\text{subject to model equations (1) and (2) and} \quad \mathbf{x}_L \le \mathbf{x}(i) \le \mathbf{x}_U \tag{4}$$

where, $p(.)$ denotes the probability density function of the argument. The term $\Pi\left[\mathbf{x}(k-N)\right]$, called the *arrival cost*, represents the negative log of the conditional density $p\left[\mathbf{x}(k-N) \mid \mathbf{Y}_{k-N}\right]$ where $\mathbf{Y}_{k-N} = \left\{\mathbf{y}(1), ...\mathbf{y}(k-N)\right\}$. The arrival cost represents the information in the prior measurement sequence $\mathbf{Y}_{k-N}$ that is not considered in the horizon at time k (Bakshi and Rawlings, 2006). The main difficulty with the arrival cost term is that, except for the linear unconstrained case, the conditional density $p\left[\mathbf{x}(k-N) \mid \mathbf{Y}_{k-N}\right]$ cannot be easily characterized using closed form algebraic expressions.

In most practical situations, the probability density functions of the state noise and the measurement noise can be well approximated using Gaussian density functions. In addition, if we further assume that the *a-priori* estimate is normally distributed

$\mathbf{N}(\hat{\mathbf{x}}(k-N), \mathbf{P}(k-N))$ such that covariance $\mathbf{P}(k-N)$ is invertible, then the MHE objective function can be reformulated as follows

$$\underset{\Omega_k}{Min}\ \Phi\left[\mathbf{x}(k-N)\right] + \sum_{i=k-N+1}^{k}\left[\mathbf{w}(i-1)^T Q^{-1}\mathbf{w}(i-1) + \mathbf{v}(i)^T \mathbf{R}^{-1}\mathbf{v}(i)\right] \quad (5)$$

$$\Omega_k \equiv \left\{\mathbf{x}(k-N), \mathbf{w}(n-N+1), \ldots \mathbf{w}(k-1)\right\}$$

$$\Phi\left[\mathbf{x}(k-N)\right] = \boldsymbol{\varepsilon}(k-N)^T \mathbf{P}(k-N)^{-1}\boldsymbol{\varepsilon}(k-N) + \Phi^*\left[\mathbf{x}(k-N)\right] \quad (6)$$

$$\boldsymbol{\varepsilon}(k-N) = \mathbf{x}(k-N) - \hat{\mathbf{x}}(k-N)$$

where $\mathbf{w}(k) \sim \mathbf{N}(\bar{\mathbf{0}}, \mathbf{Q})$, $\mathbf{v}(k) \sim \mathbf{N}(\bar{\mathbf{0}}, \mathbf{R})$ and $\Phi^*\left[\mathbf{x}(k-N)\right]$ represents the optimal cost at time *(k - N).* Similar to extended Kalman filter, an approximation for the covariance $\mathbf{P}(k-N)$ can be constructed by solving the Riccati equations with local linearization of operators F[.] and H[.] (Bakshi and Rawlings, 2006; Zavala et al., 2008).

2.3. Constrained Ensemble Kalman Filter

The filter is initialized by drawing N samples $\hat{\mathbf{x}}^{(i)}(0\,|\,0)$ from the given distribution. At each time step, N samples $\left\{\mathbf{w}^{(i)}(k), \mathbf{v}^{(i)}(k) : i = 1,2,\ldots N\right\}$ are drawn randomly using the distributions of the state noise and the measurement noise. These sample points together with particles $\left\{\hat{\mathbf{x}}^{(i)}(k-1\,|\,k-1) : i = 1,2,\ldots N\right\}$ are then propagated through the system dynamics to obtain transformed particles as follows:

$$\mathbf{x}^{(i)}(k\,|\,k-1) = F\left[\mathbf{x}^{(i)}(k-1\,|\,k-1), \mathbf{u}(k-1)\right] + \mathbf{w}^{(i)}(k-1) \quad (7)$$

for i = 1,2,…N. The transformed sample points that violate the bounds are projected on the constraint boundary to obtain a cloud of predicted particles

$\left\{\hat{\mathbf{x}}_c^{(i)}(k\,|\,k-1) : i = 1,2,\ldots N\right\}$) where $\hat{\mathbf{x}}_c^{(i)}(k\,|\,k-1) = \mathbf{P}_r\left[\hat{\mathbf{x}}^{(i)}(k\,|\,k-1)\right]$ (8)

and $\mathbf{P}_r[.]$ represents the projection operator. The sample covariance is estimated as

$$\bar{\mathbf{x}}_c(k\,|\,k-1) = (1/N)\sum_{i=1}^{N}\hat{\mathbf{x}}_c^{(i)}(k\,|\,k-1) \quad (9)$$

$$\mathbf{P}(k\,|\,k-1) = (1/N)\sum_{i=1}^{N}\boldsymbol{\varepsilon}^{(i)}(k\,|\,k-1)\left[\boldsymbol{\varepsilon}^{(i)}(k\,|\,k-1)\right]^T \quad (10)$$

where $\boldsymbol{\varepsilon}^{(i)}(k\,|\,k-1) = \hat{\mathbf{x}}_c^{(i)}(k\,|\,k-1) - \bar{\mathbf{x}}_c(k\,|\,k-1)$. The updated state estimates are then obtained by solving the following set of constrained optimization problems

$$\underset{\mathbf{x}(k)}{Min}\ \left[\boldsymbol{\xi}^{(i)}(k)^T \mathbf{P}(k\,|\,k-1)^{-1}\boldsymbol{\xi}^{(i)}(k) + \mathbf{e}^{(i)}(k)^T \mathbf{R}^{-1}\mathbf{e}^{(i)}(k)\right] \quad (11)$$

$$\boldsymbol{\xi}^{(i)}(k) = \mathbf{x}(k) - \mathbf{x}_c^{(i)}(k\,|\,k-1) \quad ; \quad \mathbf{e}^{(i)}(k) = \mathbf{y}(k) - H\left[\mathbf{x}(k) + \mathbf{v}^{(i)}(k)\right]$$

subject to constraints $\mathbf{x}_L \le \mathbf{x}(k) \le \mathbf{x}_U$. The solutions of the above set of optimization problems yields updated particles $\left\{\hat{\mathbf{x}}^{(i)}(k\,|\,k) : i = 1,2,\ldots N\right\}$. The updated state estimate is then computed as follows

$$\bar{\mathbf{x}}(k\,|\,k) = (1/N)\sum_{i=1}^{N}\hat{\mathbf{x}}^{(i)}(k\,|\,k) \quad (12)$$

2.4. Generation of Truncated Distribution of Initial State

When states have bounds, it becomes necessary to generate particles that are consistent with these bounds. This can be achieved by using the concept of truncated distributions. A truncated distribution is a conditional distribution that is conditioned on the bounds on the random variable. In particular, the truncated univariate normal distribution can be obtained as follows:

$$N_T\left[0,1 \mid a \le \zeta \le b\right] = \frac{1}{\sigma\sqrt{2\pi}} \frac{\exp\left(-\zeta^2/2\right)}{\phi(b) - \phi(a)} \tag{13}$$

Where $\phi(a)$ and $\phi(b)$ are the cumulative normal distribution functions evaluated at the lower and upper bounds, respectively. Now, consider a situation in which the distribution of random variable vector $\mathbf{x}$ is approximated by truncated multivariate Gaussian density function, denoted as $\mathbf{N}_T\left[\bar{\mathbf{x}}, \mathbf{P}\right]$, and defined over bounds $\left(\mathbf{x}_L, \mathbf{x}_H\right)$. In this work, we make use of the following approach for the generation of samples from the truncated normal distribution (Prakash et al., 2007). Since $\mathbf{P}$ is a symmetric and positive definite matrix, Cholesky factorization of $\mathbf{P}$ yields a lower triangular matrix $\mathbf{S} = \sqrt{\mathbf{P}}$. Now, a transformed random vector $\mathbf{T}$ is defined such that $\mathbf{x} = \bar{\mathbf{x}} + \mathbf{ST}$. With this transformation, we can now define n-truncated univariate normal distributions $N_T^{(i)}\left[0,1 \mid t_{L,i} < t_i \le t_{H,i}\right]$ where the limits of i^{th} truncated distribution are defined as follows:

$$t_{L,i} = \left(\mathbf{x}_{L,i} - \bar{\mathbf{x}}_i - \sum_{r=1}^{i-1} s_{ir} t_r\right) / s_{ii} \quad ; \quad t_{H,i} = \left(\mathbf{x}_{H,i} - \bar{\mathbf{x}}_i - \sum_{r=1}^{i-1} s_{ir} t_r\right) / s_{ii} \tag{14}$$

where s_{ij} represents (i,j)'th element of matrix **S**. The above transformation requires that we draw samples recursively. Thus, first t_1 can be drawn from $N_T^{(1)}\left[0,1 \mid t_{L,1} \le \zeta \le t_{H,1}\right]$. Then, after setting limits $\left(t_{L,2}, t_{H,2}\right)$, t_2 can be drawn from $N_T\left[0,1 \mid t_{L,2} \le \zeta \le t_{H,2}\right]$, and so on. Thus, a sample from the truncated normal distribution $\mathbf{N}_T\left[\bar{\mathbf{x}}, \mathbf{P}\right]$ can be expressed as follows

$$\mathbf{x} = \bar{\mathbf{x}} + \mathbf{S}T \quad ; \quad T = \left[t_1 \quad t_2 \quad \ldots \quad t_n\right]^T \tag{15}$$

In the Constrained EnKF formulation, the above mentioned procedure is used for generating the initial ensemble.

3. Estimation of Arrival Cost using C-EnKF

There are two conceptual difficulties associated with the arrival cost approximation described in Section 2.2.

(a) If we decide to use normal distribution to approximate the arrival cost, it is important to use truncated normal distribution in the presence of bounds on states.

(b) The covariance update step involves linearization of nonlinear operators F[.] and H[.] in equations (1) and (2), respectively. Depending on the nature of local nonlinearity, this further introduces error in the approximation of the arrival cost.

A possible remedy to the problem of approximating arrival cost can be to construct the conditional density $p\left[\mathbf{x}(k-N \mid \mathbf{Y}_{k-N})\right]$ using a particle filter formulation that systematically handles the constraints. Since particle filters use Monte Carlo simulation approach, there is no assumption involved on the distribution of the conditional density function. If we allow infinite sample size, then, in principle, we can construct an accurate approximation of the moments of the conditional probability density function even if it is multi-modal and non-Gaussian. Moreover, operators F[.] and H[.] can be directly used for estimation of the moments without requiring the linearization step.

In this work, we retain the form of arrival cost approximation given by equation (6). The second moment of $p\left[\mathbf{x}(k-N) \mid \mathbf{Y}_{k-N}\right]$ necessary for constructing this term is approximated by employing C-EnKF over interval *[k – N - 1, k - N]*. Defining posteriori estimation error as

$$\boldsymbol{\varepsilon}^{(i)}(k-N\,|\,k-N)=\hat{\mathbf{x}}^{(i)}(k-N\,|\,k-N)-\bar{\mathbf{x}}(k-N\,|\,k-N), \quad (16)$$

the covariance $\mathbf{P}(k-N\,|\,k-N)$ can be estimated as follows

$$\mathbf{P}(k-N\,|\,k-N)=\frac{1}{N}\sum_{i=1}^{N}\boldsymbol{\varepsilon}^{(i)}(k-N\,|\,k-N)\left[\boldsymbol{\varepsilon}^{(i)}(k-N\,|\,k-N)\right]^{T} \quad (17)$$

The arrival cost is the approximated by setting $\mathbf{P}(k-N)=\mathbf{P}(k-N\,|\,k-N)$ in equation (6). It may be noted that some modifications are necessary in C-EnKF formulation described in Section 2.3 while using it for approximation of arrival cost. In the conventional formulation, the particles $\left\{\hat{\mathbf{x}}^{(i)}(k-N\,|\,k-N):i=1,2,...N\right\}$ are propagated while performing computations over interval $\left[k\text{-}N,\ k\text{-}N+1\right]$. In the proposed formulation, however, we only propagate the cloud of estimation errors $\left\{\boldsymbol{\varepsilon}^{(i)}(k-N\,|\,k-N):i=1,2,...N\right\}$ while performing the computations over the interval $\left[k\text{-}N,\ k\text{-}N+1\right]$. Thus, while estimating $\mathbf{P}(k-N+1)$, new particles at the beginning of the interval $\left[k\text{-}N,\ k\text{-}N+1\right]$ are generated as follows

$$\hat{\mathbf{x}}^{(i)}(k-N\,|\,k-N)=\tilde{\mathbf{x}}(k-N)+\boldsymbol{\varepsilon}^{(i)}(k-N\,|\,k-N)\ \ for\ \ i=1,2,...N \quad (18)$$

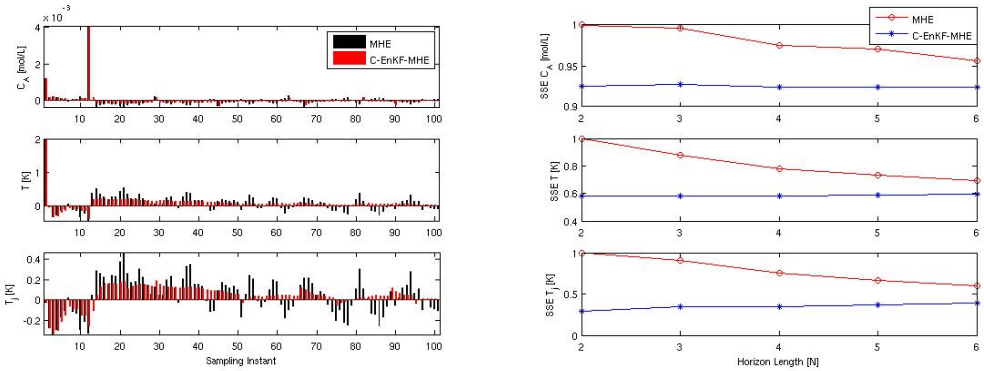
where $\tilde{\mathbf{x}}(k-N)$ represents the estimate generated by MHE problem solved over interval [*k-N, k*]. This modification facilitates *alignment* of the particles with the estimates generated using MHE.

4. Simulation Example

The performance of the C-EnKF based MHE algorithm is illustrated and compared with the MHE using a simulation example taken from the literature (Qu and Hahn, 2008). This example consists of a non-isothermal continuously stirred tank reactor model which includes reactor concentration (C_A), reactor temperature (T), and cooling jacket temperature (T_J) dynamics. The cooling water temperature is considered as the only measured variable. The horizon length used in MHE has 3 sampling times, with 20 samples used at each time point for the C-EnKF. State and measurement noise were considered zero mean Gaussian. The model parameters, initial values, and noise covariance matrices were taken from (Qu and Hahn, 2008)., The MHE problem was formulated using the simultaneous dynamic optimization formulation where the dynamic model is approximated with orthogonal collocation, and the resulting NLP problems were solved using IPOPT (see Zavala et al., 2008).

The evolution of the estimation errors is shown in **Erro! Fonte de referência não encontrada.**(a) where it is shown that the estimation errors for the C-EnKF-MHE are almost always smaller that the MHE. Figure 1(b) shows the sum of squared errors (SSE) for each state as a function of horizon lengths (from 2 to 6 sampling times) for both methods. Here, the SSE values have been normalized by the maximum SSE, which corresponds to the MHE using a horizon length of 2. From this figure it is easy to see that the performance of C-EnKF-MHE is significantly better than MHE for all the choices of horizon lengths. Moreover, there is hardly any change in the performance of C-EnKF-MHE when the horizon length is increased from 2 to 6. This improvement may be attributed to the fact that the approximation of the state error covariance matrix in the C-EnKF-MHE is statistically more consistent with bounds on states. Furthermore, at each sampling time the samples for the states used in the C-EnKF are not being redrawn. Instead, because the state samples are propagated over time, no assumption is needed on the distribution for the state estimation error. Moreover, unlike the

conventional MHE, the covariance estimation step does not involve linearization of the model as the covariance is approximated by Monte Carlo simulations. Additional computations arising from C-EnKF can be an issue for online implementation. However, when using the C-EnKF to approximate of the arrival cost, it is possible to achieve good estimator performance using even smaller horizon lengths. Working with shorter horizon lengths significantly reduces the on-line iterative computations. Also, since the measurements at the beginning of the horizon are known, the C-EnKF calculations can be done in the background between any two sampling times, thereby reducing the computation load at any sampling time.



(a) (b)

Figure 1: (a) State estimation errors. (b) Normalized SSE with as a function of horizon length.

5. Conclusions

A C-EnKF based scheme for updating the arrival cost in MHE is presented in this paper. It generates an approximation of the state error covariance matrix that is consistent with bounds on the state variables and without making assumptions on the distribution of the state estimation error. The simulation results demonstrate that the proposed formulation performs significantly better than the conventional MHE formulation. Moreover, the simulations reveals that MHE with short horizon lengths can be made to work well if the arrival cost estimation is improved.

Abstract

Petroleum has been used by society in many ways, but mainly as an energy source. To meet the increasing energy demand, oil companies seek for new technologies to optimize production in a field. For this purpose, gas is employed for artificial lift, therefore enhancing productivity of old fields which suffer from insufficient pressure to force the oil out to the surface. Often, gas lift is associated to intermittent flow regime, slug flow that promotes intense disturbances to downstream offshore processes. In the present work, three control strategies for a gas-liquid separator are proposed: (i) feedback averaging level control; (ii) feedback + feedforward level control employing an ARX estimator; and (iii) override control on the production choke valve. The control schemes attempt to minimize downstream slug effects by exploiting the separator's hold-up, while imposing limits to liquid level and maintaining pressure under satisfactory performance.

Keywords: gas-lift, phase separators, slug flow, process control, ARX.

1. Introduction

Most nations rely on petroleum to meet their energy demand, requiring increased efficiency in the extraction process. In offshore oil fields, risers are used to transport a multiphase mixture (composed by oil, gas, water and sand) from the wellheads to separation tanks on producing platforms. In case of inexistence of separation and pumping facilities near the wellheads, on the sea bottom, this multiphase mixture must be propelled to the sea surface at expenses of the reservoir pressure. For deep water, a common situation is that the reservoir is not sufficiently pressurized to promote the flow of oil at satisfactory rates, requiring artificial ascension of oil.

The method is based on reducing the production column hydrostatic pressure by reducing its average density. The reduction of de density is given by injecting an elevating fluid, usually natural gas. Reducing this hydrostatic pressure will allow the reservoir pressure to force the oil out to the surface. The injection of the gas must be controlled; otherwise, it can promote pressure surges in the ducts and related equipments (Robinson *et al*, 2001). In some cases, the continuous gas lift, associated to high injection rate, is not economically efficient, requiring reduced injection rates responsible for intermittent flow regime (Santos *et al*, 2001). Figure 1 shows a gas lift process where: (i) gas is injected in the annular region; (ii) gas passes to the production

tube through a check valve located slightly before the reservoir; (iii) in the production tube, the gas is mixed with the oil reducing its density; (iv) as the density is reduced, the base hydrostatic pressure decreases; (v) being this pressure lower than the reservoir pressure, the column fluid ascension occurs pushed by the reservoir pressure; (vi) since the gas injection rate is low, the column ascension will carry the gas out from the column, increasing the density and, hence, the bottomhole pressure what will close the check valve, stopping the gas inflow; (vii) production ceases until enough gas is injected into the annular column, restarting the cycle.

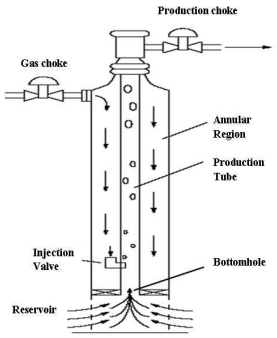

Figure 1: Gas Lift Process.

In consequence, high flow rates of gas have to be accommodated in the system of risers for further recovery by gas-liquid separators at the platform, before re-compression and re-injection. In this scenario, and depending on the flow conditions, a flow regime called *riser slugging* can develop in the pipelines. This regime, naturally highly transient, introduces severe oscillations of pressure and flow rates into the system. On the other hand, space and load constraints for offshore units favor compact equipments which increase sensitivity of downstream processes, mostly in the early stage of phase separation. Multiphase separators are, hence, a key-step in offshore facilities, with a two-fold process objective: (a) phase separation; and (b) dampening *riser slugging*, as in surge tanks. Faanes and Skogestad (2003) defined a *buffer tank* as a unit at which the holdup is explored to promote smooth operation. While in some level applications it is desirable to maintain tight regulation, such as in a reactor to achieving maximum capacity, this is seldom the case for level control in surge tanks, as it betrays the anti-surge requirement.

In the present work, three control strategies for a gas-liquid separator are proposed: (i) feedback averaging level control; (ii) feedback + feedforward level control employing an ARX estimator; and (iii) override control on the production choke valve. The control schemes attempt to minimize downstream slug effects by exploiting the separator's hold-up, while imposing limits to liquid level and maintaining pressure under satisfactory performance.

2. Process Model

For testing the control strategies and developing the stochastic predictor, a process model is developed based on Aamo *et al*, 2005. The dynamic behavior of the gas lift derives from the interaction between the annular and tubular volumes above the gas injection point, described by mass balances shown in Eqs. 1, 2 and 3, where H and W,

are, respectively, hold-up (kg), mass flow rate (kg/s). Subscripts *A*, *G*, *L*, *I*, *C*, *R* and *P*, stand respectively for annular region, gas in the production tube, liquid in the production tube, injected gas in the production tube, gas in the production choke, reservoir, production choke.

$$\frac{dH_A}{dt} = W_G - W_I \tag{1}$$

$$\frac{dH_G}{dt} = W_I - W_C \tag{2}$$

$$\frac{dH_L}{dt} = W_R - W_P \tag{3}$$

The valve responsible for injecting gas into the annular region is taken as a *swing-check-valve*. The choke valve for feeding gas to the annular region and the production choke valve are modeled as gate valves, assuming that the oil reservoir and the offshore separator are at constant pressure. The oil single phase flow section between the reservoir and the gas injection point is solved in pseudo-stationary mode with the reservoir and injection point pressures, assuming incompressible flow with friction factor given by Chilton's Equations, which comprise all hydraulic regimes.
The gas phase behavior is simplified to an isothermal ideal gas. Furthermore, temperatures in the gas lift subsystems are simplified to annular temperature equal to fed gas temperature, and production tube temperature identical to the oil temperature in the reservoir.
Figure 2a shows gas flow profiles for gas lift simulated at conditions shown on Table 1. Fixing these conditions and varying the gas injection rate leads to the identification of two distinct operating regions: (i) continuous gas lift or stable region; and (ii) intermittent gas lift or unstable region, as displayed on Figure 2b.

Table 1: Gas Lift Conditions.

	Oil	Gas
Pressure, Temperature	160 bar, 108°C	120 bar, 60°C
Density , Viscosity	850 kg/m^3, 0.012 kg/m.s	Ideal Gas
Choke Valve (opening fraction)	0.8	0.5

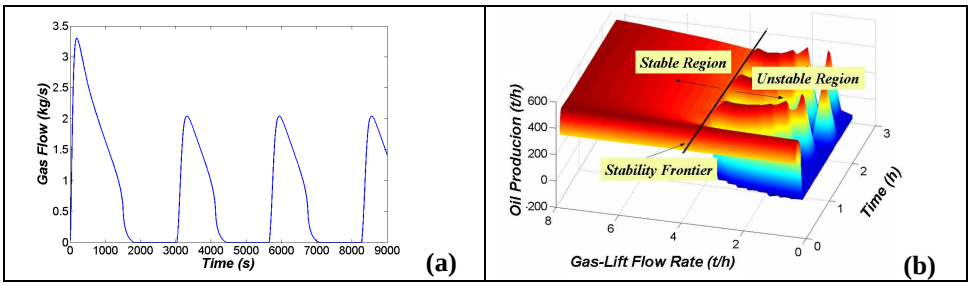

Figure 2: Simulation Results. (a) Gas Flow Profile for Gas Lift Simulated at Table 1 Conditions, (b) Sensitivity Analysis to Injection Gas Flow Rate

The gas lift model was expanded to include the operation of the gas-liquid separation. Mass balance for the liquid and gas phases yield Equations 4 and 5, where *L*, *G*, *C*, *D*

and V are respectively the liquid flow rate, the gas flow rate, separator's length, separator's diameter, and the volume. Subscripts I, o, T and L stand for, respectively, input rate, output rate, total, and liquid.

$$\frac{dh_L}{dt} = \frac{L_i - L_0}{2C\sqrt{h_L(D-h_L)}} \tag{4}$$

$$\frac{dP}{dt} = \frac{P(L_i + G_i - L_0 - G_0)}{V_T - V_L};\ V_T = C\frac{\pi D^2}{4} \tag{5}$$

3. Control Strategies

The control objectives are to maintain separator's pressure and its level in an appropriate range. Since pressure in the separator affects flow rate through the valves, it will impact the dynamics of the gas lift, and decrease the oil production. The level controller protects the separator against overflow or drainage. Also, due to the eventual occurrence of severe slug caused by the intermittent gas lift, level controller must provide buffer capacity, protecting downstream operation. For this purpose, three strategies are tested: (i) averaging level control exploiting the liquid hold up of the tank; (ii) feedback and feedforward control using an ARX predictor of separator feed flow rate; (iii) override control on the production choke valve and feedforward control. All the three strategies are shown schematically in Figure 3.

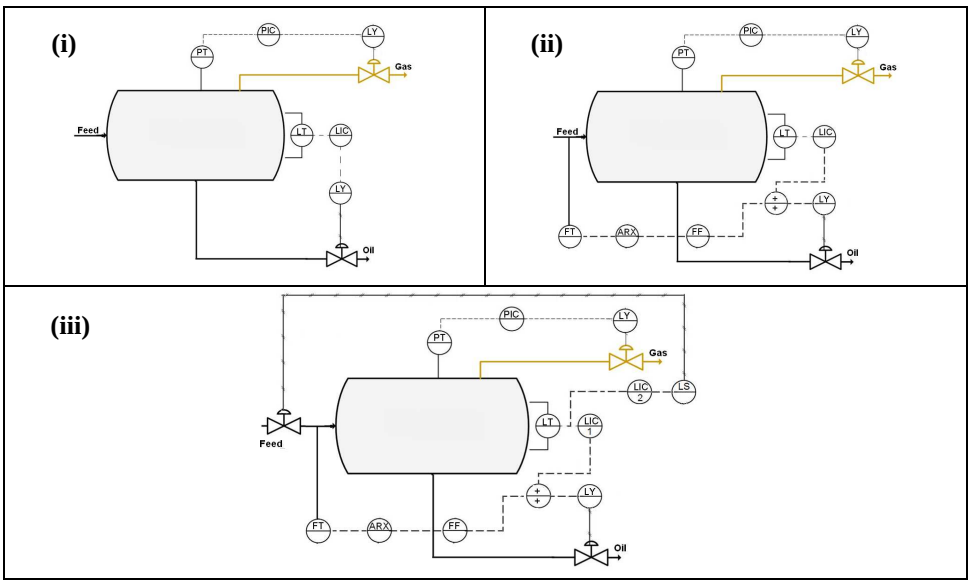

Figure 3: Control Strategies for Gas-Liquid Separators.

3.1. Averaging Level Control

Cheung and Luyben (1980) explore different level control strategies, such as the strategy proposed by Shunta and Fhervari (1976), the wide-range controller, with adaptation of PI controller tuning parameters (K_C and τ_I) according to Equation 6:

$$K_C = f\ K_{C0}; \quad \tau_I = \frac{\tau_{I0}}{f} \tag{6}$$

In this work, an alternative adaptation law proposed *f*, by Araújo *et al* (2007), is adopted, as given in Equation 7.

$$f = 1 + \frac{1}{1+e^{(\lambda_1(E_1 - abs(e))}} + \alpha\left(1 + \frac{1}{1+e^{(\lambda_2(E_2 - abs(e))}}\right) + \beta\left(1 + \frac{1}{1+e^{(\lambda_3(E_3 - abs(e))}}\right) \tag{7}$$

3.2. Feedforward + Feedback Control

For this strategy, an identification of the gas lift process is required as separators inflow is frequently not available from measurements. An ARX 3x3 with 3 inputs (gas injection rate, choke opening fraction, and separator tank pressure) and 2 outputs (oil and gas flows) is presented in Pinto (2009) and is used to inferring oil and gas flows. Faanes and Skogestad (2003) propose a model for buffer tank level response (*h(s)*) to inflow rate (*d(s)*, Equation 8) that is herein applied to a separator to obtain the feedforward control law (Equation 9). with K = -16 and τ = 343.53 s. The feedback controller is identical with same as showed at strategy 3.1.

$$h(s) = \frac{1}{\tau s + 1} d(s) \tag{8}$$

$$G_{FF}(s) = \frac{K}{\tau s + 1} \tag{9}$$

3.3. Override Control

In this strategy, under normal operating conditions, level controller (LIC1) is adapted according to Equation 7. Under severe slug, this controller is overridden though a low value switcher (LS) to a level controller (LIC2, with set-point equals to a high level limit) which acts reducing opening of the production choke valve.

Figure 4 compares the three strategies.

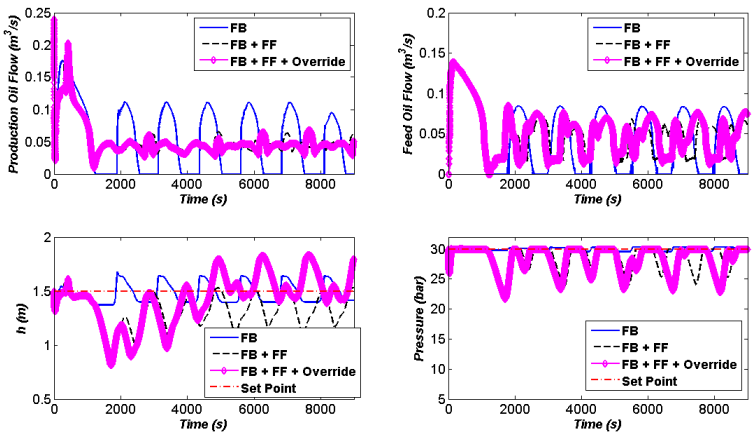

Figure 4: Comparison of Control Strategies.

Feedback level controller with adaptation law given by Equation 7 is able cope with slugs but is unable to reduce flow perturbations propagating downstream. With a feedforward combined to the adaptive feedback, it is possible to minimize the slug effects, while maintaining level and pressure in the separator within an acceptable working range. The override control is used as a security layer, preventing the separator's level from reaching dangerous values. It's possible to observe in Figure 4 that the results from both feedforward and override control (strategies ii and iii) are almost the same differing only on the level control, where the addition of the override strategy shows improves performance.

4. Conclusions

To mitigate the impact of slug flow downstream of a gas-liquid separator, this work approaches 3 control strategies. These strategies are presented to work in layers: a feedback layer, for correcting adaptively level deviations, a feedforward layer to anticipate control action based on an ARX predictor of the disturbance, the inlet liquid flow), and adopting a new level controller through override of the feedback controller.
It's possible to conclude that strategies (ii) and (iii) improve performance of an adaptive feedback controller. It is worth noting that the override layer only interferes when the separator's level reaches dangerous values.

Abstract

The ongoing globalization trend is tightening competition and setting new, higher efficiency requirements in the process industries. In order to enhance the efficiency of the production chain, new functionalities and information networking must be incorporated into the production equipment. This paper proposes a concept of equipment automation that utilizes new information and communication technologies and more flexibly adds equipment intelligence. The feasibility and applicability of the concept is demonstrated via case studies of a grinding circuit and a pulp drying process.

Keywords: Networked equipment automation, intelligent process equipment.

1. Introduction

The globalization process is tightening competition and setting, higher efficiency requirements in the process industries. In addition, factories now have to be considered as a part of sustainable development. Energy savings and pollution prevention have become priorities. Safety and maintenance are also listed as the main equipment design parameters. At the present time, however, the intelligence level of the process equipment and their networks is still low. In order to enhance the efficiency of the production chain, new functionalities and information networking must be incorporated into the production equipment. This can be further enhanced by applying embedded automation middleware to manage complex networked machines and distributed resources.

The goal of automation middleware is to increase the intelligence level of the production machines by networking and integrating the embedded systems of the machines into larger automation system entities. The functionalities embedded in the middleware cover the management of the whole process system at the life-cycle scale. The methods can utilize connections to higher-level systems and remote resources, as well as to the information-refining tools provided by the middleware platform. The middleware thus integrates lower level process resources, and further refines the collected information into a more convenient form that is subsequently presented to the users and/or to other information systems, such as MES or ERP.

The purpose of this paper is to propose a common way of incorporating the current communication technologies, and especially the communication protocol and network topology design, into process equipment in such a way that it facilitates the implementation of new methods and subsequently satisfies the efficiency requirements.

2. Survey of Industrial Automation Architecture and Communication Technologies

The evolution of communication technologies has had a strong influence on changes in the structure of industrial automation systems. Up until now, communication support in plant automation systems has been defined according to the Computer Integrated Manufacturing (CIM) concept. In this hierarchical structure, levels of functionality are identified in such a way that each device is designed for a specific task, and specific networks are used to interconnect devices at the same level, i.e. running the same task.

However, the devices have recently started to include more than one function, or module, which increases the intelligence level of the equipment automation. Devices like sensors that have traditionally been used for measurement now have to support e.g. maintenance or monitoring tasks. This means that the traditional hierarchical structure is increasingly being replaced by a distributed communication architecture. Nevertheless, the hierarchical structure still exists - and this is also advisable - in most of the process control strategies and plant automation systems, as illustrated in Fig. 1 and 2. This phase in the evolution of automation systems has been called FCS (Field Control System).

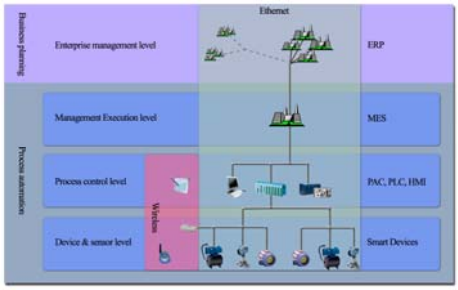

Fig. 1. Hierarchy of the plant automation.

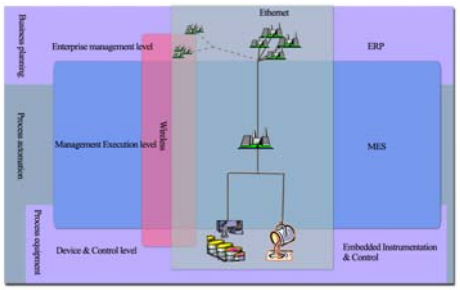

Fig. 2. Future scenario of the plant automation

2.1 Low-layer communication protocols

Currently the most widely available industrial networks can be classified into three main categories: traditional fieldbusses, Ethernet-based networks and wireless networks. A comparison of the key properties of the currently, most widely available networks in each of the three main categories is given in Table 1.

2.2 High-layer data specifications

The information standards for process operation and maintenance are driven by OpenO&M Initiative joint working groups, which mainly represent three industrial organizations: MIMOSA, the OPC Foundation, and ISA's SP95. One of the most strongly established standards, the OPC, also enables the use of state-of-the-art technologies such as web services. On the other hand, the traditional fieldbusses (like Profibus or Foundation Fieldbus) have defined concepts for the manufacturer-independent integration of field devices such as FDT/DTM.

3. Proposed Architecture for the Networked Equipment Automation

3.1 Components of the automation concept

The concept of equipment automation must be applicable over a wide range of different industrial processes. The main starting point is to bring the automation, with intelligent software-based functionalities, near to the process equipment while, on the other hand,

designing a communication network that robustly provides the services that are already incorporated. Therefore, the automation devices for one specific piece of equipment or sub-process are networked into one process system node, thereby providing connectivity to other parts of the process. The equipment 'intelligence' is embedded as a part of the automation devices, using software-based modules (Fig.3.)

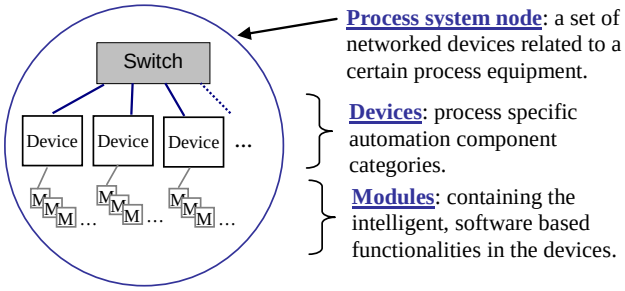

Fig. 3. Structure of the process system node.

The process system nodes are further connected to the supervisory automation level with a high bandwidth network (Fig. 4). In addition, the nodes can also provide a wireless connection link. Finally, in order to implement the equipment's advanced operating algorithms and procedures, a data processing unit (PLC or soft-PLC) is needed as a part of the process system node. This leads to a scheme in which the equipment automation provides the intelligent operating functionalities related to a specific task, which typically means one unit operation in the process chain. Compared to the traditional DCS hierarchy, the addition of intelligence offers a more dynamic platform for autonomous systems. Intelligent devices can act more independently and the improved communications enable interaction between the distributed assets. In fact, the FCS hierarchy provides a new platform for the implementation of agent technologies in the process industry.

3.1. Communication network topology

The architecture of the concept relies on a *backbone* that is capable of providing the main connectivity between the different devices. Moreover, it includes the connection point to remote resources via the Internet. The process system nodes, which are linked to the backbone, form sub-networks. These provide supplementary networks for establishing the instrumentation power supply and wireless links. It also manages the mutual interconnections between local devices. Redundancy is also provided for the backbone. The network system topology is presented in Fig. 5.

The communication protocol applied in the backbone should be able to link with office and remote resources and, as a result, have the same low layer technology as used in Internet networks, to provide a large bandwidth to integrate all the sub-networks, and also to support several high layer technologies, such as web and multimedia applications. The use of *Ethernet* networks is therefore proposed. The Ethernet technology is applied in the process system node network level. The connection to the devices is shared by using *switch* in order to improve the time determinism and isolate the local traffic. The Ethernet also has the advantage of facile connectivity to traditional fieldbusses. Additionally, Ethernet ensures device interoperability by supporting open standards, such as OPC.

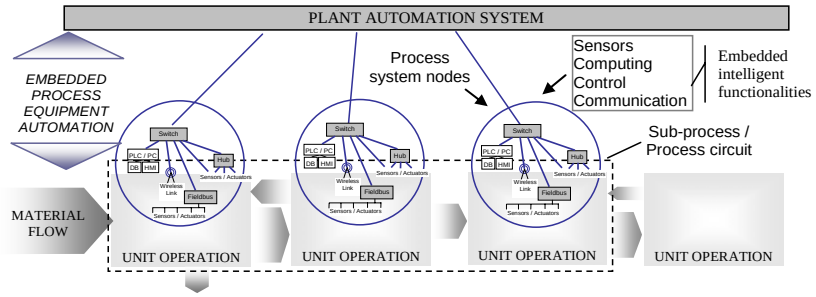

Fig. 4. Concept of the equipment automation level between the physical process and the supervisory plant automation system.

	ControlNet	Rockwell Automation	5Mb/s	<0.5 ms	5km (5Mb/s), 30km+ optical fiber)	max. 99	
	Interbus	Phoenix Contact	500kb/s	1,8 ms, 7,4 ms, 140 ms	~13km	max. 512	
	AS-i	Siemens	167kb/s	4,7 ms	100m/seg, 300m	max. 64	Power over network solution
	Foundation Fieldbus H1	Fieldbus Foundation	31.25 kb/s	36 ms,100 ms, 600 ms	max 1900m	max. 32	Power over network solution
Type	Protocol	Manufacturer	Throughput	Cycle Time	Range (Length)	Number of Devices	Energy Efficiency
Ethernet Based	Ethernet/IP	Rockwell Automation	10Mb/s, 100Mb/s, 1Gb/s	>10 ms			
	Foundation Fieldbus HSE	Fieldbus Foundation	100Mb/s		100m/seg		
	EtherCat	Beckhoff	100Mb/s	<50 µs	100m/seg	~65535	Power over network solution
	Powerlink	B&R	100Mb/s	<500 µs	100m/seg		
	ProfiNet IO	Siemens	100Mb/s	1 ms, 10ms	100m/seg		
	Sercon III	Bosch Rexroth	100Mb/s	31,5 µs	100m/seg	max. 254	
	Modbus TCP	Schneider	10Mb/s, 100Mb/s, 1Gb/s	>10 ms			
Type	Protocol	Manufacturer	Throughput	Cycle Time	Range (Length)	Number of Devices	Power Consumption
Wireless	IEEE 802.11 (b/g/n)		54Mb/s, 100Mb/s		30-100m		Medium
	Bluetooth, IEEE 802.15.1		1Mb/s		10m	7	Low
	IEEE 802.15.4 /ZigBee		20kb/s, 40kb/s, 250kb/s		10m	~65k	Very Low
	WirelessHart	Hart Communication Foundation	250 kb/s		10m		

4. Add–On Service Modules of the Intelligent Process Equipment

Intelligent process equipment in modern automation systems can also be thought of as forming a functional hierarchy. The equipment provides *services* designed to meet the higher level *objectives*. There are production management services consisting of daily operations, abnormal event management, operator support and training, product data and lifecycle management services. All these consist of lower level *activities*, such as process control, performance monitoring and field management. The implementation of the activities consists of *tools and routines* as presented in Fig. 6.

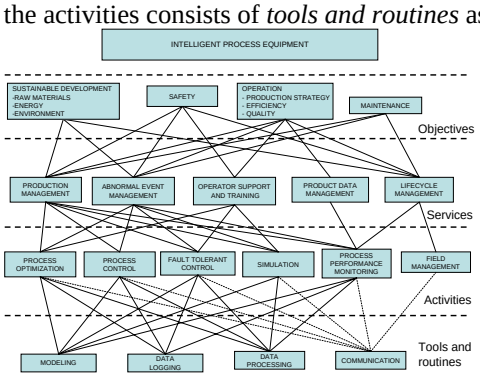

Fig. 6. Functional hierarchy of the intelligent process equipment

5. Case Examples

5.1. Case example: applying the concept of equipment automation to a grinding circuit

The proposed equipment automation concept is applied to an example of a mineral grinding process. It is proposed that the instrumentation of the process is grouped into four categories, typical for the process. These are: basic sensors, machine vision, process analyzers, and data processing units.

The process system nodes are divided according to the data processing units for the operation and monitoring of the mill, pump and hydrocyclone. The fourth node is reserved for an elemental analyzer, which is located physically further from the grinding circuit. One of the most important nodes, which includes the 'mill automation' data processing unit, has a wireless link enabling connection to the particle size and elemental assay analyzers. Other wireless sensors located in problematic points, such as the rotating mill shell, can also be added to the system. The industrial Ethernet connection is favored for all the instrumentation connections, as illustrated with the 'machine vision' device in the figure. The network topology of the equipment automation in this case is illustrated in Fig. 7.

5.2. Case example: applying the concept to monitor a pulp drying process

The concept was also implemented and deployed in the drying section of a Finnish pulp mill. The application is primarily intended to be used for production management services through process optimization and performance monitoring tools. It is also useful for abnormal event management, lifecycle management and operator support. The tools available for process optimization and performance monitoring include clustering, conditional histogram and control loop monitoring. An extensive performance measurement system has also been developed. The measurement system is hierarchical representing the whole system, subprocesses, control loops and the

equipment. On the equipment level features of intelligent field devices were exploited while on the control loop level a control loop monitoring tool called LoopBrowser was used. Examples of subprocess measurements are relative energy consumption and relative variations of controlled variables. The whole drying process was represented by an OEE indicator.

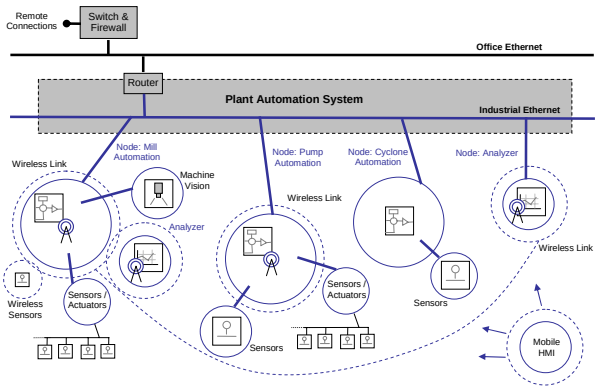

Fig. 7. Simplified abstraction of the network topology, with device connections for the process.

The clustering method is based on a modified K-means algorithm for identifying operating points and for detecting abnormal situations. The algorithm was chosen based on its computational simplicity enabling easy online implementation. The information is also used for diagnostic purposes because the application provides a contribution plot for showing the deviations of the input variables from their typical values. The conditional histogram method is used for constructing a database representing normal performance in each operating point. The method also includes routines for detecting whether the current measured performance deviates from the normal performance. The control loop monitoring system produces data about the performance of the monitored control loops. Four performance indices are used, which basically measure the accuracy and stability of the control loops.

The refined information serves the lifecycle module by providing monitoring performance throughout the equipment lifecycle. Intelligent field devices can be incorporated to deepen the scope of the application through embedded device level monitoring, as well as diagnostics which provide valuable information about the performance and ambient conditions of the field devices. For example, valve positioners typically provide control error and stiction measurements that can be used for determining whether a detected abnormal situation originates from the monitored valve-actuator-positioner package or from an outside source. Efficient exploitation of field device level information requires the use of device integration technologies, such as FDT/DTM. The overall performance measurement system was designed to give a comprehensive picture of the overall state of the whole process through the use of sub-process performance indicators. These measure e.g. relative variations in the controlled variable and efficiency measures.

6. Conclusions

In order to meet the tightening performance requirements in the process industries, the efficiency of the process equipment must be improved. Therefore, an equipment automation concept was formulated and proposed The concept outlines the procedure for efficient utilization of the latest information and communication technologies.

Abstract

This paper describes the use of multiple on-line sensors including electrical resistance tomography (ERT), dynamic light scattering (DLS) and ultrasound spectroscopy (USS) for real-time characterization of process operations processing emulsions and nanoparticle slurries. The focus is on making novel use of the spectroscopic data to develop multivariate statistical process control (MSPC) strategies. The ERT data at different normal operating conditions was processed using principal component analysis and used to derive two MSPC statistics, T^2 and SPE (squared prediction error) for detecting abnormal changes in mixing conditions. The corresponding particle size distribution was monitored using DLS and USS. Two case studies, a sunflower oil–water emulsion system and a silica suspension system, were examined.

Keywords: dynamic light scattering, acoustic spectroscopy, process tomography, multivariate statistical process control.

1. Introduction

An experimental system for studying on-line sensing techniques for nanoparticle slurries and emulsions has been built at the University of Leeds. The rig is equipped with dynamic light scattering (DLS) and ultrasound spectroscopy (USS) instruments for particle size and z-potential measurement, as well as electrical resistance tomography (ERT) for characterising the mixing conditions and solid concentration. In addition, flowrate, pH and temperature are also measured. This paper describes a novel method for making effective use of the spectroscopic to develop multivariate statistical process control (MSPC) charts.

2. Materials, Instruments and Experiments

2.1. Materials

Two materials were investigated in this study, a sunflower oil – water emulsion and a silica suspension. The emulsion was manufactured by a membrane emulsification rig in our lab. The oil volume concentration is 33%, and the mean size of droplets is around

700 nm. The silica suspension, Nissan SnowTex ZL, of 24.0% vol solid concentration and particle mean size between 70 nm – 100 nm was purchased from Nissan America Incorporation.

2.2. Experimental Rig and Instruments

Figure 1 shows the flow diagram of the experimental rig. It consists of mainly two parts, a 10 litre jacket reactor and a circulation loop. The 10 litre reactor is used as a buffer tank to store the multi-phase fluid. It is equipped with sensors of temperature, pH and conductivity. A Julabo water bath (FP50) is used to control the temperature inside the tank. Mixing in the tank was achieved using a pitched-blade stirrer. A mono pump with flow control is used to feed fluid to the circulation loop. A flow metre and a glass window were also fitted into the loop for visual observation of the flow. The ERT and USS systems were directly connected to the circulation pipe. A by-pass pipe with flow control and indication was designed for connection of the DLS sensor.

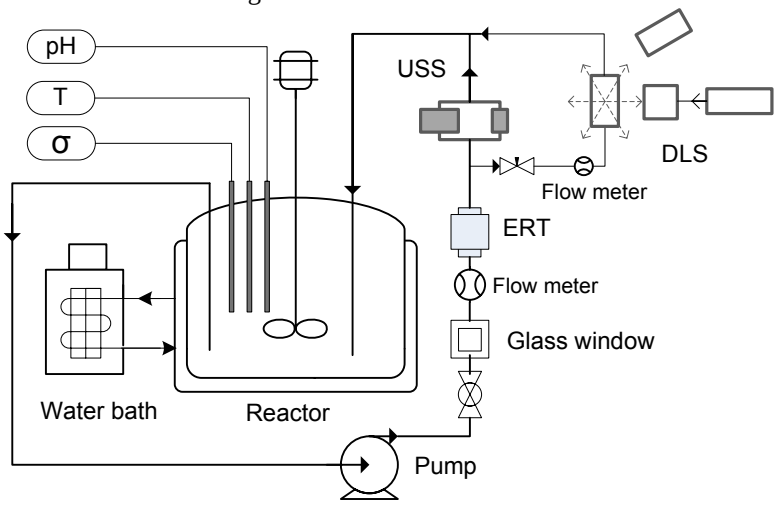

Figure 1. The experimental rig

The ERT instrument was provided by Industrial Tomography Systems Ltd [1]. It has 16 electrodes and can make 104 voltage measurements in approximately 25 ms. The tomography images are reconstructed from the 104 voltage measurements using a reconstruction algorithm. Both USS and DLS are supplied by Malvern Instruments Ltd [2].

2.3. Experiments

The purpose of the experiments is to investigate the mixing performance and measure particle size for two particulate processes at various concentrations and flowrates. During the experiments, in order to obtain different concentrations, the original emulsion, or suspension was gradually diluted to lower concentrations by adding sodium dodecyl sulfate surfactant solution or water into the concentrated emulsion or suspension. Under each concentration of the emulsion or suspension, different flowrates to the circulation loop were used to study the effect of flowrate on the mixing performance and particle size. During the experiments, tomography measurement was recorded at a rate of 60 frames per minute. At each concentration and each flowrate, one acoustic measurement was recorded by USS. In addition three size and three zeta-potential measurements were taken by the on-line DLS at every concentration and every

flowrate. Table 1 summarises the concentrations, flowrates and the numbers of each type of measurement obtained during the experiments for the two materials.

Table 1. Summary of measurements

Material	Volume concentration	Flowrate (l/s)	Number of DLS particle size measurement	Number of DLS zeta potential measurement	Number of USS particle size measurement
SunflowerOil – Water Emulsion	33%, 30%, 25%, 20%, 15%, 10%, 5%, 3%, 2%, 1%	0.190, 0.166, 0.133, 0.108, 0.083, 0.055, 0.041	3×10×7	3×10×7	10×7
SnowTex-ZL Suspensions	24%, 20%, 16%, 12%, 8%, 4%, 2.3%, 1.6%, 0.8%.	0.190, 0.166, 0.133, 0.108, 0.083, 0.055, 0.041	3×9×7	3×9×7	9×7

3. Multivariate Statistical Process Control Based on ERT Measurements

A significant development in multivariate statistical process control (MSPC) in recent years has been due to the introduction of principal component analysis (PCA) and Independent component analysis (ICA) for compression of data prior to deriving the MSPC's two statistics[4,5], Hotelling's T^2 and SPE. If PCA is used, the latent variables, i.e., the first few PCs are used rather than the original variables. The Hotelling's T^2 can then be calculated by

$$T^2 = \sum_{i=1}^{k} \frac{t_i^2}{S_{ti}^2} \tag{1}$$

where S_{ti}^2 is the estimated variance of t_i, k the number of PCs used, and t_i the ith score. The second statistic SPE (squared prediction error) model is:

$$SPE = \sum_{i=1}^{m} (y_{new,i} - \hat{y}_{new,i})^2 \tag{2}$$

where $\hat{y}_{new,i}$ and $y_{new,i}$ are the reconstructed value of the ith process variable from the reference PCA model and the measured value of this variable respectively. SPE is also refereed to as Q statistic or distance to the model. It represents the squared perpendicular distance of a new multivariate observation from the projection space. The procedure for developing the tomography based MSPC is described below.

The first step is the collection of normal operational data. The data is then pre-processed using two scaling methods. Since the tomography measurements (in this case the measurements are a set of voltages between different electrodes) are dependent on the conductivity and concentrations of fluids in the pipeline, it is necessary to remove the effect of these parameters on the measurements so that the developed MSPC model can be generalised and is independent of the concentrations and conductivity of the fluids.The first scaling method, called scaling over a frame, is applied to each frame of the collected data:

$$V_{new}(i,j) = \frac{V_{raw}(i,j) - V_{\min}(i)}{V_{\max}(i) - V_{\min}(i)} \quad (\text{j} = 1,2,3,\ldots,104) \tag{3}$$

where $V_{new}(i, j)$ and $V_{raw}(i, j)$ are the j[th] pre-processed and raw voltage measurement on the i[th] frame in the collected data, $V_{\min}(i)$ and $V_{\max}(i)$ the minimum and maximum raw measurement values on the i[th] frame, respectively. The second method for pre-processing the data is auto scaling to make each measurement have the same variance.

In the third step, the pre-processed data is analysed using PCA. A smaller number of latent variables, i.e. principal components (PCs) are derived. This transformation reflects the correlations between the tomography measurements at normal mixing states. The T^2 and SPE control limits at different confidence levels are derived.

Finally, the MSPC model is applied to new tomography data for mixing condition monitoring. It needs to point out that all new measurements were also pre-processed using the two scaling techniques described above. If the SPE is over the control limits, it could be an indication that the current mixing state had gone out of or was very different from the predefined normal mixing states. If the SPE is in the control limit and T^2 out of the limit, this could be an indication of bad mixing. After poor mixing is detected, contribution plots can be applied to analyse the key measurements contributed to the abnormal mixing.

4. Results and Discussions

4.1. Sunflower-oil – water emulsion

The ERT voltage measurements of sunflower oil – water emulsion, at flowrates 0.166, 0.133 and 0.108 l/s of concentrations from 33% to 5%, were used to develop the PCA based MSPC model. There are 23768 frames in total. The voltage data were firstly pre-processed using the scaling methods described in the previous section. Then PCA was applied to the pre-processed data to develop the MSPC models. 20 PCs were selected which explained about 73% variance of the data. Based on the selected PCs, control limits of two statistics SPE and T^2 at different confidence levels were calculated. The MSPC models were applied to monitor the mixing performance at different operating conditions. Figure 2 shows an example of emulsion at 20% concentration and various flowrates. It can be seen that significant increases of both SPE and T^2 occurred after the flowrate was reduced to 0.055 and 0.041 l/s. This indicates that the mixing became poor at these flowrates. The reconstructed conductivity tomography during the flowrate change, shown in the Figure 3, confirmed the deteriorating mixing at reduced flowrates.

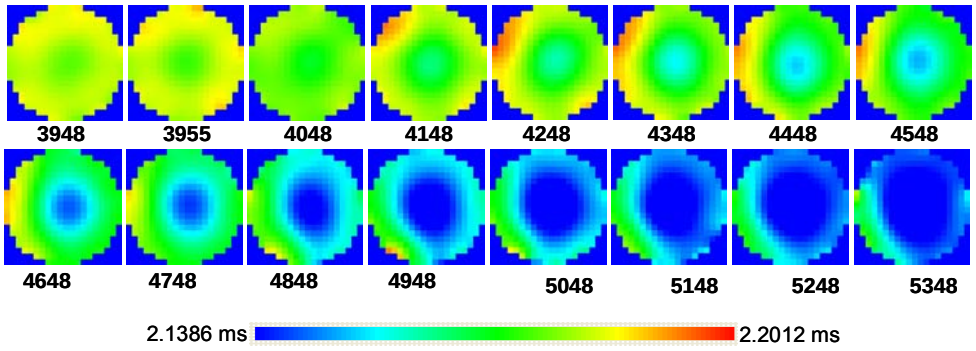

Figure 3. Reconstructed conductivity tomography images for the sunflower oil – water emulsion system. Concentration is fixed at 20%, but flowrate changes.

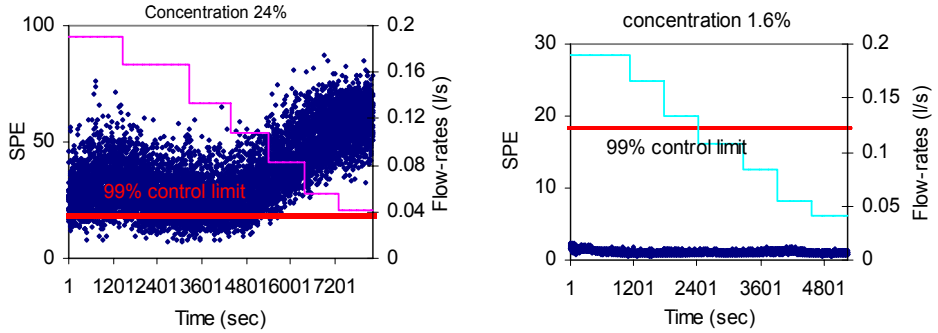

Figure 4. SPE charts for silica suspension at solid volume concentrations of 24% and 1.6%.

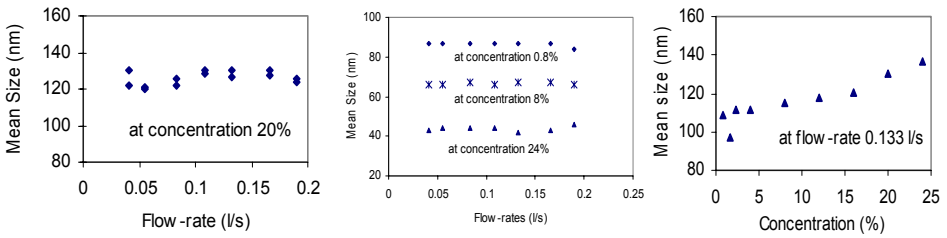
4.2. Mixing performance of SnowTex-ZL silica suspension

MSPC models were developed based on the tomography measurements at flowrates of 0.166, 0.133 and 0.108 l/s, for all concentrations studied. Twenty principal components were chosen, capturing about 88% of the variance.

The MSPC models were applied to monitor the suspension at different concentrations and flowrates. Figure 4 shows the SPE control charts at concentrations 24% and 1.6%, which indicates that the higher the concentration, the poorer the mixing.

4.3. Particle size measurements by on-line Zetasizer and Ultrasizer

Particle size distribution was measured using DLS and USS for both materials at different concentrations and flowrates. For the silica suspension, both DLS and USS gave consistent results when the flowrate was changed while concentration remained constant, as indicated by figures 5(a) and 5(b). However with the increase of solid concentration, the mean size measured by the DLS is increased, while the mean size measured by the USS is decreased, as shown in figure 5 (b) and (c), reflecting the effects of solid concentration on the measurement results.



(a) (b) (c)

Figure 5. Particle mean size measurements. (a) DLS result at a fixed concentration; (b) USS result at different flowrates and concentrations, and (c) DLS result at a fixed flowrate but varied solid concentrations.

5. Final Remarks

Nanoparticle processing in industry faces major challenges in process scale-up and in maintaining consistency and reproducibility in product quality. Online characterization of product quality and process conditions can help industry effectively address the challenges, because based on real-time measurements, process control and quality assurance strategies can be developed. The work has investigated the use of dynamic light scattering (DLS), ultrasound spectroscopy (USS) and electrical resistance tomography (ERT) for online characterization of processes of nanoparticle suspensions and emulsions. The system provides real-time information of particle size distribution (PSD), zeta potential, conductivity and solid concentration and visualizes the mixing behaviour. In addition, ERT provides solid concentration data that is needed by DLS and USS for PSD characterization. This study proposed the use of multivariate statistical process control, or MSPC for making use of the data for process monitoring and control. Two cases studies proved the feasibility of the proposed approach. The combined sensors and the MSPC system together provide a platform for on-line characterization of emulsions and nanoparticle slurries.

Abstract

Saccharomyces cerevisiae biomass is still one of the most important biotechnological products in the world, mainly in the form of baker's yeast. Costs of substrates have an important position in the overall economics of baker's yeast production, which is usually run in fed-batch bioreactors. In this context, the maximization of biomass yields, aiming at the highest achievable volumetric productivity is a driving force for improving the control of the process. Classical model-based control strategies for this process, however, face difficulties due to the inherent variability of this system: microorganisms have a complex growth dynamics, lumped in very simplified growth models; raw materials are variable and may be not traceable; the system response depends on non-controlled previous process stages, such as strain selection and inoculum preparation. Hence, the possibility of using feedback information from *in situ* sensors for re-tuning control parameters is an important issue to ensure sub-optimal performances, at least. A capacitance sensor is a device that can monitor cell concentration on-line. In fed-batch cultivations, the feed rate and correlated inputs can be controlled by systems coupled with softsensors that infer the state of the system from on-line measurements of primary variables. Several estimation techniques have been proposed in the literature, and among them the gas balance technique is widely used. The specific respiration rate (qO2), the specific carbon dioxide production rate (qCO2), and the respiratory quotient (RQ) are the main variables determined from the gas balance. Values of RQ for complete oxidation of some carbon sources to carbon dioxide and water are found in the literature. For the baker's yeast production process growing in glucose, a value of RQ close to unity indicates the preponderance of the aerobic route. The capacitance sensor, after calibration, may provide information about cellular growth and viability: the capacitance of the medium is linearly proportional to viable cell concentration. In this work, the signal of capacitance sensor and the RQ value are coupled to a fuzzy algorithm in order to control the glucose feed rate during baker's yeast aerobic cultivation.

Keywords: biomass, process control, *Saccharomyces cerevisiae*, soft-sensor.

1. Introduction

One of the most important variables in bioprocess control is the viable biomass concentration, which can be monitored by capacitance probe (Kiviharju et al. 2007; Xiong, et al., 2008). Until today, the feed rate in fed-batch fermentation was controlled based only in gas balance technique and in simulations results. Some works, as the one

of Xiong et al. (2008), demonstrate that the capacitance probe is a powerful tool for monitoring *Saccharomyces cerevisiae* fermentation, providing a more reliable process control when it is employed.

The capacitance probe functioning principles are shortly described in the followings. At frequencies between 0.1 and 10 MHz, the undamaged cell membrane, *i.e.* a viable cell, acts as an electric capacitor. The dielectric permittivity (ε in pF/cm) is proportional to the viable biomass concentration (Neves et al., 2000). The permittivity and the conductivity (σ in mS/cm) values can be calculated by the Equation 1 and 2 respectively. K (cm^{-1}) is the geometric constant of the electrodes (Markx and Davey, 1999).

$$\varepsilon = C \cdot K \quad (1)$$

$$\sigma = G \cdot K \quad (2)$$

At low frequency, the oscillation of the electric field is slow enough to completely polarize the cells and the medium. When the frequency of the electric field is slow enough, cell polarization reaches a plateau which corresponds to the maximal polarization. At high frequency, the field oscillates quickly and the intracellular charges (ions) do not have time to reach the plasma membrane before the change in the field polarity. Therefore the higher the frequency is, the lower the cell polarization will be. At high frequency, only the rotation of charged molecules induces a permittivity signal. Thus the permittivity value at 10 MHz gives a measurement of the medium's influence only. The difference of the permittivity measurements at low and high frequency is proportional to viable cellular concentration, as illustrated at Figure 1.

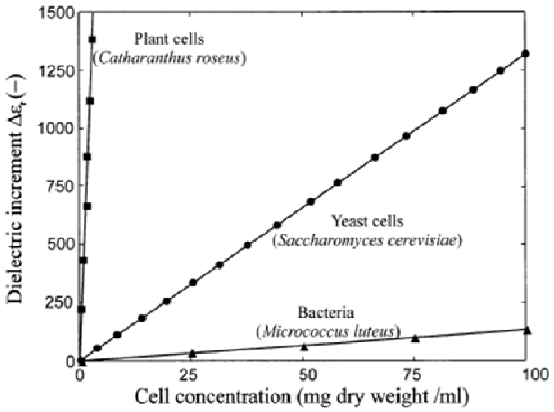

Figure 1. Permittivity (dielectric) increment of the β-dispersion as a function of biomass concentration, for a number of cell types (Markx and Davey, 1999).

2. Materials and Methods

2.1. Experiment

Experiments were carried out in a 6 L stirred tank bioreactor (5 liters working volume), filled with 4.0 liters of medium solution (glucose, 1.2 g/l; KH_2PO_4, 5.0 g/l; $MgSO_4 \cdot 7H_2O$, 0.5 g/l; $(NH_4)_2SO_4$, 4.5 g/l, yeast extract, 3.0 g/l), in fed-batch mode. The inoculum was inserted at concentration of 1 g/l and the cultivation process takes place. Stirrer speed was set to 350 rpm. The level of dissolved oxygen (DO) was maintained

over 45% of saturation (Kasperski and Miskiewicz, 2008). A schematic representation of the experimental set-up used in this study is shown in Figure 2.

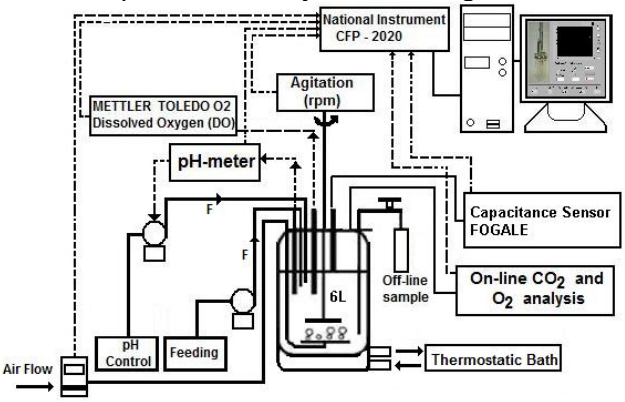

Figure 2- Schematic representation of the experimental system used in this study.

2.2. Off line variables

Dry cell weight (DCW, g/l) was measured by gravimetric method (samples were centrifuged at 8000×g for 15 min followed by drying at 100°C for 24 h). Cell viability was assessed through the Methylene Blue staining method, followed by counting of stained and non-stained cells in Neubauer chamber (Antonini, 2004).
Glucose and ethanol concentrations were measured by HPLC.

2.3. On-line variables

Cell concentration (viable cells) was measured by Biomass System – Viable Cell Density Monitoring (Fogale Nanotech). Equation 3 presents a calibration curve relating viable cell concentration (C_x) and permittivity (ε).

$$C_x(t) = 0.029 \cdot \varepsilon(t) - 3.23 \quad (3)$$

pH was monitored by pHmeter (GLI PRO P3, Hach, USA). The exhaust gas (oxygen and carbon dioxide molar fraction) was measured by the gas analyzer (SICK-MAIHAK S710, German). The dissolved oxygen concentration was monitored (O_2 4050, Mettler Toledo, Switzerland).

2.3.1. The control algorithm

In this study, a Mamdani configuration for the fuzzy algorithm was used. A basic fuzzy logic control structure consists of a *Fuzzifier* to transform measured data into suitable fuzzy sets; an *Inference engine-fuzzy rule base* to evaluate assigned fuzzy rules and has the capability of simulating human decision making by performing approximate reasoning; a *Defuzzifier* to convert fuzzy sets into a single number.
There are several methods for extracting a crisp value from a dispersion of experimental data to build up a fuzzy set. The center-of-gravity method was adopted in this work for the *defuzzification* step. It should be stressed that the decision on which *defuzzification* method should be applied relies mostly on heuristics and on the experience of the programmer. More details about fuzzy logic can be found in Zadeh (1965), Hisbullah et al. (2003), Tahera (2008) and Karakuzu et al. (2006).
The first step in designing a fuzzy control is to identify fuzzy input and output monitoring variables. During *S. cerevisiae* cell growth, a strong relationship was observed between experimental permittivity and carbon dioxide concentration in the exhaust gas. The fuzzy

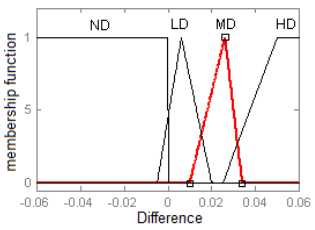
logic algorithm presented here has 16 rules (Table 1). It was written in MatLab® and implemented in a LabVIEW® environment. Data strings were exchanged in real time between the MatLab program and the data acquisition system (programmed in LabVIEW).
The variables chosen as input to the fuzzy algorithm were the Respiratory Quotient (RQ) and the error (e), a variable defined as the difference between the reference cellular growth coefficient (μ_{REF}) and its on-line estimated value (μ). The reference value had to be modified during cultivation because the growth behaved differently as the experiment progressed. Its value ranged from 0.06 to 0.1. The output variable was glucose feed flow rate powered by peristaltic pump (Ismatec, Switzerland). The rules of fuzzy logic algorithm included the two input variables, each one associated to four fuzzy sets: a) antecedent: input RQ – Low (RQL), Good (RQG), High (RQH) and Very High (RQVH); input error (e) – Negative Difference (ND), Low Difference (LD), Medium Difference (MD) and High Difference (HD); b) consequent: glucose feed flow rate – Null Flow (NF), Low Flow (LF), Medium Flow (MF) and High Flow (Table 1).

Table 1 – Fuzzy set rules of input and output variables.

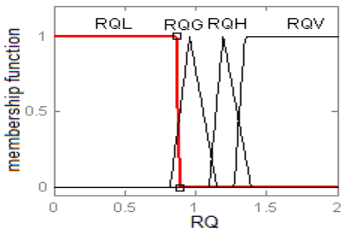
Rule	IF (antecedent)	THEN (consequent)
1	RQL **AND** ND	LF
2	RQG **AND** ND	LF
3	RQH **AND** ND	LF
4	RQV **AND** ND	NF
5	RQL **AND** LD	MF
6	RQL **AND** MD	MF
7	RQL **AND** HD	HF
8	RQG **AND** LD	LF
9	RQG **AND** MD	LF
10	RQG **AND** HD	MF
11	RQH **AND** LD	NF
12	RQH **AND** MD	NF
13	RQH **AND** HD	NF
14	RQV **AND** MD	NF
15	RQV **AND** ND	NF
16	RQV **AND** HD	NF

3. Results and Discussion

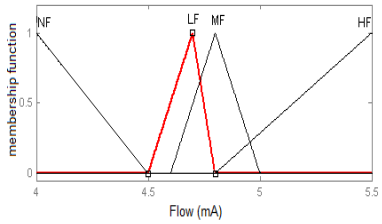
The correct choice of membership function plays an essential role in achieving a successful design of fuzzy logic controller. Unfortunately, this is not deterministic and has no unique solution. Furthermore, this choice is based on subjective decision criteria and relies heavily on time consuming trial and error. Different membership functions were tested during the fuzzy parameters tuning (*Gaussian*, *Bell*, *Triangular* and *Trapezoidal*) and the best result was obtained using triangular and trapezoidal membership functions, as illustrated in Figure 3. Figure 4 shows the cell, glucose and ethanol concentrations during the experiment.
The exponential growth phase started shortly after the inoculation. Glucose was exhausted within 1 hour of cultivation. Figure 5 shows the behavior of the manipulated variable (glucose feed flow rate) and controlled variable as well (RQ).
At the start of the feed (between 1 and 4.5h), the parameters of the fuzzy controller were changed by the operator, leading to sharp fluctuations of the feeding pump. After the right set of parameters were adjusted, the behavior of the glucose feed flow rate stabilized, as can be seen in Figure 5.



(a) Input variable – error (μ_{REF}- μ).



(b) Input variable- RQ.



(c) Output variable - Glucose feed flow rate.

Figure 3- Final membership functions of antecedent after parameters tuning: (a) input variable (μ_{REF} - μ); (b) input variable RQ; (c) consequent part – Glucose feed flow rate.

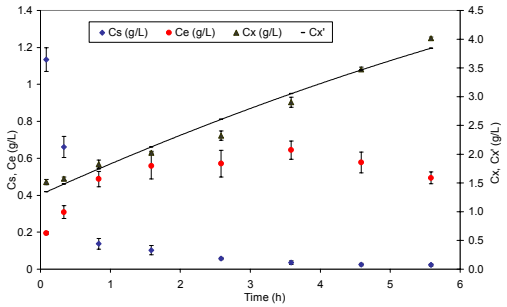


Figure 4 - Glucose concentration (Cs), ethanol concentration (Ce), biomass concentration measured by dry weight (Cx) mass, viable biomass concentration provided by capacitance probe (Cx').

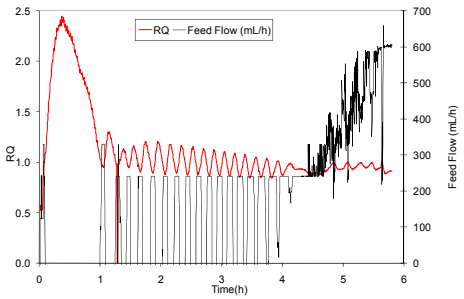

Figure 5 - Behavior of the manipulated variable (glucose feed flow rate) and controlled variable (RQ).

4. Conclusion

The fuzzy control algorithm using the permittivity and the RQ values as input variables was successfully implemented. The glucose concentration into the medium was kept at low values (close to zero) during the whole assay. As a consequence, ethanol concentration was kept low. Cellular growth rate was kept constant until the end of the experiment. The cell viability remained at 98% throughout the experiment. This information allows to correlate directly the probe signal to the cell concentration. The cell productivity ($\Delta Cx/\Delta t \cong 0.45 g/l/h$) reached was considered high if compared to others reported at the litterature, as $\Delta Cx/\Delta t \cong 0.41 g/l/h$ obtained by Oliveira (2006). The results demonstrate that the use of the capacitance sensor to reach the optimun control of system is viable, and the fuzzy control was able to control glucose feed flow rate efficiently using this probe signal.

Abstract

This article introduces the use of in-line and *in situ* monitoring of the dynamic evolution of PVC morphological properties in suspension polymerization reactions based on near infrared spectroscopy (NIRS) intended for control applications. It is shown for the first time that it is possible to follow the dynamic evolution of morphological properties (such as the bulk density, BD, and the cold plasticizer absorption, CPA) in real time. The obtained results indicate that closed-loop control schemes can be properly implemented to control end-use resin properties, which depend upon the morphology of PVC polymer particles. Suspension polymerization of vinyl chloride performed in bench and pilot scale showed that process variables, such as the agitation speed and the amount of suspending agents) can be successfully manipulated in order to control the morphological parameters of PVC resin. Based on this information, a control scheme for these parameters is proposed.

Keywords: Near Infrared Spectroscopy (NIRS), MVC Suspension Polymerization, Dynamic Evolution of Morphological Properties, Control of Polymer Particle Morphology.

1. Introduction

It is well known that profits and plant operation quality may be significantly increased through the implementation of plant automation and the adoption of advanced control strategies. This is particularly true in the polymer industry, as polymer materials are characterized as “product-by-process” materials, which means that the history of the reaction is of great importance to define the final product properties and quality. In the polymer industry it is generally very difficult to minimize specifications drifts caused by process disturbances and uncertainties through blending of different batch products and/or additional separation steps, as usually performed in other fields (Vieira et al., 2002). Specifically, in the case of poly(vinyl chloride) (PVC) resin, a sophisticated arrangement of particles morphology appears as a special feature of PVC resins

‡ Current Address: Instituto de Química, Universidade de Brasília, *Campus* Universitário Darcy Ribeiro, CP 04478, 70910-900, Brasília, DF, Brazil, E-mail: fmachado@unb.br

obtained from suspension polymerization process. Very poor solubility of PVC in the vinyl chloride monomer (VCM) causes precipitation of PVC in the VCM droplet at early stages of polymerization, proceeding with the generation of complicated particle structures. This PVC particle structure is very important for understanding of process capability and quantities of produced product (Saeki and Emura, 2002).

The production of polymers with pre-specified properties has placed great emphasis on the development of accurate and robust instruments for the on-line monitoring of polymerization reactions. The complex nature of polymerization systems is one of the main contributing factors to the difficulty of on-line measurements. The presence of long measurement delays and poor reliability are two common problems associated with the on-line characterization of the polymer quality. Even the off-line measurement of many polymer properties is a difficult task, requiring sophisticated and time-consuming analytical techniques. In addition, the development of on-line polymer sensors requires a multidisciplinary effort, including mathematical modeling and data processing, improved knowledge and understanding of the process, reactor design, and modern advanced control and instrumentation engineering (Machado and Bolzan, 1998; Kammona et al., 1999).

An important problem is that, generally, in batch processes, the polymer quality can be assessed only a certain period of time after the end of the reaction. Therefore, many times, the quality of raw material changes (e.g. the quality of monomer) during this period and probably these changes, that could probably affect the resin quality parameters, may not be detected immediately. Consequently, off-specification products can be produced. In addition, as the process will be in a different state, adjustments in the formulation performed based on this delayed information would not assure the solution of polymer quality problems. With the methodology proposed here, it will be possible to track the dynamic evolution of PVC morphological parameters in real time, which means that the long delay times involved in the suspension polymerization of PVC will be properly eliminated, making possible the use of control actions related to the real state of the process.

2. Experimental Procedure

A standard recipe consisting of poly(vinyl alcohol), initiator, water, monomer and additives was fed into the reactor to perform the polymerization reactions. The detailed recipe cannot be presented for proprietary reasons. Detailed description of reactor apparatus is presented by de Faria Jr. et al. (2009), and the reader is referred to this publication for a more detailed description of the protocol.

The studies were divided in three groups. The first one was performed to obtain the dynamic evolution of bulk density (BD) and cold plasticizer absorption (CPA). The second one was performed to verify if changes in the agitation speed would lead to modifications of the BD, CPA and average diameter of final PVC particles. The tests were performed in a bench stainless-steel reactor with a volume of 0.01 m^3 and maximum working pressure and temperature of 20 bar and 250ºC, respectively. A thermocryostatic bath was used to control the reaction temperature. The agitation speed could be varied in the range between 0 and 2400 rpm and a Pt 100 thermocouple was used to monitor and control the reactor temperature.

After 20 minutes of reaction, the normalized agitation speed was changed in the range from 0.40 to 1.00. In all batches the normalized agitation speed at the beginning of the reaction was equal to 0.6. The runs were replicated to analyze the process

reproducibility. For each run, BD, CPA and PSD of the final PVC powder were obtained.

The third group of studies was performed by dosing suspending agent into the reaction medium in order to verify if changes of the suspending agent concentration would lead to modifications of the BD, CPA and average diameter of final PVC particles, as in the previous. Tests were performed in a pilot stainless-steel reactor with volume of 0.1 m^3. A cascade control mode (PID-PI) combined with a Distributed Control System was used to control the flow rate of hot water in the jacket. After 20 minutes of reaction, the normalized amount of suspending agent was dosed into the reactor (0.58, 0.75, 0.83, 1.00). Additions were performed in different batches, using a solution of dispersant agent in water. The solution was kept inside a process vessel that was isolated from the reaction medium by a handle valve. After 20 minutes of reaction, the valve was opened, allowing for the solution to flow into the reactor.

3. Results and Discussion

The correlations obtained to predict BD and CPA were excellent and able to represent qualitatively the dynamic evolution of both variables during the polymerization reactions, as shown in Figure 1. The quality of prediction for both BD and CPA, as obtained with the calibration model, can also be regarded as very good. It is very important to emphasize that calibration was performed only with samples obtained at the end of the batch, because quality parameters can only be measured when the polymerization is finished. In spite of that, the dynamic evolution of BD and CPA are predictable and follow very well defined trajectories, showing the robustness of the proposed monitoring scheme (in Figure 1, only the last points of the BD and CPA dynamic trajectories are real experimental points).

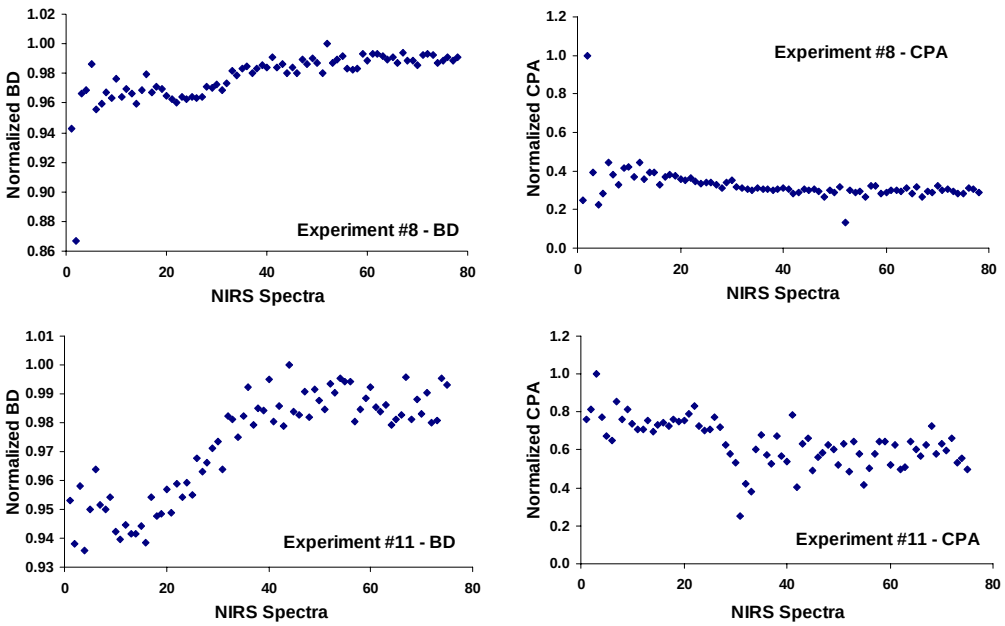

Figure 1 - Dynamic Evolution of BD and CPA during the VCM Polymerization, as predicted by the PLS model.

Figure 1 shows that *in situ* and on-line monitoring of morphological PVC properties using NIRS can be employed successfully in MVC suspension polymerization process, as dynamic trajectories are smooth and well-behaved, indicating that model predictions can be useful along the whole reaction course and used for monitoring and control purposes.

The average diameter of PVC particles obtained at the end of the polymerization reactions was analyzed by screening and light scattering, showing good agreement, as shown in Figure 2. This figure illustrates the effect of agitation speed on the average particle size of PVC. Based on these results, one can conclude that it is possible to vary the agitation speed in order to control the particle size distribution and CPA of PVC particles. As shown, the sudden increase of the agitation speed during the polymerization leads to the diminishment of the average droplet diameter and consequently of the final PVC particle (Dp). After attainment of a minimum Dp value, the overall superficial particle area increases so much that PVC particles agglomerate to reduce the interfacial energy of the system. If stirring continues to increase, the break-up rates due to the high shear forces predominates and Dp decreases again (see in Figure 2 the value of normalized agitation speed equal to 1).

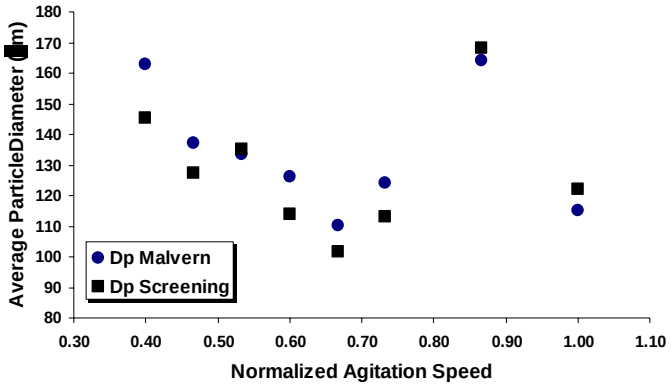

Figure 2 - PVC Particle Diameter Obtained by Screening and Light Scattering.

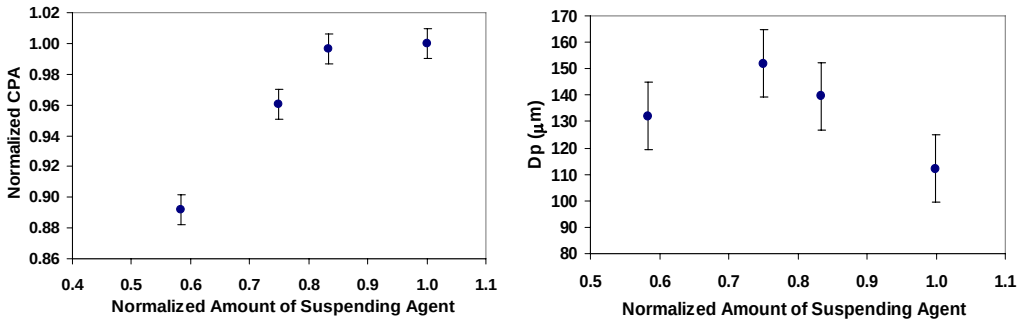

Figure 3 - Effect of Dosing of Suspending Agent on the Bulk Density and Cold Plasticizer Absorption.

According to the results obtained from the third group of experiments, one can conclude that it is possible to dose suspending agent during the reaction to control the particle size distribution, BD and CPA of the final PVC resins, since polymer particles with different diameters, BD and CPA can be obtained when the dispersant agent is dosed

into the reaction medium during the run, as shown in Figures 3. It is important to observe that these experiments were performed in a pilot reactor, where the reactor volume was bigger than the bench reactor volume where the experiments of group two were performed. These observations are in very good agreement with independent observations in the industrial process (although not shown here).
Based on the results presented in Figures 1 to 3, a control scheme is proposed for monitoring and control of important morphological properties of PVC obtained in suspension polymerization process. The scheme takes into account the acquisition of signal available at polymerization site plus the signal from de NIR probe. Among the signals of practical interest available in the polymerization system, one may cite the agitation speed (that provides information about the evolution of the medium viscosity), the reactor pressure (that provides information about the monomer conversion), the reactor temperature (that provides information about the reaction rate, the medium viscosity and the relative volatility of VCM), the inlet and outlet jacket temperature (that allows for implementation of calorimetric schemes for evaluation of monomer conversion, heat transfer coefficients and reaction rates). Figure 4 shows the proposed scheme for the monitoring and control of PVC morphology and the reaction state in real time.

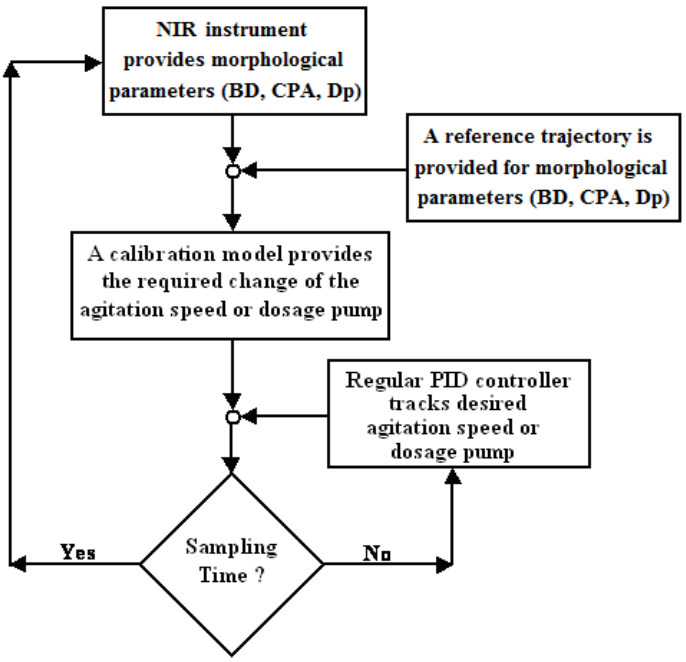

Figure 4 - Scheme for Monitoring and Real Time Control of the Morphological Properties of PVC Particle.

The implementation of the proposed in-line monitoring and control scheme will permit to follow, in real time, the evolution of conversion, of morphological features of PVC particles and the quality of the heat exchange. According to this scenario, the measured trajectories can be compared with ideal trajectories designed off line for control purposes. These ideal trajectories can result from optimization of any variable of interest (for example, minimum reaction time) or from a standard run that can be regarded as a reference one. In the second case, the NIRS signal obtained along a

standard run can be transformed into average size, CPA and/or BD (obtained from calibration model) and used as setpoints for others batch runs. In this case, different setpoints can be used to produce different PVC grades. According to this scheme, the process model can also be used to estimate in real time the monomer conversion and the quality of heat exchange (with the help of a simple balance model).
Reactor temperature should not be manipulated for control of morphological characteristics of PVC particles because it affects the K-value of the resin very significantly. When it is not possible to manipulate the initiator concentration along the polymerization batch, the reaction time can be manipulated through selection of initiator cocktails in the initial charge. Finally, the morphological variables (BD, CPA and average particle size, predicted by NIRS signal) can be controlled through proper manipulation of agitation speed and\or dosing of suspending agent. Thus, whenever a deviation in the variable of interest is detected (for example, Dp), based on the obtained calibration model, a control action must be sent to the agitation speed and/or dosing pump, allowing for satisfaction of the desired trajectories (Dpset). For example, if Dp is bigger than the Dpset, the stirring can be increased and/or the dosing pump can feed an additional amount of suspending agent into the reactor vessel. On the other hand, if Dp is lower than Dpset, the system agitation can be reduced.

4. Conclusions

It was shown for the first time that it is possible to follow the dynamic evolution of morphological properties (such as the bulk density, BD, and the cold plasticizer absorption, CPA) in real time during the PVC suspension polymerization. The obtained results indicated that closed-loop control schemes can be properly implemented to control end-use resin properties, which depend upon the morphology of PVC polymer particles. Suspension polymerization of vinyl chloride performed in bench and pilot scale showed that process variables, such as the agitation speed and the amount of suspending agents) can be successfully manipulated in order to control the morphological parameters of PVC resin. Based on this information, a control scheme for these parameters is proposed.

Abstract

In state estimation problems, often, the true states satisfy certain constraints that need to be incorporated during the estimation procedure. Amongst various constrained nonlinear state estimation algorithms proposed in literature, the unscented recursive nonlinear dynamic data reconciliation (URNDDR) proposed by Vachhani et al. (2006) seems to be promising since it is able to incorporate constraints while maintaining the recursive nature of estimation. In this article, we propose a modified URNDDR algorithm that gives superior performance compared to basic URNDDR. The improvements are obtained via better constraint handling and are demonstrated via a representative case study. **Keywords**: URNDDR, Kalman Filter.

1. Introduction

Kalman filter (KF) based state estimation techniques are widely employed to produce accurate estimates of the true states in the presence of noisy sensor information and an uncertain process model. For most of the real world problems of interest, the system dynamics and observation equations are nonlinear (NL) in nature. Most of the NL estimators proposed in literature are extensions of KF. The most widely used estimator for nonlinear systems is extended KF (EKF). The EKF involves simple linearization of the nonlinear terms in the model so that the traditional linear KF equations can be applied. However, the implementation of EKF requires the Jacobian matrices which may be expensive to compute and are prone to numerical errors, especially for higher order systems. Further, the linear approximation of the system may introduce significant errors in the state estimates, which may even lead these estimates to diverge over time. To overcome these difficulties, Julier et al. (1995) proposed the unscented KF (UKF). It yields performance equivalent to the KF for linear systems, and can be used for nonlinear systems without the linearization steps, which are required by the EKF. The fundamental component of UKF is the unscented transformation (UT), which uses a set of deterministically chosen weighted points (called as sigma points) to parameterize the mean and covariance of a probability distribution. However, the UKF suffers from two drawbacks: (i) the updated state estimates are obtained using a linear estimator (Vachhani et al., 2006), (ii) similar to EKF, UKF also does not incorporate constraints on states during estimation. This can lead to meaningless estimates (such as negative concentrations, etc.) in several applications. The recursive nonlinear dynamic data

reconciliation (RNDDR) method developed by Vachhani et al. (2005) to incorporate constraints on state estimates, also does not account for the effect of nonlinearity in state and measurement equations as well as the effect of constraints while calculating covariance matrices of the error in the predicted and estimated states. The subsequent work by Vachhani et al. (2006) overcame this limitation by combining merits of RNDDR and UKF to propose the unscented recursive nonlinear dynamic data reconciliation (URNDDR). A rigorous analytic method of incorporating state equality constraints in the KF by projecting the unconstrained KF estimates onto the boundary of the feasible region at each time step was developed by Simon and Chia (2002). But this method is applicable only for equality constraints and requires Jacobian calculation. Recently, Kandepu et al. (2008) proposed a simple procedure of projecting transformed infeasible sigma points onto the boundary of feasible region in order to include state constraints in the UKF algorithm. However, this projection idea was not applicable to the case of nonlinear equality constraints. Due to various limitations of alternative constraint handling algorithms as discussed above, the URNDDR proposed by Vachhani et al. (2006) seems to be promising. The key idea in URNDDR is to replace the update step in UKF by a set of optimization problems that are solved at each sigma point to satisfy the constraints on the states. The updated (filtered) state is then obtained as a weighted combination of the individual updated sigma points. Recently, Teixeira et al. (2008) have proposed various approaches based on UKF and URNDDR combinations to solve constrained, nonlinear state estimation problems. However, URNDDR fails to yield feasible state estimates if the constraints are non-convex. Hence, URNDDR can lead to state estimates which do not satisfy state constraints. In this article we propose a modified URNDDR (MURNDDR) formulation that ensures that the filtered state estimate satisfies the specified constraints irrespective of the nature of the constraints (linear/nonlinear, convex/nonconvex, etc.). The improvements due to the modified approach over the basic URNDDR algorithm are demonstrated on a representative case study. Section 2 presents a brief summary of the URNDDR and MURNDDR approach. The utility of the modifications is demonstrated in Section 3 by applying it to a gas phase reaction simulation case study.

2. Estimation Algorithms

2.1. Unscented Recursive Nonlinear Dynamic Data Reconciliation (Vachhani et al., 2006; Narasimhan and Rengaswamy, 2008)

Consider the following state-space description of the process:

$$x_{k+1} = f(x_k, u_k) + w_k \tag{1}$$

$$y_{k+1} = h(x_{k+1}, u_{k+1}) + v_{k+1} \tag{2}$$

$$\text{s.t. } x_L \le x \le x_U; \quad d(x) \le 0; \quad g(x) = 0 \tag{3}$$

In the above model $x_k \in \Re^n$, $u_k \in \Re^m$ and $y_k \in \Re^r$ are respectively the states, manipulated inputs and the measurements at k^{th} time instant. Process noise $w_k \in \Re^n$ and measurement noise $v_k \in \Re^r$ are assumed to be Gaussian with zero mean and covariance matrices Q_k, R_k and uncorrelated with each other. Functions $f()$ and $h()$ represent the process and the measurement model respectively. x_L and x_U are lower and upper bounds on the state vector and $d(x)$ and $g(x)$ represent inequality and equality constraints. For given estimated state $\hat{x}_{k(+)}$ and covariance $P_{k(+)}$, URNDDR can be summarized as:

A) Prediction Step: The UT is used to determine mean and covariance of the propagated states. A set of $(2(n+r)+1)$ sigma points and associated weights (z_i) are calculated from following augmented matrices as:

$$\hat{x}_k^a = \begin{bmatrix} \hat{x}_k(+) \\ y_k \end{bmatrix} \text{ and } P_k^a(+) = \begin{bmatrix} P_k(+) & [0]_{nxr} \\ [0]_{rxn} & R_k \end{bmatrix}$$

$$\chi_{i,k}^a(+) = \begin{cases} \left[\hat{x}_k^a(+)\right] & i = 0 \\ \left[\hat{x}_k^a(+) + \theta_{i,k} S_{i,k}\right] & i = 1, \ldots, 2(n+r) \end{cases} \tag{4}$$

where, $S_{i,k} = \left[\sqrt{P_k^a(+)}\right]_i, i = 1, \ldots, n+r$ and $S_{i,k} = -\left[\sqrt{P_k^a(+)}\right]_{i-(n+r)}, i = n+r+1, \ldots, 2(n+r)$ where $\left[\sqrt{P_k^a(+)}\right]_i$ is the i^{th} column of square root of $P_k^a(+)$ matrix and indicates the direction along which the sigma points are selected. In URNDDR, for better approximation of covariance information in presence of bounds, the sigma points used in propagation step are located asymmetrically and the step size $\theta_{i,k}$ for i^{th} sigma point is chosen as:

$$\begin{aligned} \theta_{i,k} &= min(\sqrt{n+\kappa}, \theta_{1,k}, \theta_{2,k}) \\ \theta_{1,k} &= \min_{j:S_{i,k}^j > 0} (\infty, (x_U^j - \hat{x}_k^j(+))/S_{i,k}^j); \quad \theta_{2,k} = \min_{j:S_{i,k}^j < 0} (\infty, (x_L^j - \hat{x}_k^j(+))/S_{i,k}^j) \end{aligned} \tag{5}$$

In the above, $S_{i,k}^j$ is j^{th} entry of i^{th} column at k^{th} time instant. Since sigma points are not symmetric the weights corresponding to each sigma points are selected as:

$$z_i = a\theta_{i,k} + b \tag{6}$$

where, $a = \frac{2\kappa - 1}{2(n+r+\kappa)(S_\theta - (2(n+r)+1)(\sqrt{n+r+\kappa}))}, b = \frac{1}{2(n+r+\kappa)} - \frac{2\kappa - 1}{2\sqrt{n+r+\kappa}(S_\theta - (2(n+r)+1)(\sqrt{n+r+\kappa}))}, S_\theta = \sum_{i=1}^{2(n+r)} \theta_i$

where κ is a tuning parameter. For any symmetric prior distribution with kurtosis *Ku,* choosing κ such that $0 < n + r + \kappa \le Ku$, leads to mean and covariance predictions that are more accurate than those of EKF (Julier et al., 1995) . The transformed set of sigma points are obtained by propagating each sigma point through process model as:

$$\chi_{i,k+1}(-) = f(\chi_{i,k}(+), u_k) \tag{7}$$

The predicted mean and state prediction error covariance matrix (SPECM) are then computed as:

$$\hat{x}_{k+1}(-) = \sum_{i=0}^{2(n+r)} z_i \chi_{i,k+1}(-) \tag{8}$$

$$P_{k+1}(-) = \sum_{i=0}^{2(n+r)} z_i [\chi_{i,k+1}(-) - \hat{x}_{k+1}(-)][\chi_{i,k+1}(-) - \hat{x}_{k+1}(-)]^T + Q_{k+1} \tag{9}$$

In order to account for the effect of Q_{k+1}, sigma points are regenerated from computed $\hat{x}_{k+1}(-)$ and $P_{k+1}(-)$. The new predicted sigma points and modified weights are computed in the same manner as in Equations (4)-(6). These new predicted sigma points and weights are used for update step.

B) Update Step: The optimization problems are solved to obtain the updated sigma points set. The optimization problem corresponding to the i[th] sigma point is given by:

$$\begin{aligned} \min_{\chi_{i,k+1}(+)} \quad & \left(\chi_{i,k+1}(+) - \chi_{i,k+1}(-)\right)^T (P_{k+1}(-))^{-1} \left(\chi_{i,k+1}(+) - \chi_{i,k+1}(-)\right) + \\ & \left(y_{i,k+1} - h(\chi_{i,k+1}(+), u_{k+1})\right)^T (R_{k+1})^{-1} \left(y_{i,k+1} - h(\chi_{i,k+1}(+), u_{k+1})\right) \end{aligned} \tag{10}$$

subject to the following constraints

$$x_L \le \chi_{i,k+1}(+) \le x_U; \quad d(\chi_{i,k+1}(+)) \le 0; \quad g(\chi_{i,k+1}(+)) = 0$$

The updated sigma points $\chi_{i,k+1}(+) \quad i = 0,1,...,2(n+r)$, are obtained from the solution of above optimization problems, one for each i[th] point. The updated state and state estimation error covariance matrix (SEECM) are then calculated as:

$$\hat{x}_{k+1}(+) = \sum_{i=0}^{2(n+r)} z_i \chi_{i,k+1}(+); \quad P_{k+1}(+) = \sum_{i=0}^{2(n+r)} z_i [\chi_{i,k+1}(+) - \hat{x}_{k+1}(+)][\chi_{i,k+1}(+) - \hat{x}_{k+1}(+)]^T \tag{11}$$

It can be seen from the formulation (10) that while the individual updated sigma points will satisfy the state constraints (3), the same cannot be said for the updated state since it is a convex combination (11) of the individual updated sigma points. If the feasible region defined by the constraints is nonconvex, then there is no guarantee that a convex combination of the feasible points will yield another feasible point.

2.2. Modified Unscented Recursive Nonlinear Dynamic Data Reconciliation

In order to account for constraints on individual sigma points as well as on the updated state (which is a convex combination of the individual sigma points), in this work we propose to solve the following single optimization problem for the update step:

$$\begin{aligned} \underset{\substack{\chi_{i,k+1}(+) \\ i=0,...,2(n+r)}}{min} \quad & \sum_{i=0}^{2(n+r)} \left[\begin{array}{l} \left(\chi_{i,k+1}(+) - \chi_{i,k+1}(-)\right)^T (P_{k+1}(-))^{-1} \left(\chi_{i,k+1}(+) - \chi_{i,k+1}(-)\right) + \\ \left(y_{i,k+1} - h(\chi_{i,k+1}(+), u_{k+1})\right)^T (R_{k+1})^{-1} \left(y_{i,k+1} - h(\chi_{i,k+1}(+), u_{k+1})\right) \end{array} \right] \\ \text{s.t.} \quad & x_L \le \chi_{i,k+1}(+) \le x_U; \quad d(\chi_{i,k+1}(+)) \le 0; \quad g(\chi_{i,k+1}(+)) = 0; \quad i = 0,...,2(n+r) \\ & x_L \le \sum_{i=0}^{2(n+r)} z_i \chi_{i,k+1}(+) \le x_U; \quad d(\sum_{i=0}^{2(n+r)} z_i \chi_{i,k+1}(+)) \le 0; \quad g(\sum_{i=0}^{2(n+r)} z_i \chi_{i,k+1}(+)) = 0 \end{aligned} \tag{12}$$

In the above formulation, constraints are imposed on individual updated sigma points as well as on the updated state. The decision variables for this optimization problem are the *2(n+r)+1* updated sigma point vectors. It is also to be noted that in absence of constraints for linear system models, the updated state as computed by the modified optimization problem will be the same as that given by linear KF (this feature is similar to URNDDR). The advantage of (12) over URNDDR is that we are directly minimizing the error in state estimates subject to the constraints on individual sigma point vectors as well as convex combination of the individual updated sigma points. Hence, modified URNDDR approach is guaranteed to satisfy arbitrary nonlinear and nonconvex constraints on the states. In the proposed approach, at the k^{th} time instant, a single optimization problem with *(2(n+r)+1)n* decision variables is solved instead of solving *2(n+r)+1* separate optimization problems each with *n* decision variable as was the case in URNDDR. Rest of the procedure is the same as discussed in section 2.1. The proposed modification ensures that individual sigma points as well as the updated state estimate satisfy the given constraints irrespective of the nature of the constraints. The utility of the proposed algorithm is now demonstrated by applying it to a simulation gas phase reaction case study.

3. Results and Discussion

The URNDDR methodology as proposed by Vachhani et al. (2006) and modified approach as proposed in this article are applied on the gas phase reaction simulation case study (Haseltine and Rawlings, 2003). It involves an irreversible gas phase reaction: $2A \rightarrow B$, with reaction rate $r = k_e P_A^2$. The partial pressure (P.P.) of species A (P_A) and B (P_B) are the state variables and the measurement is of total pressure (i.e. $P=P_A+ P_B$). The discretized nonlinear model for the system is (Haseltine and Rawlings, 2003) given in equation (13) where $x=[P_A \quad P_B]^T$. The initial state ($\hat{x}_0$) and associated covariance matrix (P_0) are taken as $[0.001,0.045]^T$ and $3600*I_{2X2}$ (where I is identity matrix) respectively, and other parameters are taken from Haseltine and Rawlings (2003).

$$x_{k+1} = \begin{bmatrix} \frac{x_{k,1}}{2k_e\Delta t x_{k,1}+1} \\ x_{k,2} + \frac{k_e\Delta t x_{k,1}^2}{2k_e\Delta t x_{k,1}+1} \end{bmatrix} + w_k; \quad y_k = [1 \quad 1]x_k + v_k \tag{13}$$

The number of time samples considered is 150. The states as estimated by URNDDR and MURNDDR approach are presented in Figures 1 and 2 respectively. It can be seen from the figures that both approaches accurately track the true states while satisfying the upper and lower bounds (100 and 0 respectively). To demonstrate the ability of the MURNDDR approach to handle arbitrary nonlinear constraints which cannot be incorporated in basic URNDDR, we introduce an additional nonlinear constraint on state as:

$$193 \le D \le 259 \tag{14}$$

where at k^{th} time point, $D_k = \frac{(\hat{x}_k^1(+)-15)^2}{1} + \frac{(\hat{x}_k^2(+)-15)^2}{4}$. The values of upper and lower bounds in (14) are specified such that the true state satisfies this constraint and hence this constraint should improve the quality of estimation. In basic URNDDR, at the k^{th} time point, 7 (number of sigma points) optimization problems, each involving 2 decision variables (number of states) are solved. For the i^{th} optimization problem, constraint (14) is imposed as:

$$193 \le D_{k,i} \le 259; \text{ where } \quad D_{k,i} = \frac{(\chi_{k,i}^1(+)-15)^2}{1} + \frac{(\chi_{k,i}^2(+)-15)^2}{4} \tag{15}$$

On the other hand, in the MURNDDR approach, at the k^{th} time point, a single optimization problem is solved that involves 14 (i.e. 7x2) decision variables and the constraints (14) are given as:

$$193 \le D_{k,i} \le 259 \ \text{for } i = 1, 2, ..., 7; \text{ and } \quad 193 \le D_k \le 259 \tag{16}$$

The corresponding performances of URNDDR and MURNDDR at first time point are shown in Figures 3 and 4 respectively. It can be seen from these figures that the state (weighted sigma point) estimated by URNDDR violates the nonlinear constraint whereas the state estimated by the proposed MURNDDR satisfies the specified nonlinear constraint. Note that the URNDDR state estimate violates this constraint even though individual sigma points satisfy it since it was incorporated in the optimization formulation corresponding to the i$^{\text{th}}$ sigma point. This is due to the inability of URNDDR to guarantee satisfaction of nonconvex constraints by the updated state. However, MURNDDR suggested in this article is able to handle the specified constraint. The performance of URNDDR and MURNDDR with nonlinear constraints is compared by calculating average mean square error (MSE) in estimated states and the average time required for computation for a time point**.** All the computations were performed in Matlab version 7 running in Windows XP environment on a P4, 2GB RAM machine. The results are shown in Table 1. It can be seen from the Table that the quality of estimates is better for MURNDDR due to its ability to handle arbitrary nonlinear constraints. To summarize, this formulation enables incorporation of any arbitrary nonlinear, non-convex constraints on the states while retaining the recursive feature of URNDDR for nonlinear state estimation. These features, as illustrated by the presented case study, make the modified URNDDR a promising tool for nonlinear constrained state estimation. Implementation of the proposed approach on larger problems is currently under investigation.

Table 1 Comparison of performance of URNDDR and MURNDDR

Description	Average MSE	Time (sec)/iteration
URNDDR	0.0301	0.5
MURNDDR	0.0186	2.5

A performance study of dynamic RTO applied to a large-scale industrial continuous pulping process

Pablo A Rolandi[a], José A Romagnoli[b]

[a]*Process Systems Enterprise Ltd, London, UK*
[b]*Louisiana State University, Luisiana, USA*

Abstract

A first-principle model-centric approach for advanced control-and-optimisation of industrial manufacturing processes is presented in this work. The elements of this advanced framework are described along with performance studies conducted on industrial control problems using an optimiser based on linear and nonlinear models. The optimal operation of an industrial continuous pulping system is used as a case-study. The software implementation is executed in this dynamic real-time-optimisation (DRTO) environment.

1. Introduction

We envision flexibility and interoperability as the key technological breakthrough of the next generation of model-based APC systems. For example, such APC engine would allow embedding linear models as easily as nonlinear models. Similarly, the APC engine would support empirical/semi-empirical models derived from identification- or reduction-based techniques, as well as fundamental mechanistic models derived from first principles. Concurrently, the APC system would allow unconstrained, quadratic cost problem formulations or general constrained control problems. Finally, this next-generation APC engine would support discrete- and continuous-time formulations interchangeably, and would be integrated into the MPC multivariable control and/or RTO economic optimisation layers of the APC hierarchy. Of course, the form of the optimal control problem does not depend on the characteristics of the APC application and, therefore, a set of mechanisms to formulate (and subsequently interpret) this control problem must be provided. In summary, we argue that the next generation of APC systems should be founded on a domain framework and software platform that allows the interchange of models, solutions methods and control/optimisation settings and strategies seamlessly. Ultimately, such a framework/platform would enable a transparent comparison of controller design and control architecture alternatives.

In this paper, a model-centric platform for advanced process control-and-optimization of industrial processing systems is presented. It provides the appropriate framework through which the aforementioned research issues can be investigated and addressed in a thorough and systematic way. In this work, we present the architecture of the DRTO platform, and we discuss the formulation of industrial optimisation-and-control problems and its subsequent interpretation into a mathematical formalism. The analysis of the controller/optimiser performance using linear and nonlinear models is studied.

2. A Framework for Dynamic Real-Time Optimisation

2.1. Control hierarchy

In this work we devote our attention to the performance of online real-time dynamic optimisation (DRTO) and, therefore, we adopt a control-hierarchy architecture where DRTO directly provides the setpoints of PID controllers (i.e. the regulatory control system), as opposed to the conventional industrial approach where (steady-state) RTO provides the optimum targets to the multivariable MPC controllers.

2.2. Component architecture

The dynamic RTO engine (DRTOE), a software application developed in this work, comprises several software entities: the process-data server (PDS) (which interfaces to OPC servers), the modelling-and-solution engine (MSE), the problem-definition manager (PDM) and the solution-feasibility supervisor (SFS). These are described next.

2.3. Modelling and Solution Engine

The MSE encapsulates all modeling-and-solution services needed by the DRTOE kernel. The advanced process modelling package gPROMS, from Process Systems Enterprise Ltd, has been chosen as the MSE. gPROMS is a state-of-the-art, equation-oriented modelling system that supports hybrid continuous/discrete (HCD) integro-partial-differential-algebraic systems (IPDAEs) of arbitrary complexity. gPROMS meets the requirements of a model server as well as a robust, efficient, general-purpose solution engine.

2.4. Optimiser and virtual plant models

By choosing gPROMS as the MSE, no restrictions are imposed on the type of models that can be embedded in DRTOE. Implicit differential-algebraic systems (DEA) are the most common class of models arising from first-principles' modeling, as well as ordinary differential systems (ODE). In general, these models are highly nonlinear due to natural phenomena such as kinetics, transport and equilibrium (thermodynamics) relationships.

Linear models are a common class of models used in linear constrained/unconstrained APC. Although these models rarely arise from first principles' modelling, they result from linearising nonlinear models around one or more nominal operating points. In the former case, this result in a linear time-invariant (LTI) model; in the latter case, known as successive linearisation, the model is linear time-variant (LTV). gPROMS has built-in linearisation capabilities based on a hybrid structural and numerical algorithm which presents the model in a linear state-space form. LTI models are fully supported by the DRTO engine and LTV models will be included in future work.

A large-scale first-principles' model is available from previous work. This model is used as the virtual plant for all closed-loop runs. In order to avoid plant/model mismatch, this model is also embedded in the control/optimisation engine; naturally plant/model mismatch does exist when this model is subject to linearisation.

2.5. Problem Definition Manager

The industrial operation of continuous and batch processes demand control-and-optimisation problems that change constantly as time progresses. This is due to changes in process conditions and operation specifications. The translation of the control-and-optimisation problem into a high-level dynamic optimization problem is executed by the Problem Definition Supervisor component (PDM). This component interprets the control events posted by users/operators and implements the resulting dynamic-optimisation problem formulation as requested by the MSE. This could be either input

arguments to low-level numerical routines or high-level constructs of declarative modeling languages.

In practice, multivariable, constrained control-and-optimisation problems seeking to improve process performance are difficult to pose and may even result in incorrect or infeasible formulations. Previous studies show that approximately a dozen different types of control events are needed to define a typical industrial control/optimitsation problem. These events have been presented in previous work (Rolandi & Romagnoli, 2008). The so-called "elementary events" have a direct interpretation into the parameterisation of dynamic optimisation problems. For instance, in the case of gPROMS, this means that these events have a direct representation into the gPROMS optimisation entity language. On the other hand, "composite events" are high-level nontrivial instructions that must be reinterpreted into elementary events. Path and zone constraints are two of the most common composite events, and they are supported in the current version of the software. In principle, this concept can be extended to encompass whole transition planning and scheduling scenarios. Overall, the introduction of these composite events greatly simplifies the definition of industrial control-and-optimisation problems by encapsulating operation recipes.

Scaling of decision variables is performed automatically by gPROMS (and most optimisation routines). Scaling of constraints, which is not normally built-in in optimisation modules, is performed by the PDM using the event mechanism described above. This transformation, which is derived from understanding of the optimality criterion, allows fine control of the enforcement of constraints which is needed to improve the robustness and efficiency of industrial control problems.

2.6. Solution and Feasibility Supervisor

The outcome of the PDM is, in general, a constrained dynamic optimisation problem whose solution demands not only optimality but also feasibility considerations. Indeed, the existence of a feasible solution is a key issue to be addressed by any control application. As a consequence, the proposed framework/platform has different build-in strategies to recover from infeasibilities: the Solution-Feasibility Supervisor (SFS) is a dedicated component of the DRTO engine for monitoring the solution and handling of infeasibilities. The SFS is composed by a Solution Interpreter (SI) and a Constraint Manager (CM).

Ideally, the SI would continuously monitor the progress of the open-loop optimisation computation to detect slow convergence between successive iterations due to constraint infeasibility/inconsistency. Due to technical restrictions, the current implementation of the SI logs the magnitude of control variables and constraints violations and overall computation statistics (e.g. number of NLP iterations, line searches and corresponding times) upon termination of the inner optimisation loop, where failing to converge is not considered fatal.

The implementation of the Constraint Manager, a concept that had already been presented in previous publications by these authors (Rolandi & Romagnoli, 2008), is a novelty of this work. The CM is built-in with two independent infeasibility-recovery strategies: i) relaxation vs elimination and ii) ranking vs identification. These individual strategies can be combined to create four different constraint-management policies.

The most common recovery mechanism in commercial MPC packages is constraint ranking and elimination (Qin & Badgwell, 2003). Here, one or more constraints are associated to a ranking level and removed from the control problem formulation upon infeasibility when their priority is below a cut-off level. We have found that this mechanism is sub-optimal and, furthermore, does not guarantee immediate recovery,

leading to inefficient computations. Constraint identification, on the contrary, uses information on the constraints' bounds and values (or their Lagrange multipliers, if available) to detect the subset that is active at any given iteration. Constraints that are violated are either eliminated or relaxed. The relaxation takes place by applying a factor which is provided by the user/operator via a console event mechanism (by default, it is set to 1% of the nominal variable value). Identification is coupled with ranking information because only constraints below a cut-off level can be relaxed or eliminated.

3. Case-study and analysis of results

3.1. Industrial wood pulping

The case study presented in this section is based on an industrial continuous pulping digester (and its auxiliary units) of a state-of-the-art pulp and paper mill. Papermaking is a highly competitive industry where meeting quality control parameters and the demand of highly dynamic markets is paramount to the economics of the business; also, new plants with more flexible and efficient productions schemes often replace old production systems. The key unit in this process is a vertical tubular reactor with several fluid-phase extraction and introduction points along the length of the reactor. The reactor is a solid-liquid heterogeneous system with inter- and intra-particular transport phenomena, where the column of wood chips moves continuously down and the fluid phase moves in co-current or counter-current flow at different heights. Besides the tubular reactor, there is auxiliary heating and heat-recovery equipment consisting of nine unit operations (condensers, heaters, pre-heaters and a kettle-reboiler), and seven transportation and handling devices (the so-called feed line). There are approximately 50 PID control loops, switched to manual or automatic operating mode.

3.2. 3.2 First principles model

Large-scale mechanistic models (that is, models of order ~1E5 variables or so) have seldom been used in advanced model-based control systems, with only a few examples resulting from academic studies rather than industrial applications (e.g. Wisnewski & Doyle, 2001). In this work, a mechanistic model of the continuous pulping system described above has been implemented in gPROMS, resulting in a system of approximately 14,000 algebraic, 1,000 differential equations, and 300 degrees-of-freedom.

3.3. Other implementation aspects

In this work, real-time dynamic optimisation provides the setpoints of key loops of the regulatory control system, condensing the two intermediate optimisation/control layers of a conventional hierarchical control structure (i.e. MPC and RTO) into a single, consistent model-centric application (DRTO).

Depending on the configuration, either this full nonlinear model is embedded in the optimizer or a reduced-order linear model. The latter is obtained by exact linearisation and minimal realisation of the former (the first-principles' nonlinear model) at the nominal steady-state starting point (in both case studies this is at 600.0 ad.ton/day); this is computed by the MSE (gPROMS). Linearisation requires full knowledge of the operating point, that is, degrees-of-freedom and initial conditions of the system. In order to satisfy this requirement as well as the need for state feedback during the movement of the receding horizon, a perfect observer is implemented. This is achieved by accessing the values of states and inputs of the dynamic model used as virtual plant, which is implemented via gPROMS' FOI/FPI communication mechanisms.

While a perfect observer is not feasible in an industrial setting, this choice allows us to focus on algorithmic and performance aspects and avoid any issues introduced by the ubiquitous plant/model mismatch that would characterise any real industrial application.

3.4. Case-study 1

In this case study the main target is to control a production-rate transition from 600.0 ad.ton/day to 650.0 ad.ton/day. From an operations-and-control perspective, the goal is to maximise the pulp yield (Y) at a given production target (P) while maintaining the deviation of pulp selectivity from its quality-control target below a given threshold. Selectivity is measured in terms of the "kappa number" and it is an indication of the proportion of non-cellulosic components present in the wood pulp. The process is initially at steady-state and control actions start taking place three hours before the scheduled production-rate change. The manipulated variables (MVs) optimized by DRTO are the setpoints of three key PID controllers: the chip meter (CM) speed (feed rate of wood chips), and the temperature of the lower (LH) and wash (WH) circulation heaters (which perform indirect heating of the chip column). Two interior-point and two end-point constraints are imposed on the trajectories and final values of selectivity and pulp production rate, and one path constraint is introduced for the deviation of selectivity with respect to its control target. The prediction and control horizons are set to 7 and 5 hr, respectively, and the control window is 1 hr; these settings are representative of industrial practices.

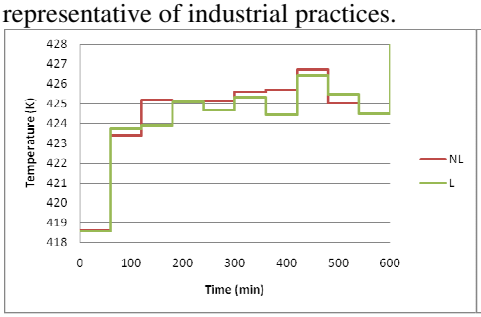

Figure 1: Wash heater (WH), MV.

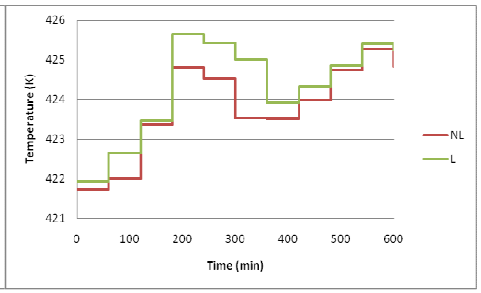

Figure 2: Lower heater (LH), MV.

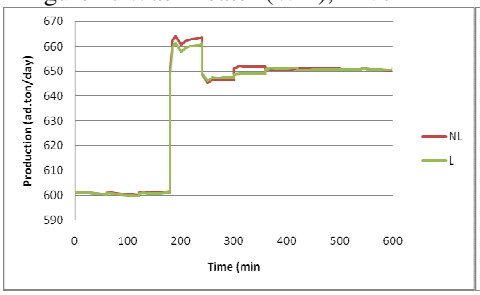

Figure 3: Production (P), CV.

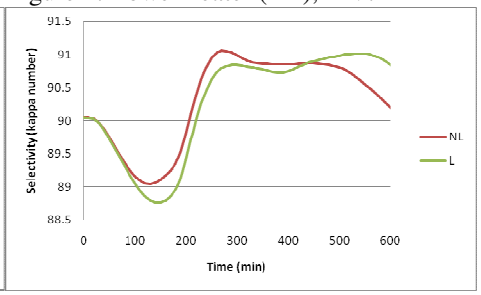

Figure 4: Selectivity (S), CV.

Figures 1 to 4 show the trajectories of key process variables for this case-study, for the linear (L) and nonlinear (NL) embedded model. While the progression of control moves (MVs) is similar for both controllers, the L-controller imposes a higher temperature setpoint for the LH PID loop and a lower setpoint for the WH PID than the NL-controller does. In general, the selectivity trajectories are within the control limits (between kappa number 89 and 91), although the L-controller slightly violates this constraint between 100min and 200min approximately. Overall, the NL-controller and the L-controller exhibit similar control performance. The good performance of the L-

controller is due to fact that the plant is reasonably linear in this limited range of operation and an accurate model of the plant has been obtained by exact linearisartion of the first principles' nonlinear model. Also, the prefect observer periodically corrects the effects of plant/model mismatch by resetting the linear model to the true operating point at every control window. While both controllers execute roughly the same number of NLP iterations, the L-controller is approximately 5 times faster than the NL-controller. Finally, the L-controller hits one infeasibility and recovers, while the NL-controller always remains feasible.

3.5. Case-study 2

This case study is a variation of case study 1. Again, a production-rate transition from 600.0 ad.ton/day to 650.0 ad.ton/day is scheduled, this time, two hours in advance. However, two hours after the transition a failure in downstream processing equipment triggers a production slow-down to the original rate of 600.0 ad.ton/day, which is enforced two hours later. This is a common yet challenging operating scenario in integrated pulp and paper mills which have low inventories by design.

See figures 5 and 6. This time, the NL-controller outperforms the L-controller, since it is able to maintain the constraint on selectivity at all times. The NL-controller also gives a higher mean yield (objective function) throughout the operation horizon, which is an indication that optimality has been achieved (at least locally).

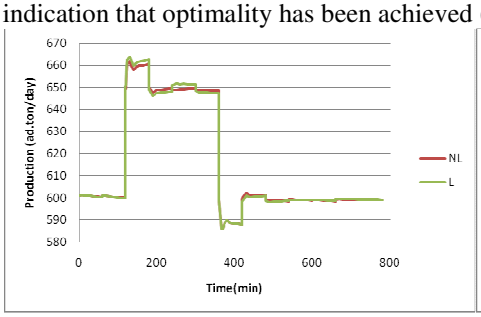

Figure 5: Production (P), CV.

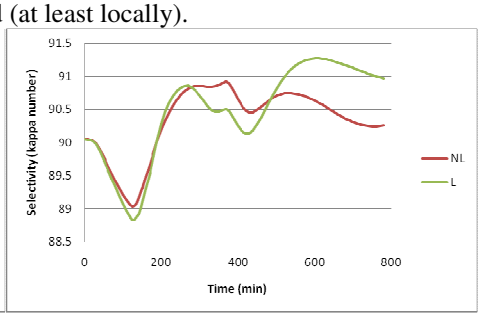

Figure 6: Selectivity (S), CV.

4. Conclusions and Future Work

In this manuscript we presented a framework and software platform that enables the adoption of different model types, solutions methods, and control-and-optimisation strategies transparently and effectively. We examined the performance of a novel DRTO engine through two industrial case studies using linear and nonlinear models. Both first principles model-based controllers performed well and were able to drive the plant through production transitions satisfactorily; while the nonlinear model handled constraints better, the linear model resulted in much faster computational times. The constraint identification and relaxation mechanism for recovery of infeasibilities performed well. Future work will involve refinements to this framework as well as the development of observers for realistic closed-loop feedback with plant/model mismatch.

5. Acknowledgements

The authors wish to acknowledge the contribution of Dr Joseph Zeaiter to this work, who enthusiastically shared his vast experience in and knowledge of industrial APC.

Abstract

In this contribution, the selection of control structures based upon rigorous stationary process models is extended to include the dynamic performance in a consistent manner. A key problem in the comparison of control structures with respect to dynamic performance is that the performance depends on the type and the parameterization of the controllers that are used. In our approach, linear MPC-controllers are assumed and the weights of these controllers are optimized for each structure to yield an optimal economic performance for the disturbance scenarios considered. Thus the result is a good approximation of the best performance that is attainable for each structure and the structures are compared on equal grounds. The approach is demonstrated for a distillation problem.

Keywords: Control structure selection, economic performance, distillation control.

1. Introduction

Control structure selection deals with the choice of manipulated and measured variables used in feedback control. The result of it often has a stronger influence on the performance of the resulting closed-loop system than the choice of control algorithms. Most of the published work from the control community on control structure selection focuses on the dynamic tracking and regulation performance rather than the resulting economic performance of plant, which however should be the main goal of control design for chemical processing plants (see e.g. Engell, 2007). Morari et al. (1980) discussed several important aspects of the control of chemical processes from the point of view of plant performance. This was followed by Skogestad (2000) with the idea of "self-optimizing" control which means that a close-to-optimal steady state performance of the process in the presence of disturbances is established by a well chosen linear control structure. The focus is on the resulting performance at the steady state, and a stepwise approach is proposed to determine the most promising structures. Engell et al. (2005) extended this idea by some refinements replacing the informed judgement by objective criteria and optimization procedures, in particular considering the effect of measurement errors. After the static analysis, the remaining structures were screened by using dynamic performance indicators from linear control theory (Engell et al, 2004).
In the work mentioned above, the disturbances are assumed to be slowly time-varying or constant, so the steady-state behavior is dominant in the economic performance. An incorrect judgment of the performance of the controlled plant may result because the reaction to fast disturbances is not included. In this paper, we extend the procedure

proposed in (Engell et al, 2005, Scharf, 2007) by an evaluation of the dynamic closed-loop performance based upon full rigorous process models.

2. Plant Performance and Control Structure Selection

From a process engineering point of view, the role of automatic feedback control is to keep the process operation as close as possible to the economic optimum in the presence of disturbances and differences between the plant model used for the design of the plant and the real plant. The goal is to regulate the controlled variables to their setpoints in the presence of disturbances in such a way that the optimal manipulated variables u_{opt} are approximated. The effect of feedback control on the profit function J can be expressed as (Engell et al., 2005, Engell, 2007):

$$\Delta J = \left(J(\underline{u}_{nom}, 0) - J(\underline{u}_{nom}, \underline{d}_i) \right) + \left(J(\underline{u}_{nom}, \underline{d}_i) - J(\underline{u}_{opt}, \underline{d}_i) \right) + \left(J(\underline{u}_{opt}, \underline{d}_i) - J(\underline{u}_{con}, \underline{d}_i) \right)$$

The first term is the loss if the manipulated variables are fixed at their nominal values when disturbances occur, the second term is the effect of the optimal adaptation of the manipulated variables in the presence of disturbances, and the third term is the difference between the optimal adaptation and the one which is realized by the chosen feedback control structure. If the first term is large compared with the other terms then changing the manipulated variables will bring little profit, neither online optimizing nor feedback control is useful here. On the other side if the third term is large then online optimizing control (Engell, 2007) should be used instead of feedback control. The overall static performance of a control structure can be quantified by the expected loss of profit (Engell et al., 2005):

$$\Delta J = \int_{-d_{1,\max}}^{d_{1,\max}} \dots \int_{-d_{n,\max}}^{d_{n,\max}} w(\underline{d})(J(\underline{u}_{nom}, \underline{d}_i) - J(\underline{u}_{con}, \underline{d}_i))dd_1 \dots dd_n$$

where $w(\underline{d})$ is the probability of the occurrence of the disturbance $\underline{d}$. Practically this expression is approximated by the weighted sum over a set of disturbance scenarios.

There are two kinds of disturbances which affect the process: slow and fast varying disturbances. The effect of the former ones can be taken by into account by using a static optimization which analyzes the worst case performance of the regulatory control keeping the controlled variables within a range around the set-points defined by the measurement errors (Engell et al., 2005, Scharf, 2007). How to include the effect of the latter ones is discussed in this paper.

It is proposed to include the dynamic performance in a consistent manner by extending the above analysis to incorporate a full dynamic process model, dynamic controllers, and fast disturbances. In order to avoid the assumption of simple linear control structures and to be reasonably close to the best possible performance that a control structure can yield without excessive numerical effort, linear MPC controllers are assumed As the focus is on the economic performance, the weights used in the cost functions of the MPC-controllers are optimized for each structure with respect to the optimal economic performance for all disturbance scenarios considered.

3. Control Structure Selection Procedure

The proposed control structure selection procedure consists of 6 steps:

3.1. Define the optimization problem:

Analyze the available degrees of freedom of the process during plant operation and choose the manipulated variables. Formulate a profit function *J* to be maximized and specify the constraints that have to be satisfied during the process operation.

$$\max_{u} J(\underline{x}, \underline{u}, \underline{d}_i)$$

s.t system model

$$\underline{h}(\underline{x}, \underline{u}) \le 0$$

The system model can be either dynamic or static, $\underline{h}(\underline{x}, \underline{u})$ are the process constraints, d_i are the disturbances. The output mapping is given by: $\underline{y} = \underline{m}(\underline{x})$, in steady state $\underline{y} = \underline{M}(\underline{u}, \underline{d}_i)$.

3.2. Choose the disturbances:

It is distinguished between two types of disturbances: measurement errors and external disturbances. The former ones can be obtained from the instrument data-sheets. The latter ones may be caused by errors in the assumed model, disturbances, etc.

3.3. Pre-selection of the control structures

The number of possible control structures is given by:

$$C_n^k = \binom{n}{k} = \frac{n!}{(n-k)!\,k!}$$

with *n*: the number of available measurements and *k*: the number of controlled variables. This number increases rapidly with the number of measurements. Pre-screening of the unpromising structures is useful here especially for large problems. Several indices can be used, e.g. sensitivity to measurement errors (Engell et al., 2004) or linear performance indicators (Engell et al., 2004).

3.4. Selection of the set-points for regulatory control

The set-points are determined by optimization over the set of disturbance scenarios to fully utilize the potential of feedback control. The optimal set-points are found by solving:

$$\max_{\underline{y}_{set}} \sum_{i=1}^{n} J(\underline{x}, \underline{u}_i, \underline{d}_i)$$

$$s.t.: \forall \underline{d}_i :$$

$$\dot{\underline{x}} = f(\underline{x}, \underline{u}_i, \underline{d}_i) = 0$$

$$\underline{h}(\underline{x}, \underline{u}) \le 0, \underline{y}_{set} = \underline{m}(\underline{x})$$

$$u_{\min} \le u_i \le u_{\max}, x_{\min} \le x \le x_{\max}$$

If the above optimization problem is infeasible, it means that there is no common set-point which can be attained for all disturbances and the given constraints.

3.5. Quantitative evaluation of the benefits of the control structures with constant disturbances

For all scenarios of disturbances $\underline{d}_i$, the worst case control performance for regulation of the controlled variables to values in the range around the nominal set-point $\underline{y}_{set}$ defined by the measurement error $\underline{e}_{sensor}$ is obtained by solving the following optimization problem:

$$\min J(\underline{x}, \underline{u}_i, \underline{d}_i)$$

$$s.t.: \dot{\underline{x}} = f(\underline{x}, \underline{u}_i, \underline{d}_i) = 0$$

$$\underline{h}(\underline{x}, \underline{u}) \le 0, \underline{y} = \underline{m}(\underline{x})$$

$$\underline{y}_{set} - \underline{e}_{sensor} \le \underline{y} \le \underline{y}_{set} + \underline{e}_{sensor}$$

A comparatively large value of the maximum loss means that the corresponding control structure is not able to avoid a poor stationary performance in the presence of the measurement errors and should be excluded.

3.6. Quantitative evaluation of the benefits of the control structures with dynamic disturbances

After the controlled variables that are regulated to their set-points have been determined, the maximum attainable dynamic performance of the controlled system is compared. In order to accomplish this, a simulation of a linear MPC controller which is based upon a linearized model of the plant is employed. The objective function of the MPC controller is defined as

$$P(t_k) = \min_{\mathbf{u}} \left(\int_{t=t_k}^{t_k+H_P} \left(\|\Delta y(t)\|_P + \|\Delta u(t)\|_Q \right) dt \right)$$

$$s.t.: \quad \Delta \dot{x}(t) = A\Delta x(t) + B\Delta u(t) + C\Delta d(t) \qquad (P1)$$

$$\Delta y = D\Delta x(t)$$

where $\|.\|_X$ denotes the norm which is defined by: $\|u\|_X = u^T Xu$, X is a positive semi-definite matrix. A, B, C, D are matrices which are obtained by linearizing the system at the operating points found in step 4. P and Q are degrees of freedom and should be chosen such that the economic profit function J is maximized. The prediction horizon H_p is chosen long enough to capture all effects of the disturbances. An upper layer optimization is used in order to compute P and Q over all disturbances:

$$\max_{P,Q} \int_{t=0}^{t=t_{end}} \sum_{i=1}^{n} J(\underline{x}, \underline{u}_i, \underline{d}_i) dt$$

$$s.t.: P, Q \succ 0$$

$$(P1)$$

Thus the result is a good approximation of the attainable performance for each structure. The structure which yields the best performance using the same criterion as step 5 will be chosen.

4. Case study

The methodology described above is applied to a continuous distillation column shown in Figure 1. The distillation column is used for the separation of a binary mixture of Methanol and n-Propanol. The model of the process (Diehl, 2001) is based on the following assumptions: total condenser, negligible vapour holdup, variable liquid holdup, liquid outflow determined by Francis weir formula, constant pressure losses, perfect mixing, the mixture is at equilibrium temperature, Murphree efficiency is applied for each tray. The system model for 40 trays is large and stiff with 82 differential and 122 algebraic variables. There are two operating degrees of freedom after closing the inventory loops: the reflux rate and the heat supply. A composition measurement is assumed to be too expensive so the controlled variables are two tray temperatures. There are: $C_{40}^2 = 780$ possible control structures. The profit function is:

$$J = c_{Methanol} \tanh(x_{Methanol} - desiredvalue)\dot{n}_{Methanol} - c_{heat}\, heatinput$$

tanh implies that the purity of distillate product should satisfy the specification which is 0.99 in our case. The disturbances are chosen to be: a step change in the feed flow rate

by ±4 l/h, a step change in the feed concentration by ±0.1, a step change in the feed temperature by ±5 K for both the steady state and the dynamic analysis. For the steady state case, additional disturbances are considered: a change in the condenser temperature by ±5 K, a change in the heat loss by ±0.2 kW. In the dynamic scenario, the disturbances are assumed to be uniformly distributed within the lower and upper bound. The sensor error is assumed to be ±0.33 K. The heat input and the reflux flow rate are restricted to 5 kW and 7 l/h.

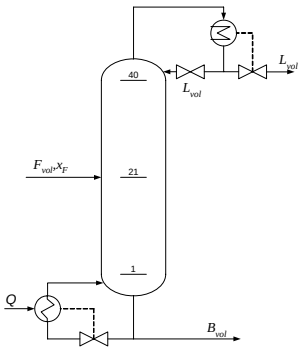

Fig. 1. Distillation Column

First a pre-screening is performed to take unpromising structures out of the large number of options. The generalized criterion of non square RGA (Skogestad and Postlethwaite, 1996) is used. 429 structures with a sum of the elements in row of the RGA less than 0.1 are discarded. Next, a measurement error sensitivity analysis is performed and 78 structures are left for the next step. In step 4, all the structures have a common set-point so 78 structures are considered further in step 5. Only those structures which lead to a profit larger than 85% of the nominal operating profit of 114.893 in the worst case are retained in the final step. 12 structures that satisfy this criterion are compared in the final step with respect to their dynamic performance using the linear MPC simulation with the nonlinear rigorous process model. For the optimization of the weights of the MPC controllers, a gradient-free optimization procedure was used (Berghen and Bersini, 2005). The performance indices of several structures are given in Table 1. Structure (10,31) yields the best performance.

Structure	Profit
(6,35)	107.67
(7,33)	106.36
(10,31)	111.02
(11,32)	109.85

Table 1. Performance indices of several structures resulting from a simulation of optimized linear MPC controllers

The results of the MPC simulation of this structure and of the structure (6,35) with disturbances of the feed flow and of the feed temperature are shown in Fig. 2 and Fig. 3. It can be seen that in the presence of strong disturbances in the feed flow by 30% of the nominal flow, the controller with the structure (10,31) manages to keep the controlled variables at their set-points and the top product purity still satisfies the requirement. The structure (6,35) could not keep the purity at the specified value. In the case of a disturbance in the flow rate, the purity drops down close to 0.985. This result verifies the heuristics that the best positions for controlling the composition of a distillation column using two tray temperatures are somewhere in the middle of the rectifying and stripping sections.

5. Conclusion

A methodology for control structure selection was presented with the aim of optimizing the plant performance taking into account the presence of both steady-state and dynamic disturbances. The method was applied successfully to the example of a distillation column. Because of the large computation times for NMPC simulations and in view of the industrial practice to use linear MPC controllers, the performance evaluation in the dynamic case is based upon linear MPC controllers with weights that are optimized for economic performance in an outer loop. Steps 1 – 6 of the control structure selection procedure yield a set of control structures that lead to good performance with respect to

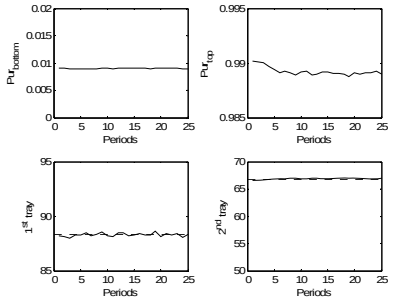

Fig. 2.aSimulation of linear MPC for structure (10,31) with disturbance in the feed flow rate

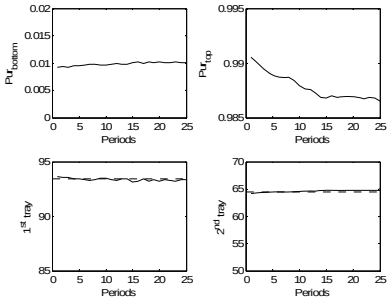

Fig. 2.b Simulation of linear MPC for structure (6,35) with disturbance in the feed flow rate

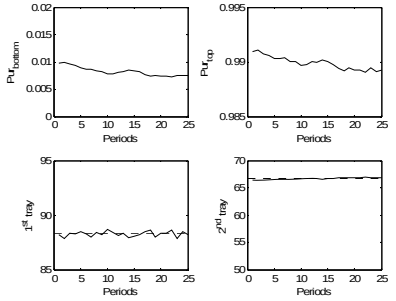

Fig. 3.a Simulation of linear MPC for structure (10,31) with disturbance in the feed temperature

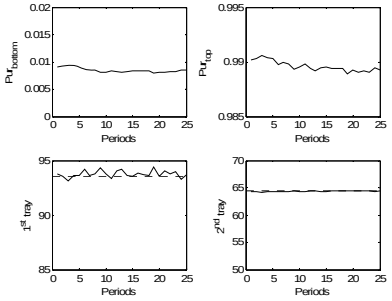

Fig. 3.b Simulation of linear MPC for structure (6,35) with disturbance in the feed temperature

the economic performance of the plant both for stationary or slowly-varying and for fast-varying disturbances. However, it may happen that some of these structures are not suitable for dynamic operation in the presence plant-model mismatch (lack of robustness). To check this, a linear dynamic controllability analysis should also be performed, cf. Engell at al. (2004).

Model-Based Fault-Tolerant Control of Particulate Processes: Handling Uncertainty, Constraints and Measurement Limitations

Arthi Giridhar[a], Sathyendra Ghantasala[a], Nael H. El-Farra[a]

[a]*Department of Chemical Engineering and Materials Science, University of California, Davis, One Shields Avenue, Davis, CA 95616, USA*

Abstract

This paper presents a methodology for the integrated synthesis of a fault detection and isolation (FDI) and fault-tolerant control (FTC) system for particulate processes described by population balance models. The approach is based on a suitable low-order model of the process and accounts explicitly for model uncertainty, control constraints and measurement errors. The main idea is to shape the fault-free closed-loop dynamics via robust control in a way that enables the derivation of FDI and reconfiguration criteria that are less sensitive to the uncertainties and measurement errors. The results are illustrated through an application to a continuous crystallizer with a fines trap.

Keywords: Robust control, Process monitoring, FDI, Reconfiguration, Crystallizer.

1. Introduction

Particulate processes characterized by the co-presence of continuous and particulate phases are encountered in a large number of processing industries including agricultural, chemical, food, minerals, and pharmaceuticals. Despite the significant and growing body of research work on particulate process control (e.g., see Semino and Ray (1995), Christofides (2002), Zhang and Rohani (2003), Park et al. (2004), Larson et al. (2006) for some results and references in this area), the problem of designing model-based fault diagnosis and fault-tolerant control systems for particulate processes has received limited attention. This is an important problem given the fact that the erosion of controller authority caused by control system malfunctions can directly impact the end product quality and lead to substantial production losses (El-Farra and Giridhar, 2008). It is also a challenging problem due to the infinite-dimensional nature of particulate process models, which precludes their direct usage for control and monitoring purposes, the presence of model uncertainty, control constraints and the inherent limitations on the number and accuracy of process measurements, which can seriously erode the diagnostic and fault-tolerance capabilities of the control system if not explicitly accounted for at the controller design stage. In this paper, we present a robust fault diagnosis and fault-tolerant control (FTC) structure for particulate processes with control actuator faults. Unlike our previous work in El-Farra and Giridhar (2008), the structure presented here addresses explicitly the problems of time-varying model uncertainty and measurement errors. Initially, a finite-dimensional system that captures the dominant process dynamics is derived and decomposed into a number of interconnected subsystems that are each excited by a single manipulated input. A bounded Lyapunov-based controller that satisfies the control constraints is then

designed for each subsystem, leading to an explicit characterization of (1) the fault-free behavior of each subsystem in terms of a time-varying bound on the dissipation rate of the corresponding Lyapunov function, and (2) the robust stability region where constraint satisfaction and robustness with respect to the uncertainty and measurement errors are guaranteed. Using the fault-free bounds as alarm thresholds for fault detection and isolation (FDI), faults in a given actuator are diagnosed by monitoring the evolution of the process within the stability region and declaring a fault when the corresponding threshold is breached. The threshold depends on the achievable degree of asymptotic uncertainty attenuation and thus can be adjusted by properly tuning the controller. To ensure robustness of the FDI scheme to measurement errors, the monitoring region is confined within a subset of the stability region, and the FDI thresholds are enlarged appropriately. The robust FDI scheme is integrated with a controller reconfiguration strategy that orchestrates stabilizing transitions from the faulty actuators to a well-functioning fallback configuration following FDI. Practical implementation issues, such as robustness to model reduction errors when the model-based FTC architecture is implemented on the particulate process, as well as the problem of incomplete state measurements, are also discussed. Finally, the proposed methodology is applied to robustly stabilize a continuous crystallizer with a fines trap under control actuator faults**.**

2. Particulate processes with uncertainty, constraints and actuator faults

2.1 Process modeling using population, mass and energy balances

We focus on spatially homogeneous particulate processes modeled by the following general nonlinear system of partial integro-differential equations:

$$\begin{aligned}
&\frac{\partial n}{\partial t} = -\frac{\partial\left(G(x,r)n\right)}{\partial r} + w\left(n,x,r,\theta(t)\right) + g_1\left(n,x,r\right)\left[u_1^k + f_{a1}^k\right], n(0,t) = b(x(t)) \\
&\dot{x} = f(x) + g_2(x)\left[u_2^k + f_{a2}^k\right] + \chi\left(x,\theta(t),\int_0^{r_{\max}} q\left(n,x,r\right)dr\right) \\
&\left\|u_i^k(t)\right\| \le u_{i,\max}^k, i = 1,2; \left\|\theta(t)\right\| \le \theta_b, k(t) \in \{1,2,...,L\}, L < \infty
\end{aligned} \tag{1}$$

where $n(r,t)$ is the particle size distribution function, which is assumed to be continuous and sufficiently smooth in its arguments, $r \in [0, r_{max})$ is the particle size, t is the time, $x \in R^n$ is the vector of state variables that describe properties of the continuous phase (e.g., solute concentration, temperature and pH in a crystallizer), $u^k_1 \in R$ is the manipulated input associated with the particulate phase (e.g., fines destruction rate), $u^k_2 \in R$ is the manipulated input associated with the continuous phase (e.g., solute feed concentration in a crystallizer), $u^k_{i,max}$ is a real number that captures the size of constraints on the magnitude of the *i-th* manipulated input, $f^k_{a,i} \in R$ denotes a fault in the *i-th* control actuator, $k(t)$ is a discrete variable that denotes which control configuration is active at time t, $\theta \in R^q$ denotes the vector of uncertain process variables (e.g., unknown process parameters and time-varying external disturbances), θ_b is a known bound on the size of the uncertainty. In the population balance of Eq.1, $G(x,r)$ is the growth rate, $w(n,x,r,\theta) := w_0(n,x,r) + w_u(n,x,r)\theta$ is the net rate of introduction of new particles into the system, and $f(\cdot), q(\cdot), g_1(\cdot) g_2(\cdot), \chi(\cdot)$ are smooth nonlinear functions. The term containing the integral accounts for mass and heat transfer from the continuous phase to all the particles in the population and has the form $\chi(\cdot,\cdot,\theta) = \chi_0(\cdot,\cdot) + \chi_u(\cdot,\cdot)\theta$.

2.2 Model order reduction using the method of weighted residuals

To derive a finite-dimensional system that captures the dominant dynamics of the distributed parameter system of Eq.1, we first expand the solution in an infinite series in

terms of an orthogonal and complete set of basis functions, $\{\phi_k(r)\colon r\in [0,r_{max})\}$, as $n(r,t)=\Sigma_{k=1}^{\infty} a_k(t)\phi_k(r)$, where $a_k(t)$ are time-varying coefficients. Substituting the series expansion into Eq.1, multiplying the population balance with appropriate weighting functions, integrating over the entire particle size spectrum, and finally truncating the series expansion up to order N (keeping the first N equations), we obtain the following approximate finite-dimensional system:

$$\dot{z}_i = h_i(z_1,z_2)+m_i(z_1,z_2)\left[u_i^k + f_{ai}^k\right]+d_i(z_1,z_2)\theta, i=1,2 \quad (2)$$

where $z_1=a^N=[a_1^N \ \dots \ a_N^N]^T$, $z_2=x_N$, x_N and a_k^N are the approximations of x and a_k, respectively, obtained by an *N-th* order truncation of the infinite series, h_i, m_i, d_i are nonlinear functions whose explicit forms are omitted for brevity. The asymptotic validity of the approximation can be justified using standard results from perturbation theory (Christofides, 2002). In the next section, we present the design methodology for the FDI-FTC structure on the basis of the reduced-order system of Eq.2, and then discuss in Section 4 its implementation on the infinite-dimensional system of Eq.1.

3. Methodology for integrated robust FDI and fault-tolerant control

3.1 Bounded Lyapunov-based controller synthesis

The objectives of this step are to: (a) synthesize, for each control actuator configuration, a family of feedback controllers that enforce (in the absence of faults) constraint satisfaction and robust stability with an arbitrary degree of asymptotic attenuation of the effect of uncertainty on the closed-loop system, and (b) explicitly characterize the robust stability region associated with each configuration in terms of the constraints and the size of the uncertainty. To this end, we first design the controllers assuming the availability of accurate full-state measurements and then analyze the effects of measurement errors to derive sufficient conditions for closed-loop stability. Specifically, let V_i be a robust control Lyapunov function (Freeman and Kokotovic, 1996) for the *i-th* subsystem in Eq.2, and consider the feedback control law given by:

$$u_i^k(z)=-\left(\frac{\alpha_i(z)+\sqrt{\alpha_i^2(z)+\left(u_{i,\max}^k\beta_i^k(z)\right)^4}}{\left(\beta_i^k(z)\right)^2\left[1+\sqrt{1+\left(u_{i,\max}^k\beta_i^k(z)\right)^2}\right]}\right)L_{gi}V_i, i=1.2, k(t)\in\{1,2,...,L\} \quad (3)$$

where $\alpha_i = L_{hi}V_i + (\rho_i|z_i|+\chi_i\theta_b|L_{di}V_i|)(|z_i|/(|z_i|+\phi_i^k))$, $\beta_i^k = |L_{mi}V_i|$, $L_{hi}V_i$, $L_{mi}V_i$ and $L_{di}V_i$ are Lie derivatives of V_i, $z=[z_1\ z_2]^T$ and $\rho_i>0$, $\chi_i>1$, $\phi_i^k>0$ are adjustable parameters. It can be verified that each controller satisfies the control constraints within the state space region described by the set $I\Gamma_i^k:=\{z\in R^{n+N}\colon \alpha_i(z,\rho_i\chi_i\phi_i^k,\theta_b)\le u_{i,\max}^k\beta_i^k(z)\}$. To account for measurement errors, let $z_m(t)=z(t)+e(t)$ be the actual state measurement used to implement the controllers, where $e(t)$ is a bounded time-varying function ($|e(t)|\le\mu$) that captures the measurement error. From the continuity of the control laws, it follows that the error in the implemented control action is also bounded, i.e., $|u_i^k(z_m)-u_i^k(z)|\le M_i(\mu)$ for some class $\mathcal{K}$ function M_i (a function is said to be of class $\mathcal{K}$ if it is non-decreasing and vanishes at zero; see Khalil (2002)). To ensure that the control constraints continue to be satisfied, evolution of the closed-loop states must be restricted within the sub-region defined by $\Lambda_i^k:=\{z\in I\Gamma_i^k\colon |u_i^k(z)|\le u_{i,\max}^k - M_i(\mu)\}$. Specifically, it can be shown using a Lyapunov argument that if $z(t)\in\Lambda_i^k$ and $f_{ai}^k(t)=0$, for some t and i, then for sufficiently small ϕ_i (and/or sufficiently large χ_i), the time-derivative of V_i along the trajectories of the *i-th* fault-free closed-loop subsystem of Eqs.2-3 satisfies:

$$\dot{V}_i(z(t)) \le -\gamma_i V_i(z_i(t)) + \sigma_i(\phi_i) + \Xi_i(\mu) := B_i(z_{m,i}(t), \gamma_i, \phi_i, \mu) \quad (4)$$

for some constant $\gamma_i>0$ and some class $\mathcal{K}$ functions σ_i and Ξ_i. Furthermore, if $f^k_{a,i}=0$ for all i and the closed-loop system is initialized within any invariant subset of $\Lambda^k := \Lambda^k_1 \cap \Lambda^k_2$, e.g., $z(0) \in \Omega^k_s(\theta_b, u^k_{\max}) := \{z \in \Lambda^k : V_1(z)+V_2(z) \le \delta_s\}$ for some $\delta_s>0$, then each controller in the *k-th* control configuration (implemented with measurement errors) satisfies the control constraints and drives the trajectory of its corresponding subsystem in finite-time into a small neighborhood around the desired steady-state where it remains confined for all future times. The size of this terminal set can be made small by proper tuning of the controller parameters, but is ultimately constrained by the size of the measurement error μ. The set $\Omega^k_s(\theta_b, u^k_{\max})$ therefore represents an estimate of the robust stability region starting from where practical closed-loop stability is guaranteed.

3.2 Robust fault detection and isolation scheme

Since the inequality of Eq.4 provides an explicit characterization of the expected fault-free behavior of each subsystem, it can be used to derive rules for FDI. Specifically, any breach of the given bound while $z(t) \in \Omega^k_s(\theta_b, u^k_{\max})$ is an indicator of a fault in the corresponding actuator. However, since verifying this requires monitoring of the state, which is known with only limited accuracy, we introduce two key modifications to safeguard against possible false alarms due to measurement errors. The modifications include (1) limiting the monitoring region to an appropriate subset of the stability region, i.e., $\Omega^k_c \subset \Omega^k_s$ where $z_m(t) \in \Omega^k_c \Rightarrow z(t) \in \Omega^k_s$ (this is needed to be able to infer the location of z in the state-space from the available measurement, z_m) and (2) enlarging the bounds on the dissipation of the Lyapunov functions. Specifically, by exploiting the continuity of both V_i and its time-derivative in their arguments, one can show that given any desired subset $\Omega^k_c \subset \Omega^k_s$, there always exists a class $\mathcal{K}$ function $X_i > \Xi_i$ such that:

$$\dot{V}_i(z_m(t)) \le -\gamma_i V_i(z_{m,i}(t)) + \sigma_i(\phi_i) + \mathrm{X}_i(\mu) := B^*_i(z_{m,i}(t), \gamma_i, \phi_i, \mu) \quad (5)$$

Note that any breach of Eq.5 while $z_m(t) \in \Omega^k_c$ implies that Eq.4 is breached while $z(t) \in \Omega^k_s$. Therefore, by using the time-derivative of V_i as a residual, and the right hand side of Eq.5 as an alarm threshold, a fault in the *i-th* actuator can be declared at time T_d if $z_m(T_d) \in \Omega^k_c$ and $\dot{V}_i(T_d) > B^*_i(z_{m,i}(T_d), \gamma_i, \phi_i, \mu)$. Comparing Eqs.4 and 5, wee see that the alarm threshold is essentially increased to ensure that any discrepancy between the actual and fault-free residuals exceeds what can be accounted for by measurement errors alone, and thus is due solely to faults.

3.3 Control system reconfiguration

Following FDI, the supervisor needs to determine based on the available (inaccurate) measurements which backup configuration can be activated to maintain robust closed-loop stability. To this end, consider the closed-loop system of Eqs.2-3 with $k(0)=j$, $z(0) \in \Omega^k_s$ and let T_d be the earliest time that a fault is detected in the *i-th* actuator. Then choosing the configuration $k(t)=\nu$ for $t \ge T_d$ where $z_m(T_d) \in \Omega^\nu_c(\theta_b, u^\nu_{\max})$ ensures that the origin of the closed-loop system remains practically stable. Recall from the definition of Ω^k_c in Section 3.2 that $z_m(t) \in \Omega^k_c \Rightarrow z(t) \in \Omega^k_s$; therefore, the switching logic ensures that the fallback actuator configuration that is activated and implemented following FDI is one whose stability region contains the state at the time of switching. In the event that multiple configurations satisfy this stability condition, additional performance criteria can be introduced to aid in choosing the appropriate configuration.

4. Implementation issues

While the FDI-FTC structure presented above is designed on the basis of an approximate reduced-order model of the particulate process, it can be shown using regular perturbation techniques (e.g., see El-Farra and Giridhar (2008)) that it continues to enforce the desired stability and fault-tolerance properties in the infinite-dimensional system of Eq.1 provided that the reduced-order model is of a sufficiently high-order and the FDI rules are appropriately modified to account for the approximation errors. Specifically, the closeness of solutions between the approximate and infinite-dimensional systems can be exploited to obtain new alarm thresholds that can be chosen as close as desired to the bounds obtained for the approximate system for sufficiently large N. Furthermore, the problem when only measurements of the principal moments of the particle size distribution and the continuous-phase variables are available for on-line implementation can be addressed by incorporating a suitable nonlinear state observer to generate estimates of z from the measured outputs, which are then used to implement the controllers, FDI and reconfiguration laws. The observer must be designed to ensure sufficiently fast convergence of the state estimates. This property is necessary to ensure that the same diagnostic and fault-tolerance properties obtained under full-state feedback control can be practically recovered under output feedback control by proper choice of the observer tuning parameters (see El-Farra and Giridhar (2008) for an example observer design that satisfies this requirement).

5. Case study: Application to a continuous crystallizer with a fines trap

To demonstrate the implementation of the proposed FDI-FTC methodology, we consider in this section an example involving an isothermal continuous crystallizer with a fines trap. The trap is used to remove small crystals and increase the mean crystal size. The process model and parameters can be found in Christofides (2002). The control objective is to regulate the crystal and solute concentrations at desired set points by manipulating the flow rate of suspension through the fines trap and the inlet solute concentration in the presence of (1) actuator constraints and faults, (2) time-varying errors in the crystal and solute concentration measurements, and (3) time-varying uncertainties in the nucleation rate and the density of crystals. To ensure actuator fault-tolerance, a backup actuator is assumed to be available for each manipulated input for use in the event that the primary actuator fails. Using the method of moments and approximating the size distribution function using a Laguerre polynomial expansion to close the set of moment equations (Lei et al., 1971), an approximate fifth-order nonlinear ODE system describing the evolution of the first four moments of the crystal size distribution and the solute concentration is obtained and used for the synthesis of the FDI-FTC structure which is then implemented on a sufficiently high-order discretization of the process model obtained using a finite-difference scheme. The model derivation and controller synthesis details are omitted due to space limitations.

To detect and isolate faults during crystallizer operation, we consider the following two residual signals. The first is dedicated to faults in the first manipulated input (flow rate through fines trap) and captures the discrepancy between the actual and fault-free evolutions of z_1 in Eq.2 (the fault-free behavior is estimated from Eq.5). The second residual is dedicated to faults in the second manipulated input (solute feed concentration), and captures the discrepancy between the actual and fault-free evolutions of z_2 in Eq.2. To account for the effects of uncertainties, state estimation, measurement and model reduction errors in the absence of faults, the alarm thresholds for FDI are set at $\delta_1=\delta_2=0.012$ by properly tuning the controllers and observers. To

demonstrate how the integrated FDI-FTC scheme works, the process is initialized using the healthy controllers which, as can be seen from the solid profiles in the top plots in Fig.1, successfully steer the crystal (left) and solute (right) concentrations near the desired set points very quickly. At *t=15 hr*, a fault is introduced in the actuator manipulating the suspension flow rate through the fines trap (valve stuck in the closed position; see dashed line in the left middle plot of Fig.1). The bottom plots in Fig.1 depict how this failure is detected and isolated since it causes the corresponding residual, r_1, to cross the specified threshold at *t=15.5 hr*, while practically not influencing r_2. Following FDI in the first controller, the supervisor switches to a backup actuator that maintains the closed-loop outputs near their desired set-points, as can be seen by the solid profiles in the top plots in Fig.1. After recovering from the first fault, a second failure in the actuator manipulating the solute feed concentration occurs at *t=25 hr* as shown by the dashed line in the right middle plot of Fig.1. By examining the residual profiles, it can be seen that this failure is detected and isolated in a timely manner since it causes r_2 to cross the threshold at *t=25.07 hr*, while r_1 remains within its threshold limit. Following the detection and isolation of the second actuator failure, the supervisor switches to the available backup actuator to preserve robust closed-loop stability. The dashed profiles in the top two plots of Fig.1 show the destabilizing effect of the two consecutive faults when no corrective action is taken.

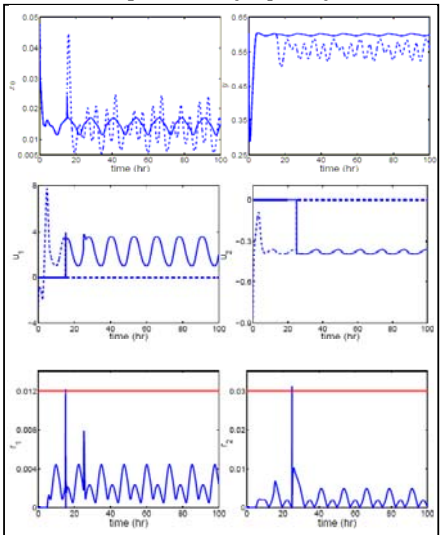

Fig.1. Evolution of the crystallizer's controlled outputs (top), manipulated inputs (middle) and FDI residuals (bottom) under two consecutive failures in the control actuators and subsequent reconfiguration.

Abstract

Direct tuning is investigated as an alternative to iterative model estimation and control design for state space systems in case of unsatisfactory loop performance. Direct tuning of the model parameters in the feedback control and the observer design by Iterative Feedback Tuning, optimize loop performance when the initial designs are based on an uncertain model estimate. The certainty equivalence design is kept throughout the iterations when the model parameters is updated. This methodology constitutes a promising algorithm when developing tools for online tuning of state space control systems.

Keywords: LQG control, Iterative Feedback Tuning.

1. Introduction

The need for optimal process operation has rendered methods for optimization of control loop parameters an active research area. Much attention has been directed on performing control oriented system identification, which implies model estimation from closed loop data [1,2]. Optimizing the parameters in a control loop is an iterative procedure since the data from one experiment will depend on the current controller, and repeated iteration is necessary for the loop performance to converge to a minimum. An alternative would be a direct data driven approach to tuning without utilizing a model estimate. Data driven tuning methods have mainly been reported for systems given in transfer function form. The most established method is Iterative Feedback Tuning [3]. This method optimizes the closed loop performance by adjusting the control parameters through a gradient based scheme. The gradient of the cost function is replaced by an unbiased estimate evaluated from special closed loop experiments. Direct tuning is often computationally less demanding than identification and model based control design. Direct tuning methods can be used when insufficient knowledge of the model structure limits nominal performance, where the system is tuned based on the certainty equivalence principle.

This paper investigates the use of the direct tuning method, Iterative Feedback Tuning, for optimization of the parameters in the feedback loop and the state observer for a control loop based on a state space system description. Based on the certainty equivalence principle, analytical solutions for optimal values of the feedback and Kalman gain exist. This assumption renders the loop performance sensitive to model

errors and bias. Direct controller tuning of the uncertain model parameters may serve as an interesting alternative, when fine tuning a control loop is desired or when degrading loop performance is observed.

This paper is organized as follows. In the following section a short introduction to the system and control loop description is given. Section 3 discusses optimal control and tuning. In Section 4 an illustrative simulation example is given before final conclusions eventually are drawn.

2. The state space control loop

Given the following linear, discrete time, single input/single output, time-invariant system description:

$$\begin{aligned} \boldsymbol{x}_{t+1} &= \boldsymbol{A}\boldsymbol{x}_t + \boldsymbol{B}u_t + \boldsymbol{e}_t^P, & \boldsymbol{e}_t^p &\in N(0, \boldsymbol{P}_{e^P}) \\ y_t &= \boldsymbol{C}\boldsymbol{x}_t + e_t^m, & e_t^m &\in N(0, \sigma^2_{e^m}) \end{aligned} \tag{1}$$

Where $\boldsymbol{x}_t$ represents the system states, u_t is the manipulated variable and y_t is the measurement at discrete time instants. $\boldsymbol{e}^p{}_t$ represents process noise and $e^m{}_t$ is measurement noise. Both $\boldsymbol{e}^p{}_t$ and $e^m{}_t$ will be assumed white and the cross correlation between these types of noise will be assumed zero. It is desired to control this system using the feedback law:

$$u_t = -\boldsymbol{L}\boldsymbol{x}_t + Mr_t \tag{2}$$

Where $\boldsymbol{L}$ is a constant feedback gain matrix and M is a controller gain for the reference signal. Since the exact values of the states are not known, an observer is used to generate the state estimates used in the control law based on measurements of the process output and a process model. The observer has the form of the predictive Kalman filter with the constant gain matrix $\boldsymbol{K}$, assuming stationary conditions.

$$\hat{\boldsymbol{x}}_{t+1|t} = \hat{\boldsymbol{A}}\hat{\boldsymbol{x}}_{t|t-1} + \hat{\boldsymbol{B}}u_t + \boldsymbol{K}(y_t - \hat{\boldsymbol{C}}\hat{\boldsymbol{x}}_{t|t-1}) \tag{3}$$

The structure of the state space feedback loop consisting of equation (1) and (3) is shown in Figure 1.

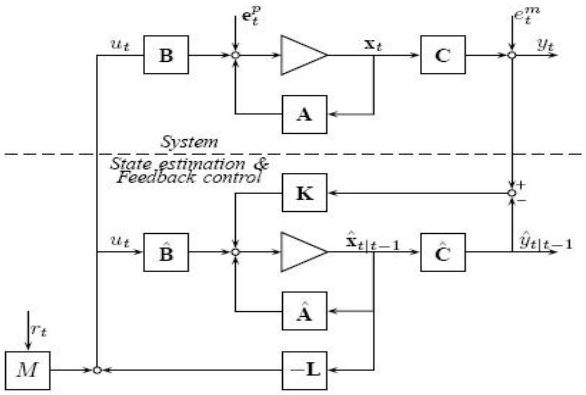

Figure 1. Block diagram of the closed loop state space system with state observer

In order to ensure a static gain from the reference to the estimated output of unity, the following requirements can be derived:

$$M = [\hat{\boldsymbol{C}}(\boldsymbol{I} - \hat{\boldsymbol{A}} + \hat{\boldsymbol{B}}\boldsymbol{L})^{-1}\hat{\boldsymbol{B}}]^{-1} \tag{4}$$

Introducing the state estimation error: $\tilde{\boldsymbol{x}}_t = \boldsymbol{x}_t - \hat{\boldsymbol{x}}_t$, provides a convenient description with a more clear distinction between feedback control and state estimation dynamics [4]. If the system (1) is stabilizable and detectable a set {***L,K***} exists which renders the system stable [5]. Hence if optimal values for the feedback and Kalman filter gains are used stability is guaranteed.

3. Optimal control and tuning

Optimal values for both the observer gain ***K*** and the feedback gain ***L*** exist and have known analytical solutions if the true system is known [6]. The optimal, stationary value for the gain matrix in the Kalman filter can be evaluated based on the process model and information of the noise intensities, from an algebraic Riccati equation. The optimal controller gain will also depend on the optimization criterion. In this paper the control design will minimize the value of a cost function for the loop performance for a single input/single output system:

$$F(y,u) = \frac{1}{2N}\sum_{t=1}^{N} y_t^2 + \lambda u_t^2 \tag{5}$$

Where λ determines the weighting between the penalty on the output and the control. For optimal tracking the output is replaced by the tracking error in the cost function. The optimal Linear Quadratic Gaussian controller (LQG) produces an optimal feedback gain which minimizes the quadratic cost function:

$$F_{LQG}(y,u) = \frac{1}{2N}\sum_{t=1}^{N} \hat{\boldsymbol{x}}_t^T \boldsymbol{Q}_R \hat{\boldsymbol{x}}_t + \lambda u_t^2 \tag{6}$$

using the linear system description in (3) and assuming that *N* approaches infinity. As for the observer gain, the solution is given by an algebraic Riccati equation. In case $\boldsymbol{Q}_R = \boldsymbol{C}^T\boldsymbol{C}$ the cost function (6) is equivalent to (5).

In absence of an accurate process model, direct tuning of the closed loop can provide the optimal control parameters. It has been shown in [7] that Iterative Feedback Tuning can be applied to a state space control system with state observer. The iterative procedure converges towards the optimal values for the two gains, when the observer is constructed from full model information. This result has more academic than practical interest since analytical solutions are known when a model is available. It is on the other hand interesting to investigate the potential for using direct tuning in case of model uncertainty. Parametric model uncertainty will give the following equations for the state and the estimation error:

$$\begin{aligned}
\boldsymbol{x}_{t+1} &= (\boldsymbol{A}-\boldsymbol{BL})\boldsymbol{x}_t + \boldsymbol{BL}\tilde{\boldsymbol{x}}_t + \boldsymbol{B}Mr_t + \boldsymbol{e}_t^P \\
\tilde{\boldsymbol{x}}_{t+1} &= (\hat{\boldsymbol{A}}-\boldsymbol{K}\hat{\boldsymbol{C}})\tilde{\boldsymbol{x}}_t - \boldsymbol{K}\boldsymbol{e}_t^m + \boldsymbol{e}_t^P + \boldsymbol{\Delta} \\
\boldsymbol{\Delta} &= [(\boldsymbol{A}-\hat{\boldsymbol{A}}) - \boldsymbol{K}(\boldsymbol{C}-\hat{\boldsymbol{C}})]\boldsymbol{x}_t + (\boldsymbol{B}-\hat{\boldsymbol{B}})[Mr_t - \boldsymbol{L}(\boldsymbol{x}_t - \tilde{\boldsymbol{x}}_t)]
\end{aligned} \tag{7}$$

Only if the true process and the model estimate are equivalent will the term $\boldsymbol{\Delta}$ be zero. In this case the optimal closed loop performance can be achieved by solving the Riccati equations for the two gains. In case of parametric uncertainty, a certainty equivalent control design will not produce optimal closed loop performance. Hence either model re-estimation with a subsequent update of the feedback and observer gain or direct tuning can be used for optimization. In [8] direct tuning of the two gains was performed using Iterative Feedback Tuning in order to investigate to which extent adjusting the gains could compensate for the erroneous model parameters in the state estimator. The loop performance was improved iteratively, and in some cases the performance degradation caused by an erroneous parameter could be completely compensated. This paper will move further and tune the model parameters in the state estimator by direct tuning. Given an updated set of model parameters, new optimal feedback and Kalman filter gains are recalculated from the Riccati equations.

4. Case study

In order to illustrate the potential of using direct tuning in form of the Iterative Feedback Tuning method the discrete time, scalar, state space system with state observer (8) is investigated. This system is too simple to have any industrial relevance but the objective of this example is to show the principles in the tuning method and it's ability to converge to optimality. The general method described in the paper concerns higher order linear models too.

$$\begin{aligned}
x_{t+1} &= 0.98x_t + 0.02u_t + e_t^P, \qquad e_t^P \in N(0,1^2) \\
y_t &= 1x_t + e_t^m, \qquad\qquad\quad e_t^m \in N(0,0.01^2)
\end{aligned} \tag{8}$$

In the optimization criterion λ= 0.001 is used. In the case when only the noise variance is unknown and all other parameters in the observer are correct, only the Kalman filter gain needs to be tuned. In case any of the parameters *a*, *b* or *c* in model estimate are erroneous, it will affect both the values of the Feedback and Kalman gains and the state estimate. In the following, three experiments are performed where one of the parameters *a*, *b* or *c* in the state estimate is wrong respectively. By direct tuning of the parameter in question and subsequent update of the Feedback and Kalman gains, to ensure optimality by certainty equivalence in each iteration, the closed loop performance is optimized. Fig. 2, 3 and 4 show the results from 15 iterations of the tuning, when the erroneous parameters is either too large or too small. All experiments are able to converge to the optimal solution in 5-10 iteration which is very good when tuning is conducted for the disturbance rejection case. The method also allows tuning of all the model parameters simultaneously and for multivariable systems, but these results have been omitted due to the spatial constraints of this contribution. It is however ongoing work.

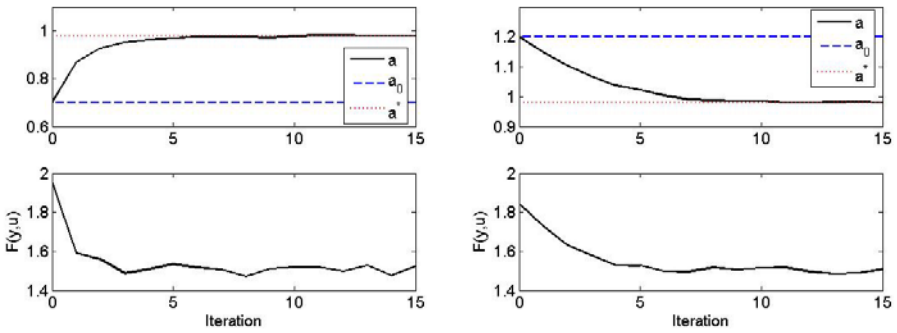

Figure 2. 15 iterations by the tuning method when the parameter *a* in the observer is erroneous. Both the iteration of the parameter value and the corresponding closed loop performance are given.

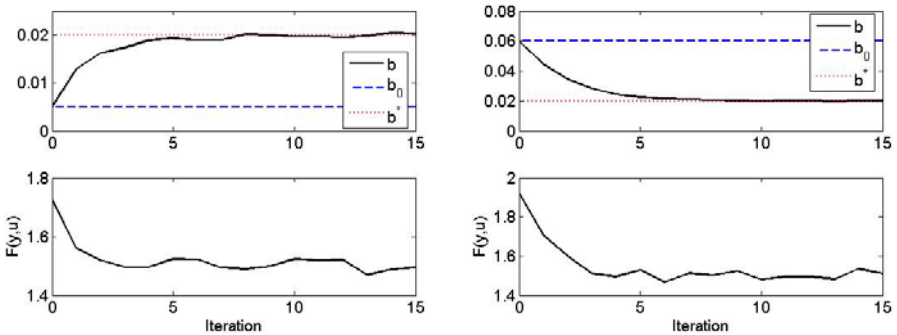

Figure 3. 15 iterations by the tuning method when the parameter *b* in the observer is erroneous. Both the iteration of the parameter value and the corresponding closed loop performance are given.

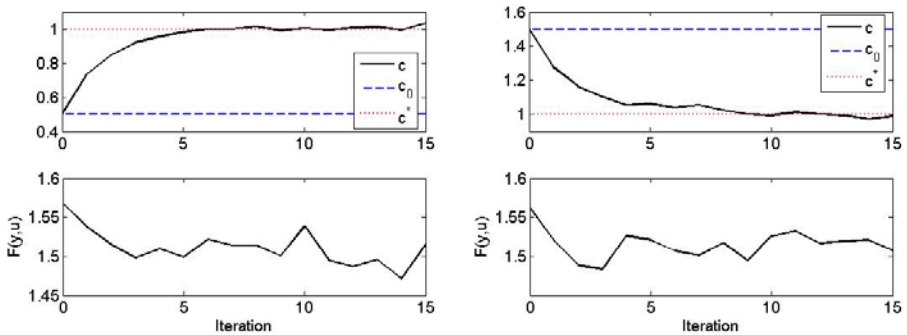

Figure 4. 15 iterations by the tuning method when the parameter *c* in the observer is erroneous. Both the iteration of the parameter value and the corresponding closed loop performance are given.

The cost function gradient estimate used in a Newton scheme by the Iterative Feedback Tuning method, utilizes a transfer function description of the state space control loop on Fig. 1 which is given in [7]. This estimate is constructed by filtering closed loop

input/output data through a filter which contains the gradient of the controller with respect to the tuning parameters. Since the feedback and the feed forward controller in the transfer function description of the state space control loop are functions of both the model estimate and the gain matrices, the partial derivatives of the optimal gains are needed with respect to the tuning parameters. These have been obtained by a first order forward difference approximation in the results presented here.

The results presented are by far superior to the results in [8] where gains were tuned while the erroneous parameters in the state estimator were kept constant. The increased complexity of tuning the system parameters and adapting the gains seems to be rewarded since convergence of the model estimate to the true system leads to optimality for the closed loop performance.

5. Conclusions

Direct tuning in form of Iterative Feedback Tuning has been used to adjust the system model parameters in the observer in a state space control loop in order to minimize the closed loop performance cost. When the model in the control and the observer design is iteratively updated so are the Feedback and Kalman gains in order to ensure optimality by certainty equivalence in the design. The tuning parameters converged to the true system hence the achieved closed loop performance converged to optimality.

Abstract:

This paper studies a simplified methodology to integrate the real time optimization of a continuous system into the model predictive controller in the one layer strategy. The gradient of the economic objective function is included in the cost function of the controller. One of the control objectives is to zero the reduced gradient of the economic objective while maintaining the system outputs inside their zones. Optimal conditions of the process at steady state are searched through the use of a rigorous nonlinear process model, while the trajectory to be followed is predicted with the use of a linear dynamic model that can be obtained through a plant step test. Moreover, the reduced gradient of the economic objective is computed taking advantage of the predicted input and output trajectories. The main advantage of the proposed strategy is that the resulting control/optimization problem can be solved with a quadratic programming routine at each sampling step. Simulation results show that the approach proposed here is comparable to the strategy that solves the full economic optimization problem inside the MPC controller where the resulting control problem becomes a nonlinear programming with a high computer load.

Keywords: Real Time Optimization, Model Predictive Control, Fluid Catalytic Converter, Non-linear programming

1. Introduction

Typically, the RTO application optimizes the process operating conditions and updates the set-points to local MPCs, which are based on linear dynamic models. A steady-state RTO may not be sufficient if, for instance, the set of active constraints with significant economic importance changes frequently. For this type of process, it is more suitable to use dynamic optimization with a non-linear model, which may be achieved using dynamic RTO (DRTO) or non-linear MPC with economic objective (Kadam et al., 2003; Tosukhowong et al., 2004). However, the dynamic optimization of a complex process is still not achievable with the available computing resources (Lu, 2003). Aske et al. (2008) propose the use of a coordinator MPC, which explores the degrees of freedom of the system in order to maximize throughputs at the bottlenecks of the system. Economic optimization studies for

oil refining and chemicals production systems have proven to be very beneficial (Georgiou et al., 1997: Rotava & Zanin, 2005). Similar algorithms to the ones of the petrochemical industry were applied by Mercangoz & Doyle III (2007) to the pulp and paper manufacturing system. To maximize the economic benefit while maintaining the desired product quality may be hard in a continuous production environment with frequent changes (Engell, 2007). Here, the focus is on the integration of real time optimization and control of continuous processes through the strategy called one-layer approach (Zanin et al. 2002) or full optimizing control (Rolandi & Romagnoli, 2005).

In process plants, the economically optimal operation is usually addressed by a two-layer structure (Marlin & Hrymak, 1996). In the upper layer, the operating point or steady state of the plant is optimized based upon a rigorous nonlinear stationary plant model. This two layer structure has some drawbacks, as optimization is only performed intermittently at a low sampling rate and inconsistencies may arise from the use of different process models at the two layers. These issues are partly addressed by schemes in which the economic optimization is integrated within a linear MPC controller. Typical sampling times for the RTO layer in a two layer approach are of the order of several hours (Engel, 2007) while the control layer provides tracking and disturbance rejection on shorter time-scales from seconds to minutes.

Zanin et al. (2002) included the economic objective computed at the predicted steady state as an additional term of the cost function of the controller. Here it is presented a simplified strategy to integrate the RTO problem into the linear model predictive controller in the one layer approach. An approximation of the gradient of the economic function is included in the MPC cost function with an appropriate weight. Simulation results obtained with the nonlinear model of Moro & Odloak (1995) are used to compare the proposed approach to the approach of Zanin et al. (2002), and show that the results of the two approaches may be comparable.

2. The one-layer RTO/MPC controller

Zanin et al. (2002) propose to integrate the real time optimization of continuous processes into the model predictive controller by solving at each sampling step k the optimization problem:

$$\min_{u(k+i);\, i=0,\ldots,m-1} \sum_{j=1}^{p} \left\| W_1 (y(k+j) - r) \right\|_2^2 + \sum_{j=0}^{m-1} \left\| W_2 \Delta u(k+j) \right\|_2^2 + W_3 f_{eco} \;\; u(k+m), y(k+\infty) \qquad (1)$$

subject to

$$h\;\; u(k+m), y(k+\infty) \;\; = 0 \qquad (2)$$

$$u_{\min} \le u(k+j) \le u_{\max} \quad j = 0,1,\ldots,m-1 \qquad (3)$$

$$\Delta u_{\max} \le \Delta u(k+j) \le \Delta u_{\max} \quad j = 0,1,\ldots,m-1 \qquad (4)$$

$$y(k+j) = g_j \;\; x(k), \Delta u_k \;\; , \quad j = 1,\ldots,p \qquad (5)$$

where

p and m are the output and input horizons, respectively; $u(k+j)$ is the control input computed at time k to be applied at time step $k+j$; $y(k+j)$ is the output prediction at time step $k+j$; r is the desired value of the output; $\Delta u(k+j) = u(k+j) - u(k+j-1)$; W_1, W_2 and

W_3 are positive weights; f_{eco} is the economic objective corresponding to the predicted steady state of the process; $y(k+\infty)$ is the process output steady state computed with Eq. (2).

Eq. (5) corresponds to the output prediction performed with the linear dynamic model of the system, and $\Delta u = \begin{bmatrix} \Delta u(k) & \Delta u(k+1) & \cdots & \Delta u(k+m-1) \end{bmatrix}^T$ is the control sequence.

In the RTO/MPC algorithm defined above, the outputs are controlled by zones, which means that the desired values *r* of the controlled outputs do not have fixed values.

Since in the general case, f_{eco} and *h* are nonlinear functions of the inputs and outputs of the system, the problem solved by the controller is a NLP while the problem solved in the conventional MPC is a QP. Although, the recent progress in the algorithms for the numerical solution of NLP problems, one can expect some difficulties in solving the RTO/MPC problem for large dimension systems. If the solver of the one layer RTO/MPC problem fails to produce a converged solution within the sampling period of the controller, no control action will be available to be implemented and the system will remain in open loop, which is highly undesirable. Thus, there is interest in developing an alternative solution to the one layer RTO/MPC problem that preserves some of the advantages of the one layer approach, but without delaying the computation of the optimizing control action.

3. The simplified one-layer RTO/MPC

Consider a multivariate system with *ny* outputs and *nu* inputs. At any time step *k*, suppose that the stationary prediction of the controlled output related to *u* is $\hat{y}$, and the economic function associated with this predicted steady state can be represented as follows:
